ELSEVIER

Operative Otolaryngology

Head and Neck Surgery

THIRD EDITION

Editors

Eugene N. Myers, MD, FACS, FRCS EDIN (HON)

Distinguished Professor and Emeritus Chair, Department of Otolaryngology, University of Pittsburgh School of Medicine, Professor, Department of Oral and Maxillofacial Surgery, University of Pittsburgh School of Dental Medicine, Pittsburgh, Pennsylvania

Carl H. Snyderman, MD, MBA, FACS

Professor, Department of Otolaryngology and Neurological Surgery, University of Pittsburgh School of Medicine, Co-Director, Center for Cranial Base Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Section Editors

Elizabeth A. Blair, MD

Jeffrey Bumpous, MD

Ricardo L. Carrau, MD

Sukgi Choi, MD

Frederic W.B. Deleyannis, MD

Johan Fagan, MD

Berrylin Ferguson, MD

Sheng-Po Hao, MD

Barry E. Hirsch, MD

Jonas T. Johnson, MD

Volume 1

Section 1. Larynx: Voice

1. Office-Based Laryngeal Procedures
    - Introduction
    - Key Operative Learning Points
    - Preoperative Period
    - Operative Period
    - Postoperative Period
    - Discussion
2. Phonomicrosurgery for Benign Vocal Fold Lesions
    - Introduction
    - Key Operative Learning Points
    - Types of Benign Vocal Fold Lesions
    - Preoperative Period

Operative Period
Postoperative Period
Discussion
3. Recurrent Respiratory Papillomatosis
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
4. Vocal Fold Injection via Microlaryngoscopy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
5. Medialization Laryngoplasty and Arytenoid Adduction
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Surgical Technique
Postoperative Period
Discussion
6. Intraoperative Medialization Laryngoplasty
Introduction
Key Operative Learning Points
Preoperative Period

Operative Period
Common Errors in Technique
Postoperative Period

Section 2. Larynx: Airway

7. Excision of Laryngocele
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Postoperative Management
Complications
Alternative Management Plan
Discussion
8. Laryngeal Trauma
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
9. Bilateral Vocal Fold Immobility
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
10. Acquired Laryngeal Stenosis

Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 3. Larynx: Oncologic Surgery

11. Transoral CO2 Laser Microsurgery for Cancer of the Larynx
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Alternative Management Plan
Evidence-Based Discussion
12. Horizontal Partial Laryngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Physical Examination
Imaging
Indications
Contraindications
Preoperative Preparation
Positioning
Perioperative Antibiotic Prophylaxis
Monitoring
Instruments and Equipment to Have Available
Key Anatomic Landmarks

Prerequisite Skills
Operative Risks
Surgical Technique
Postoperative Perlod
Complications of Supraglottic Laryngectomy
Discussion
13. Vertical Partial Laryngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
14. Supracricoid Partial Laryngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
15. Supraglottic Transoral Robotic Surgery
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Key Anatomic Landmarks
Prerequisite Skills
Surgical Technique
Common Errors in Technique
Postoperative Care

Complications
Alternative Management Plan
Discussion
16. Total Laryngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Management
17. Total Laryngopharyngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Section 4. Trachea and Mediastinum
18. Operative Otolaryngology: Bronchoscopy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
19. Open Tracheostomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period

Alternative Management Plan
Discussion
20. Percutaneous Tracheostomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
21. Operative Otolaryngology: Laryngotracheal Separation
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
22. Tracheal Resection
Introduction
Key Operative Points
Perioperative Period
Operative Period
Surgical Procedure
Common Errors in Technique
Postoperative Period
Discussion
23. Management of a Tracheocutaneous Fistula and Depressed Scar
Introduction
Key Operative Learning Points
Preoperative Period

Operative Period
Discussion
24. Stenosis of the Tracheostoma Following Total Laryngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
25. Voice Restoration After Total Laryngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
26. Closure of the Tracheoesophageal Fistula Site
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
Section 5. Oral Cavity
27. Cancer of the Lip
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period

Postoperative Period
Discussion
28. Partial Glossectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
29. Total Glossectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Complications
Alternative Management Plan
Discussion
30. Excision of Cancer of the Floor of the Mouth
Introduction
Key Objective Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
31. Operative Otolaryngology: Excision of Buccal Carcinoma
Introduction
Key Operative Learning Points
Preoperative Period

Operative Period
Postoperative Period
32. Transoral Inferior Maxillectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 6. Oropharynx

33. Transoral Excision of Oropharyngeal Malignancy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
34. Transoral Laser Microsurgery of the Base of the Tongue
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Common Errors in Technique
Postoperative Period
35. Transoral and Robotic Tonsil Surgery for Cancers of the Base of the Tongue and Pharynx
Introduction
Key Operative Learning Points
Preoperative Period

Operative Period
Transoral Technique
Tongue Base Incisions
Postoperative Period
Discussion
36. Transoral Robotic Surgery for Neoplasms of the Base of Tongue
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
37. Surgery of the Soft Palate
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
38. Transoral Removal of Elongated Styloid Process
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
39. Transcervical Pharyngotomy
Introduction
Key Operative Learning

Preoperative Period
Operative Period
Postoperative Period
Discussion
40. Pharyngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 7. Nasopharynx

41. Endoscopic Nasopharyngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
42. Robotic-Assisted Nasopharyngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
43. Maxillary Swing/Transpalatal/Midface Degloving With Le Fort I Osteotomy Approach for Nasopharyngectomy
Introduction
Key Operative Learning Points

Preoperative Period
Operative Period
Postoperative Period
Complications
Alternative Management Plan
Discussion
44. Facial Translocation Approach to the Nasopharynx
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 8. Hypopharynx and Esophagus

45. Esophagoscopy and Hypopharyngoscopy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
46. Dysfunction of the Upper Esophageal Sphincter
Introduction
Key Learning Points
Preoperative Period
Operative Period
Discussion
47. Penetrating Trauma to the Hypopharynx and Cervical Esophagus
Introduction
Key Operative Learning Points

Preoperative Period
Operative Period
Postoperative Period
Discussion
48. Partial Pharyngectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
49. Reconstruction of Hypopharyngeal Defects
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
50. Cancer of the Cervical Esophagus
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
Section 9. Surgery of Obstructive Sleep Apnea
51. Office-Based Snoring Procedures
Introduction
Key Operative Learning Points

Preprocedure Period
Procedures
Postprocedure Period
Discussion
52. Drug-Induced Sedated Endoscopy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
53. Uvulopalatopharyngoplasty and Related Modifications (Traditional Uvulopalatopharyngoplasty, Uvulopalatal Flap, Anterior Palatoplasty)
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Complications
Discussion
54. Advanced Palatal Surgery: Expansion Sphincter Pharyngoplasty & Transpalatal Advancement Pharyngoplasty
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Complications
Alternative Management Plan
Discussion

55. Volumetric Tongue-Base Reduction (Lingual Tonsillectomy, Coblation Midline Glossectomy, Trans Oral Robotic Surgery)
Introduction
Key Operative Learning Points: Endoscopic Lingual Tonsillectomy
Preoperative Period
Operative Period
Postoperative Period
Discussion
56. Hypoglossal Nerve Stimulation Therapy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Complications
Alternative Management Plan
Discussion
57. Hyoid Suspension
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
58. Genioglossus Advancement
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period

Discussion

59. Maxillomandibular Advancement for Obstructive Sleep Apnea

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Common Errors in Technique

Section 10. Neck and Parapharyngeal Space

60. Office-Based Procedures: Fine-Needle Aspiration Biopsy of a Mass in the Head and Neck

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

61. Management of the Unknown Primary Cancer

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

62. Sentinel Lymph Node Biopsy

Introduction

Key Operative Learning Points

Preoperative PERIOD

Operative Period

Postoperative Period

Discussion
63. Superselective Neck Dissection
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
64. Selective Neck Dissection
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
65. Modified Radical Neck Dissection
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
66. Radical Neck Dissection
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

67. Central Compartment Neck Dissection
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
68. Retropharyngeal Neck Dissection
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
69. Management of Tumors in the Prestyloid Parapharyngeal Space
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
70. Transoral Approach to the Parapharyngeal Space
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
71. Posterolateral Neck Dissection

Introduction
Key Operative Learning Points
Preoperative Period
Fine-Needle Aspiration Biopsy
Operative Period
Discussion
72. Excision of Neural Tumors of the Parapharyngeal Space
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Complications
Alternative Management Plan
Discussion
73. Excision of Carotid Body Tumors
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
74. Endoscopic and Robotic Applications to Neck Surgery
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

75. Management of Traumatic Soft Tissue and Vascular Injuries to the Neck

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

76. Deep Neck Abscesses

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

77. Anterior Transcervical Approach to the Cervical Spine

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

Section 11. Thyroid and Parathyroid

78. Open Thyroidectomy

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion
79. Minimally Invasive Video-Assisted Thyroidectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Complications
Discussion
80. Robotic-Assisted Thyroidectomy
Introduction
Key Operating Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
81. Massive and Substernal Goiter
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
82. Invasive Thyroid Cancer
Introduction
Key Learning Points
Preoperative Period
Operative Period
Postoperative Period

Discussion

83. Intraoperative Parathyroid Hormone Monitoring

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

84. Parathyroidectomy for Primary Hyperparathyroidism and Nonlocalizing Hyperparathyroidism

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Alternative Management Plan

Discussion

85. Parathyroidectomy for Secondary Hyperparathyroidism

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

Editorial Comment

86. Reoperative Parathyroidectomy

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period
Discussion

Section 12. Salivary Glands

87. Office-Based Procedures
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
88. Salivary Endoscopy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Hybrid Approaches
Postoperative Period
Discussion
89. Surgical Management of Ranula
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
90. Mass in the Buccal Space
Introduction
Key Operative Learning Points
Preoperative Period

Operative Period
Postoperative Period
91. Excision of the Submandibular Gland
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Common Errors in Technique
Postoperative Period
Discussion
92. Superficial Parotidectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
93. Deep Lobe Parotidectomy
Introduction
Key Operative Learning Points
Patient Selection/Preoperative Period
Preoperative Period
Preoperative Preparation
Postoperative Period
Section 13. Nasal Cavity
94. Office-Based Diagnosis of Sinonasal Disorders
Introduction
Key Operative Learning Points
Key Anatomic Landmarks
Discussion
95. Septoplasty—Classic and Endoscopic

Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
96. Nasal Septal Perforation
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
97. Surgery of the Turbinate
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
98. Sphenopalatine Artery Ligation for Epistaxis
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
99. Operative Otolaryngology: Anterior and Posterior Ethmoid Artery Ligation for Epistaxis
Introduction

Key Operative Learning Points
Operative Period
Postoperative Period
Discussion
100. Surgical Management of Hereditary Hemorrhagic Telangiectasia
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
101. Rhinectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 14. Paranasal Sinuses

102. Balloon Sinus Dilation
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
103. Antral Lavage; Endoscopic Middle Meatal Antrostomy/Antrochoanal Polyp
Introduction

Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
104. Anterior Antrostomy: The Caldwell-Luc Operation
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
105. Oroantral Fistulas
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
106. Medial Maxillectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
107. Complete Maxillectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period

Postoperative Period
Discussion
108. Endoscopic Ethmoidectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
109. External Ethmoidectomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
110. Endoscopic Sphenoidotomy
Introduction
Key Operative Learning Points
Operative Period
Postoperative Period
Discussion
111. Trephination of the Frontal Sinus
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

112. Endoscopic Approach to the Frontal Sinus
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
113. Draf III, Endoscopic Modified Lothrop
Introduction
Key Learning Points
Preoperative Period
Operative Period
Postoperative Care
Discussion
114. Osteoplastic Obliteration of the Frontal Sinus
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
115. Frontal Sinus Cranialization
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Volume 2

Section 15. Cranial Base

116. Endoscopic Management of Cerebrospinal Fluid Leaks
- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period
- Discussion

117. Endonasal Approach to the Sella and Parasellar Areas
- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period
- Discussion

118. Transcranial and Endonasal Approaches to the Anterior Cranial Base
- Introduction
- Key Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period
- Discussion

119. Endoscopic Endonasal Transpterygoid Approaches to the Middle Cranial Fossa
- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period

Discussion
120. Endoscopic Petrosal Approaches
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Tumor Removal and Reconstruction
Postoperative Period
Evidence-Based Medicine Question
121. Surgical Approaches to the Infratemporal Fossa
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
122. Juvenile Angiofibroma
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
123. Transnasal and Transoral Approaches to the Cervical Spine
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period

Discussion
124. Reconstruction After Skull Base Surgery
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 16. Otology: External Ear

125. Office-Based Procedures in Otology
Introduction
Anesthesia
Disimpaction of Cerumen
Drainage of a Hematoma of the Auricle
Incision and Drainage of an Ear Abscess
Biopsy of a Mass in the External Auditory Canal
Intratympanic Injections
Myringotomy and Insertion of Tubes
126. Foreign Bodies of the External Auditory Canal
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
127. Osteomas and Exostoses of the External Auditory Canal
Introduction
Key Operative Learning Points
Preoperative Period

Operative Period
Postoperative Period
Discussion
128. Keratosis Obturans and Canal Cholesteatoma
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 17. Otology: Middle Ear and Mastoid

129. Otitis Media, Myringotomy, Tympanostomy Tube, and Balloon Dilation
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
130. Intracranial Complications of Otitis Media
Introduction
Key Operative Learning Points
Preoperative Period
Epidural Abscess
Lateral Sinus Thrombosis
Subdural Abscess (Empyema)
Brain Abscess
Otitic Hydrocephalus
Petrous Apicitis/Gradenigo's Syndrome
131. Myringoplasty and Tympanoplasty

Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Complications
Alternative Management Plan
Discussion
132. Ossicular Chain Reconstruction
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Common Errors in Technique
Postoperative Period
Discussion
133. Otosclerosis
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Alternative Management Plan
Discussion
134. Mastoid Surgery
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period

Discussion
135. Bone-Anchored Hearing Devices
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
136. Implantable Middle Ear Devices
Introduction
Esteem Implant (Envoy Medical Corporation)
Key Operative Learning Points
Preoperative Period
Operative Period
Common Errors in Technique
Postoperative Period
Discussion
Vibrant Soundbridge Device (Med-El Corporation)
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
Maxum Hearing Implant System (Ototronix, Texas)
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

137. Cochlear Implantation in Adults
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 18. Otology: Temporal Bone

138. Facial Nerve Decompression
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period, Middle Fossa Decompression
Postoperative Period
Discussion
139. Tumors of the Facial Nerve
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
140. Acoustic Neuroma
Introduction
Key Operative Learning Points
Preoperative Period
Postoperative Period
Complications
Alternative Management

Discussion

141. Resection of the Temporal Bone

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

142. Glomus Tumors

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

143. Cholesterol Granulomas and Congenital Epidermoid Tumors of the Temporal Bone

Introduction

Preoperative Period

Operative Period

Common Errors in Technique

Postoperative Period

Discussion

144. Cerebrospinal Fluid, Otorrhea and Encephalocele

Introduction

Key Operative Learning Points

Preoperative Period

Operative Period

Postoperative Period

Discussion

145. Temporal Bone Trauma
Introduction
Key Operative Learning Points
Preoperative PERIOD
Operative Period
Postoperative Period
Discussion
146. Surgery for Vertigo
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Surgery: Meniere
Surgery for Uncompensated Peripheral VestibulopAthy
Postoperative Period
Discussion
147. Superior Semicircular Canal Dehiscence
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
Editorial Comment
148. Stereotactic Radiosurgery
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period

Postoperative Period
Discussion

Section 19. Orbit

149. Dacryocystorhinostomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
150. Optic Nerve Decompression
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
151. Orbital Decompression
Introduction
Preoperative Period
Operative Period
Postoperative Period
Discussion
152. Orbital Abscess
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period

Discussion
153. Lateral Canthotomy
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
154. Orbital Exenteration
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
Section 20. Cosmetic and Facial Plastic Surgery
155. Rhinoplasty and Surgery of the Nasal Valve
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
156. Blepharoplasty
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

157. Brow Lift
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
158. Face lift
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
159. Facial Resurfacing: Peels and Lasers
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
160. Cosmetic Botox and Fillers
Introduction
Key Operative Learning Points
161. Management of Skin Cancer of the Head and Neck
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion

Section 21. Reconstructive Surgery

162. Microvascular Reconstruction of the Head and Neck

- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period
- Discussion

163. Nasal Reconstruction

- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period
- Discussion

164. Scalp Reconstruction: Role of Tissue Expansion and Flap Reconstruction

- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period
- Discussion

165. Paramedian Forehead Flaps

- Introduction
- Key Operative Learning Points
- Preoperative Period
- Operative Period
- Postoperative Period

Discussion
166. Pericranial Scalp Flap
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
167. Temporoparietal Fascial Flap
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
168. Temporalis Muscle Transposition
Introduction
Key Operative Learning Points
Preoperative Period
Operative Period
Postoperative Period
Discussion
169. Deltopectoral Flap

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in

research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured, or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products' liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedication

The Third Edition of Operative Otolaryngology: Head and Neck Surgery is dedicated to the faculty of the Department of Otolaryngology at the University of Pittsburgh School of Medicine, the second generation (our residents and fellows), the third generation (their residents and fellows), and future generations of the Pittsburgh family.

PERSONAL DEDICATION: Eugene N. Myers

To my wife, Barbara, our daughter, Marjorie Fulbright and her husband Cary, our son, Jeffrey N. Myers MD, PhD and his wife Lisa, our grandsons, Alex and Chip Fulbright, Keith, Brett, and Blake Myers, with love and many thanks for your patience with me during the creation of this book.

PERSONAL DEDICATION: Carl H. Snyderman

To my wife, Michelina Fato, MD, for her continuous support and encouragement, to my family (Kelly, Molly, Andrew, and Lucia) for providing perspective regarding life's goals, and to the memory of my father, Sanford Snyderman, MD, who continues to be an inspiration and role model for my life in medicine.

Contributors

Julie P. Adelman, MD, Department of Otolaryngology, University of Pittsburgh, Pennsylvania

Chapter 143

William G. Albergotti, MD, Resident, Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 23, 112

Brendan Alleyne, MD, Resident, Department of Plastic Surgery, Cleveland Clinic Foundation, Cleveland, Ohio

Chapter 174

Cuneyt M. Alper, MD

Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Professor, Clinical and Translational Research Institute, Pittsburgh, Pennsylvania

Chapter 203

Samantha Anne, MD, MS, Assistant Professor of Surgery, Medical Director, Pediatric Ear & Hearing Disorders, Pediatric Otolaryngology, Head & Neck Institute, Cleveland Clinic, Cleveland, Ohio

Chapter 200

Stephanie Moody Antonio, MD, FACS, Associate Professor, Department of Otolaryngology, Eastern Virginia Medical School, Norfolk, Virginia

Chapter 141

Moises A. Arriaga, MD, MBA

Clinical Professor and Director of Otology and Neurotology, Otolaryngology and Neurosurgery, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Medical Director, LSU-Our Lady of the Lake Hearing and Balance Center, Our Lady of the Lake Regional Medical Center, Baton Rouge, Louisiana

Chapter 140

Canset Aydin, MD, Otolaryngology Head and Neck Surgery Specialist, Otolaryngology, Head and Neck Surgery, Liv Hospital, Ankara, Turkey

Chapters 33, 101

Roya Azadarmaki, MD, Division of Otology-Neurotology, Metropolitan NeuroEar Group, Rockville, Maryland

Chapter 129

Christopher Azbell, MD, Resident, Department of Otolaryngology, University of Louisville, Louisville, Kentucky

Chapter 86

Christie Barnes, MS, MD, Assistant Professor, Otolaryngology, Head and Neck Surgery, University of Nebraska Medical Center, Omaha, Nebraska

Chapter 97

Rachel Barry, MD, Resident, Department of Otolaryngology, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Chapter 89

Richard Bauer III DMD, MD

Assistant Professor, Oral and Maxillofacial Surgery, University of Pittsburgh School of Dental Medicine, Pittsburgh, Pennsylvania

Staff Surgeon, Oral and Maxillofacial Surgery, University of Pittsburgh

Medical Center, Pittsburgh, Pennsylvania

Chapters 58, 59

Nadim Bikhazi, MD, Otolaryngology, Ogden Clinic, Ogden, Utah

Chapter 102

Elizabeth A. Blair, MD, Professor, Surgery, Section Otolaryngology, Head and Neck Surgery, University of Chicago, Chicago, Illinois

Chapter 31

Charles D. Bluestone, MD

Distinguished Emeritus Professor of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Former Director, Pediatric Otolaryngology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Arturo Bonilla, MD, Founder and Director, Microtia Congenital Ear Deformity Institute, San Antonio, Texas

Chapter 207

Brian J. Boyce, MD, Assistant Professor, Otolaryngology, Head and Neck Surgery, University of Florida, Gainesville, Florida

Chapters 63, 74

Margherita Bruni, MD, Otolaryngology Attending, Department of Otolaryngology, Northshore University Hospital, Manhasset, New York

Chapters 167, 168

Craig A. Buchman, MD, Lindburg Professor and Chair, Otolaryngology, Head and Neck Surgery, Washington University in St. Louis, St. Louis, Missouri

Chapter 137

Jeffrey Bumpous, MD, J. Samuel Bumgardner Professor and Chairman, Otolaryngology, Head and Neck Surgery, and Communicative Disorders, University of Louisville, Louisville, Kentucky

Chapters 27, 83, 86

Anna M. Butrymowicz, MD, Attending Physician, Division of Otolaryngology, Jacobi Medical Center, Bronx, New York

Chapter 65

J. Kenneth Byrd, MD, Assistant Professor, Otolaryngology, Medical College of Georgia, Augusta, Georgia

Chapters 15, 117

Thomas L. Carroll, MD

Instructor, Otolaryngology, Harvard University School of Medicine, Director, Brigham and Women's Voice Program, Surgery, Division of Otolaryngology, Brigham and Women's Hospital, Boston, Massachusetts

Boston, Massachusetts

Chapter 3

Ricardo L. Carrau, MD

Professor, Department of Otolaryngology, Head and Neck Surgery, The Ohio State University, Columbus, Ohio

Professor, Department of Neurological Surgery, The Ohio State University, Columbus, Ohio

Chapters 6, 10, 46, 116, 119

Nathan Cass, MD, Resident Physician, Department of Otolaryngology, University of Colorado, Aurora, Colorado

Chapter 165

Stephen P. Cass, MD, Professor, Department of Otolaryngology, University of Colorado, Aurora, Colorado

Chapter 148

Raymond Chai, MD, Assistant Professor, Department of Otolaryngology, Icahn School of Medicine at Mount Sinai, New York

Chapters 36, 45

Michael D. Chambers, DMD, MD, Resident, Oral and Maxillofacial Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 13, *105*

C.Y. Joseph Chang, MD

Director, Texas Ear Center, Texas Ear, Nose, and Throat Specialists, Houston, Texas

Clinical Professor, Department of Otolaryngology–Head and Neck Surgery, University of Texas–Houston Medical School, Houston, Texas

Chapters 142, *145*, *148*

Douglas A. Chen, MD

Pittsburgh Ear Associates, Pittsburgh, Pennsylvania

Director, Division of Neurotology, Department of Neurosurgery, Allegheny General Hospital, Pittsburgh, Pennsylvania

Chapter 131

David H. Chi, MD, Associate Professor, Otolaryngology, University of Pittsburgh School of Medicine, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Chapters 204, *205*

Rebecca Chiffer, MD, Fellow, Pittsburgh Ear Associates, Pittsburgh, Pennsylvania

Chapter 131

Christopher J. Chin, MD, FRCSC, Clinical Fellow, Otolaryngology, Head and Neck Surgery, University of Toronto, Toronto, Ontario, Canada

Chapter 116

Robert J. Chiu, MD, Facial Plastic Surgeon, Private Practice, Pittsburgh, Pennsylvania

Chapter 193

Garret Choby, MD, Resident, Department of Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 39, 108

Sukgi Choi, MD

Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chief and Eberly Chair, Pediatric Otolaryngology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Chapters 193, 194, 195, 198

Courtney T. Chou, MD, Resident Physician, Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 180

Neil A. Christie, MD, Assistant Professor, Thoracic Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 18, 22

Apostolos Christopoulos, MD, MSc, FRCSC, Dr Azar-Angélil Chair in Head and Neck Oncology, Associate Professor Division of Otorhinolaryngology - Head and Neck

Chapter 50

William Chung, DDS, MD, Professor, Department of Oral and Maxillofacial Surgery, University of Pittsburgh School of Dental Medicine, Pittsburgh, Pennsylvania

Chapters 13, 105, 121, 185

David M. Cognetti, MD, FACS, Associate Professor, Department of Otolaryngology, Head and Neck Surgery, Sidney Kimmel Cancer Center at Thomas Jefferson University, Philadelphia, Pennsylvania

Chapters 37, 63, 74, 75

Michael S. Cohen, MD

Instructor, Department of Otolaryngology, Harvard Medical School,

Boston, Massachusetts

Division of Pediatric Otolaryngology, Massachusetts Eye and Ear Infirmary, Boston, Massachusetts

Chapter 205

Patrick Colley, MD, Assistant Professor, Department of Otolaryngology, New York Eye and Ear Infirmary of Mount Sinai, The Mount Sinai Hospital, Mount Sinai Beth Israel, New York

Chapter 124

Peter D. Costantino, MD

Professor & Chair, Department Of Otolaryngology-Head & Neck Surgery, and Oral & Maxillofacial Surgery

Professor of Neurosurgery, Hofstra-Northwell School of Medicine, Lenox Hill Hospital & Manhattan Eye Ear, & Throat Hospital

Professor of Patient Oriented Research, The Feinstein Research Institute

Senior Vice-President & Executive Director, The New York Head & Neck Institute, Otolaryngology-Head & Neck Surgery Service Line, Northwell Health, New York

Chapters 167, 168

Bernard J. Costello, DMD, MD, FACS

Professor and Fellowship Program Director, Department of Oral and Maxillofacial Surgery, Associate Dean for Faculty Affairs, University of Pittsburgh, School of Dental Medicine, Pittsburgh, Pennsylvania

Chief, Pediatric Oral and Maxillofacial Surgery Children's Hospital of Pittsburgh, Professor and Fellowship Program Director Department of Oral and Maxillofacial Surgery, University of Pittsburgh Medical Center Eye and Ear Institute, Pittsburgh, Pennsylvania

Chapters 186, 206

Michael Cunningham, MD, Professor, Department of Otology and Laryngology, Harvard Medical School, Otolaryngologist-in-Chief, Department of Otolaryngology and Communication Enhancement, Boston Children's Hospital

Chapter 201

John R. DeAlmeida, MD, MSc, Head and Neck Surgeon, Otolaryngology, Head and Neck Surgery, Princess Margaret Cancer Centre, Toronto, Ontario, Canada

Chapter 114

Kavita Dedhia, MD, Assistant Professor, Otolaryngology, Head and Neck Surgery, Emory University, Atlanta, Georgia

Chapter 130

Raj C. Dedhia, MD, MS, Assistant Professor, Otolaryngology and Sleep Medicine, Emory University, Atlanta, Georgia

Chapters 52, 54, 59

Amir R. Dehdashti, MD FACS, Director Cerebrovascular Neurosurgery Research, Neurosurgery, Northshore University Hospital, Manhasset, New York

Chapters 167, 168

Timothy DeKlotz, MD, Assistant Professor, Otolaryngology, Head and Neck Surgery, Medstar Georgetown University Hospital, Washington, DC

Chapter 150

Frederic W.B. Deleyiannis, MD, MPhil, MPH, Professor, Division of Plastic Surgery, Departments of Surgery and Otolaryngology, University of Colorado, Aurora, Colorado

Chapters 162, 163, 165

Craig Derkay, MD

Professor and Vice-Chairman, Otolaryngology, Head and Neck Surgery, Eastern Virginia Medical School, Norfolk, Virginia

Director, Pediatric Otolaryngology, Children's Hospital of the King's Daughters, Norfolk, Virginia

Chapter 196

Matilda Dhima, DMD, MS, Maxillofacial Prosthodontist, Department of Prosthodontics, University of Pittsburgh, School of Dental Medicine, Pittsburgh, Pennsylvania

Chapter 188

Joseph E. Dohar, MD, MS

Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Professor, Communication Science and Disorders, University of Pittsburgh School of Health and Rehabilitation Sciences, Pittsburgh, Pennsylvania

Chapter 192

Stephanie E. Dreifuss, MD, Plastic Surgery Resident, Department of Plastic Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 164

Umamaheswar Duvvuri, MD, PhD, Assistant Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Eye and Ear Institute, Pittsburgh, Pennsylvania

Chapters 15, 55, 61, 80

David E. Eibling, MD, FACS

Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Assistant Chief of Surgery, Surgical Service, VA Pittsburgh Healthcare System, Pittsburgh, Pennsylvania

Chapters 13, 19, 21

Donovan Eu, MBBS, MRCS, MMed, Dr, Otolaryngology, Head and Neck Surgery, National University Hospital Singapore, Singapore, Singapore

Chapter 31

Johan Fagan, MBChB, MMed, FCS (ORL), Professor and Chairman,

Department of Otorhinolaryngology, University of Cape Town, Cape Town, South Africa

Chapters 11, 29, 72

Berrylin J. Ferguson†, MD, FACS, Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 94, 100

Robert L. Ferris, MD, PhD, UPMC Endowed Professor and Vice-Chair, Director, Hillman Cancer Center, Chief, Division of Head and Neck Surgery, Associate Director for Translational Research Co-Leader, Cancer Immunology Program Co-Director, Tumor Microenvironment Center, University of Pittsburgh Cancer Institute, Pittsburgh, Pennsylvania

Chapters 62, 79

Pedro Andrade Filho, MD, Assistant Professor, Otolaryngology, Loma Linda University, Loma Linda, California

Chapter 85

Rebecca E. Fraioli

Assistant Professor, Department of Otolaryngology - Head and Neck Surgery, Albert Einstein College of Medicine, Bronx, New York

Attending Physician, Montefiore Medical Center, Bronx, New York

Chapters 48, 91, 159

Roxana Fu, MD, Oculoplastics Fellow, Ophthalmology, University of Louisville, Louisville, Kentucky

Chapter 153

Lisa Galati, MD, Associate Professor, Otolaryngology, Albany Medical Center, Albany, New York

Chapters 76, 92, 183

Paul A. Gardner, MD, Associate Professor of Neurological Surgery,

University of Pittsburgh School of Medicine, Co-Director, Center for Cranial Base Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 122, 123, 177

Catharine B. Garland, MD, Fellow in Craniofacial Surgery, Plastic Surgery, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Chapters 175, 176

Brian Gastman, MD, Director of the CCF Melanoma Program, Associate Professor of Surgery, Cleveland Clinic Lerner College of Medicine, Staff, CCF, Dermatology and Plastic Surgery Institute, Department of Plastic Surgery, Dual appointments in: Taussig Cancer Center, Lerner Research Institute, Department of Immunology, Head and Neck Institute, Cleveland Clinic Foundation, Cleveland, Ohio

Chapter 174

Mathew Geltzeiler, MD, Otolaryngology, Fellow in Head and Neck Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 62

Grant S. Gillman, MD, FRCS(C), Associate Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 95, 156

Morgan R. Godin, MD, Resident, Ophthalmology, Duke University, Durham, North Carolina

Chapter 179

Andrew N. Goldberg, MD, MSCE, FACS

Professor

Director, Division of Rhinology and Sinus Surgery, Department of Otolaryngology, Head and Neck Surgery, University of California, San

Francisco, San Francisco, California

Chapter 102

Richard A. Goldman, MD, Assistant Professor, Department of Otolaryngology, Head and Neck Surgery, Sidney Kimmel Cancer Center at Thomas Jefferson University, Philadelphia, Pennsylvania

Chapter 75

Jesse Goldstein, MD, Assistant Professor, Department of Plastic Surgery, University of Pittsburgh School of Medicine, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Chapters 175, *176*, *202*

Amit Goyal, MD, Resident Physician, Department of Neurosurgery, University of Minnesota, Minneapolis, Minnesota

Chapter 115

Emiro Caicedo Granados, MD, MS, FACS, Assistant Professor, Otolaryngology Head and Neck Surgery, University of Minnesota, Minneapolis, Minnesota

Chapter 115

Trevor Hackman, MD, FACS, Associate Professor, Otolaryngology, Head and Neck Surgery, University of North Carolina, Chapel Hill, North Carolina

Chapters 47, *87*, *171*, *172*

Steven Hamilton, MD

Assistant Professor, Otolaryngology, University of Colorado School of Medicine, Colorado Springs, Colorado

Assistant Professor, Pediatric Otolaryngology, Children's Hospital Colorado, Colorado Springs, Colorado

Chapter 201

Ehab Hanna, MD, Professor and Director of Skull Base Surgery, Vice Chairman, Department of Head and Neck Surgery, University of Texas

MD Anderson Cancer Center, Houston, Texas

Chapter 106

Sheng-Po Hao, MD

Professor and Chairman, Department of Otolaryngology, Head and Neck Surgery, Shin Kong Wu Ho-Su Memorial Hospital, Taipei, Taiwan

Director, Comprehensive Oral Cancer Center, Shin Kong Wu Ho-Su Memorial Hospital, Taipei, Taiwan

Chapters 41, 43

Michele Hargreaves, MD, MBA, ENT Specialists of North Florida, Jacksonville, Florida

Chapter 127

Bridget C. Hathaway, MD, Assistant Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapter 46

Kyle Hatten, MD, Otorhinolaryngology, Head and Neck Surgery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Chapter 70

Laura Hetzler, MD, FACS, Assistant Professor and Program Director, Otolaryngology, Head and Neck Surgery, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Chapter 178

Douglas M. Hildrew, MD, Assistant Professor, Surgery-Otolaryngology, Yale School of Medicine, New Haven, Connecticut

Chapters 126, 132, 135

Barry E. Hirsch, MD, Professor of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 126, 132

Benjamin L. Hodnett, MD, PhD, Fellow, Otorhinolaryngology, Head

and Neck Surgery, University of Pennsylvania, Philadelphia, Pennsylvania

Chapter 17

Sefik A. Hosal, MD, Professor, Otolaryngology, Head and Neck Surgery, Liv Hospital, Ankara, Turkey

Chapters 33, *101*

Chapter 67

Seungwon Kim, MD, Associate Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Eye and Ear Institute, Pittsburgh, Pennsylvania

Chapters 40, *93*

Dennis J. Kitsko, DO

Assistant Professor, Otolaryngology, University of Pittsburgh School of Medicine

Co-Director, The Hearing Center, Pediatric Otolaryngology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Chapter 130

Karen M. Kost, MDCM, FRCSC

Professor, Otolaryngology, Head and Neck Surgery, McGill University Health Centre

Director, Voice and Dysphagia Laboratory, McGill University, Montreal, Quebec, Canada

Chapter 20

Priya Krishna, MD, MS

Assistant Professor, Otolaryngology, Head and Neck Surgery, Loma Linda University School of Medicine

Co-Director, Voice and Swallowing Center, Loma Linda University

Medical Center, Loma Linda, California

Chapter 1

Summit Kundaria, MD, Director, Nuance Facial Plastics, Charlotte, North Carolina

Chapter 155

Daniel Kwon, MD, Department of Otolaryngology, Head and Neck Surgery, Loma Linda University Medical Center, Loma Linda, California

Chapter 82

Tack-Kyun Kwon, MD, PhD, Associate Professor, Otolaryngology, Head and Neck Surgery, Seoul National University, Seoul, South Korea

Chapter 7

Miriam N. Lango, MD

Associate Professor, Surgical Oncology, Fox Chase Cancer Center/Temple University Health System

Associate Professor, Otolaryngology, Head and Neck Institute/Temple University Hospital, Philadelphia, Pennsylvania

Chapters 14, *28*, *81*

Brian Lee, DO, Attending Physician, Concord Otolaryngology, Head and Neck Surgery P.A., Concord, New Hampshire

Chapters 7, *96*

Stella E. Lee, MD, Assistant Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 5, *7*, *16*, *95*, *96*, *108*

Steve Lee, MD, PhD, Assistant Professor, Otolaryngology, Loma Linda University, Loma Linda, California

Chapter 82

Paul Leong, MD, Director, Sistine Facial Plastic and Laser Surgery, Pittsburgh, Pennsylvania

Chapters 155, 157

Andrea Lewis, MD, Fellow of AAOA, Sleep Board Certification, Assistant Professor, Associate Program Director, Department of Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, Mississippi

Chapters 51, 57

Benjamin W. Light, MD, Light Facial Plastic Surgery, Decatur, Alabama

Chapters 155, 157

Chwee M. Lim, MBBS, MRCS(Edin), MMed(ORL), Assistant Professor, Otolaryngology, National University of Singapore, Consultant, Otolaryngology, Head and Neck Surgery, National University Health System, Singapore, Singapore

Chapters 31, 80

R. Jun Lin, MD, FRCSC, MSc, Assistant Professor, Otolaryngology-Head and Neck Surgery, University of Toronto, Toronto, Ontario, Canada

Chapter 5

Jason A. Liss, MD, Assistant Professor, Ophthalmology, Duke University, Durham, North Carolina

Chapter 179

Yuan F. Liu, MD, Resident Physician, Otolaryngology, Head and Neck Surgery, Loma Linda University Medical Center, Loma Linda, California

Chapter 78

Joseph Losee, MD

Ross H. Musgrave Professor of Pediatric Plastic Surgery, Department of Plastic Surgery, University of Pittsburgh School of Medicine

Chief, Division of Pediatric Plastic Surgery, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Chapters 175, 176

Charles B. MacDonald, MD, Associate Professor, Otolaryngology, University of Tennessee Health Science Center, Memphis, Tennessee

Chapter 134

Zoe M. MacIsaac, MD, Department of Plastic Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 170

Li-Xing Man, MSc, MD, MPA, Assistant Professor, Otolaryngology, Head and Neck Surgery, University of Rochester, Rochester, New York

Chapters 100, 112

David Mandell, MD

Center for Pediatric Otolaryngology, Head and Neck Surgery, Boynton Beach

Affiliate Associate Professor, Clinical Biomedical Science, Charles E. Schmidt College of Medicine, Florida Atlantic University, Boca Raton, Florida

Chapter 197

Mark Mandell-Brown, MD

Director, The Plastic Surgery Experts, Mandell-Brown Plastic Surgery Center

Volunteer Instructor, Department of Otolaryngology, University of Cincinnati College of Medicine, Cincinnati, Ohio

Chapter 158

Ernest K. Manders, MD, Professor, Department of Plastic Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 164, 170

Anastasios Maniakas, MD, Centre Hospitalier de l'Université de Montréal–CHUM, Otolaryngology, Head and Neck Surgery, Université de Montréal, Montreal, Quebec, Canada

Chapter 50

Scott Manning, MD, Professor, Otolaryngology, University of Washington, Seattle, Washington

Chapter 189

Jessica H. Maxwell, MD, MPH

Assistant Professor, Otolaryngology, MedStar Georgetown University Hospital

Staff Physician, Otolaryngology, Washington DC VA Medical Center, Washington, DC

Chapters 40, 69

J. Seth McAfee, MD, Coastal Ear, Nose, and Throat, Neptune, New Jersey

Chapter 138

Andrew A. McCall, MD, Assistant Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapter 147

Jonathan L. McJunkin, MD, Assistant Professor, Department of Otolaryngology, Washington University in St. Louis, St. Louis, Missouri

Chapter 137

Vikas Mehta, MD, MPH, FACS, Assistant Professor - Otolaryngology/Head and Neck Surgery, Montefiore Medical Center, Dept of Otorhinolaryngology, Bronx, NY

Chapters 25, 61, 68

Matthew Mifsud, MD, Fellow in Head and Neck Oncology, Otolaryngology, Head and Neck Surgery, University of Toronto, Toronto, Ontario, Canada

Chapter 114

Mark Mims, MD, Resident, Department of Otolaryngology,

University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 24

Howard S. Moskowitz, MD, PhD, Assistant Professor, Otorhinolaryngology, Head and Neck Surgery, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, New York

Chapter 139

Eugene N. Myers, MD, FACS, FRCS Edin (Hon)

Distinguished Professor and Emeritus Chair, Department of Otolaryngology, University of Pittsburgh School of Medicine

Professor, Department of Oral and Maxillofacial Surgery, University of Pittsburgh School of Dental Medicine, Pittsburgh, Pennsylvania

Chapters 23, 24, 26, 32, 39, 73, 90, 109, 169

Jeffrey N. Myers, MD, PhD, FACS, Alando J. Ballantyne Distinguished Chair of Head and Neck Surgery, Professor and Director of Research, Deputy Chair for Academic Programs, Department of Head & Neck Surgery, The University of Texas MD Anderson Cancer Center, Houston, Texas

Chapter 71

Melonie Nance, MD, Assistant Professor, Department of Otolaryngology, University of Pittsburgh

Chapter 181

Jayakar Nayak, MD, PhD, Assistant Professor, Otolaryngology, Head and Neck Surgery, Stanford University, Stanford, California

Chapters 99, 110

Jason G. Newman, MD, FACS, Associate Professor, Otorhinolaryngology, Head and Neck Surgery, University of Pennsylvania, Philadelphia, Pennsylvania

Chapters 35, 36

Daniel W. Nuss, MD, FACS, Professor and Chairman, Department of

Otolaryngology, Head and Neck Surgery, Louisiana State University, New Orleans, Louisiana

Chapters 44, 66, 121

Bert O'Malley Jr. MD, Professor and Chair, Otorhinolaryngology, Head and Neck Surgery, University of PA Health System, Philadelphia, Pennsylvania

Chapter 36

Allison Ordemann, MD, Resident Physician, Otolaryngology, Head and Neck Surgery, University of Mississippi Medical Center, Jackson, Mississippi

Chapter 57

Bradley A. Otto, MD, Assistant Professor, Department of Otolaryngology, Head and Neck Surgery, The Ohio State University Wexner Medical Center, Columbus, Ohio

Chapter 97

Harshita Pant, BMBS, FRACS, PhD, Otolaryngology Head and Neck Surgery, University of Adelaide, Adelaide, Australia

Chapter 122

Joshua S. Park, MD, Otolaryngology, Loma Linda University School of Medicine, Loma Linda, California

Chapter 84

Renee E. Park, MD, MPH, Assistant Professor, Pediatric Otolaryngology, Loma Linda University Children's Hospital, Loma Linda, California

Chapter 194

Steven Parnes, MD, Professor Surgery/Otolaryngology, Albany Medical College, Albany, New York

Chapters 65, 182

David W. Parker II DDS, MD

Oral and Maxillofacial Surgeon, Private Practice, Advanced Oral and Facial Surgery of the Triad, Kernersville

Attending Physician, Oral and Maxillofacial Surgery, Forsyth Medical Center, Winston-Salem, North Carolina

Chapter 58

Anju K. Patel, BA, MD, Physician, Department of Otolaryngology, Tufts Medical Center, Boston, Massachusetts

Chapter 3

Chirag R. Patel, MD, Clinical Instructor, Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 113

Guy Petruzzelli, MD, PhD, FACS

Physician in Chief, Curtis and Elizabeth Anderson Cancer Institute at Memorial University Medical Center, Memorial University Medical Center, Savannah, Georgia

Vice-President for Oncology Programs, Memorial University Medical Center, Savannah, Georgia

Chapter 34

Kristina Piastro, MD, Resident, Division of Otolaryngology, Albany Medical Center, Albany, New York

Chapter 182

Carlos D. Pinheiro-Neto, MD, PhD, Assistant Professor and Co-Director Cranial Base Surgery Program, Division of Otolaryngology, Albany Medical Center, Albany, New York

Chapter 183

Karen Pitman, MD, Division of Surgical Oncology, Banner MDACC, Gilbert, Arizona

Chapters 17, 64

Aron Z. Pollack, MD, Assistant Professor, Department of

Otolaryngology-Head & Neck Surgery, Lenox Hill-Manhattan Eye, Ear, & Throat Hospital, The Hofstra-North Shore-LIJ School of Medicine, New York

Chapter 98

Anna M. Pou, MD, Professor and Vice Chair, Otolaryngology, Head and Neck Surgery, LSU Health Sciences Center, New Orleans, Louisiana

Chapters 16, 178

Sanjay Prasad, MD FACS, Center for Advanced ENT, Rockville, Maryland

Chapter 129

Daniel M. Prevedello, MD, Associate Professor, Department of Neurological Surgery, Wexner Medical Center, Ohio State University, Columbus, Ohio

Chapter 119

Christopher H. Rassekh, MD, Associate Professor, Otorhinolaryngology, Head and Neck Surgery, University of Pennsylvania, Philadelphia, Pennsylvania

Chapter 70

Yael Raz, MD, Assistant Professor, Department of Otolaryngology, University of Pittsburgh, Pittsburgh, Pennsylvania

Chapter 135

Travis Reeves, BS, MD, Assistant Professor, Otolaryngology, Eastern Virginia Medical School and Children's Hospital of the King's Daughters, Norfolk, Virginia

Chapter 196

Camilo Reyes, MD, Associate Professor, Otolaryngology, skull base surgery and neurosurgery, Emory University, Atlanta, Georgia

Chapter 120

Nikisha Q. Richards, MD

Ophthalmic plastic, Reconstructive and Aesthetic Fellow, Ophthalmology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Assistant Professor, Ophthalmology–Oculoplastics, Virginia Commonwealth University Health System, Richmond, Virginia

Chapter 152

Franklin L. Rimell, M.D. MSc., Department of Otolaryngology, University of Minnesota, Pediatric ENT and Facial Plastic Surgery, Children's Hospital and Clinics of Minnesota, Minneapolis, Minnesota

Chapter 195

Alexander Rivero, MD, Resident Physician, Department of Otolaryngology—Head and Neck Surgery, Kaiser Permanente, Oakland, California

Chapter 133

Kenneth D. Rodriguez, MD, Assistant Professor, Department of Otolaryngology, Head and Neck Surgery, University Hospitals Case Medical Center, Chief of Rhinology, Allergy, and Anterior Skull Base Surgery, Department of Otolaryngology, Head and Neck Surgery, University Hospitals Case Medical Center, Cleveland, Ohio

Chapter 184

Pamela Roehm, MD, PhD, Director, Division of Otology and Neurotology, Department of Otolaryngology, Head and Neck Surgery, Temple University School of Medicine, Philadelphia, Pennsylvania

Chapter 143

Clark A. Rosen, MD

Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Director, University of Pittsburgh Voice Center, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 1, 2, 5, 8, 9

Nicholas R. Rowan, MD, Resident Physician, Department of Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 103

Nivedita Sahu, MD, Resident Physician, Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 103

Joshua M. Sappington, MD, Fellow, Neurotology, Otology and Lateral Skull Base Surgery, Otolaryngology, Head and Neck Surgery, Louisiana State University Health Science Center and Our Lady of the Lake Regional Medical Center, New Orleans, Louisiana

Chapter 140

Barry M. Schaitkin, MD, Professor, Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 88, 103, 111, 112, 180

Amy Schell, MD, Resident Physician, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 51, 53

Alex Senchenkov, MD, Associate Professor, Department of Plastic Surgery, The University of Tennessee Health Sciences Center, Memphis, Tennessee

Chapters 164, 170

Gaurav A. Shah, DMD, MD, MPH, Resident, Department of Oral and Maxillofacial Surgery, University of Pittsburgh, Pittsburgh, Pennsylvania

Chapter 185

Jack A. Shohet, MD, Shohet Ear Associates Medical Group, Newport Beach and Seal Beach, Clinical Professor (Volunteer), Department of Otolaryngology-Head and Neck Surgery, University of California-Irvine, Orange County, California

Chapter 136

Julie P. Shtraks, MD, Resident Physician, Department of Otolaryngology-Head and Neck Surgery, Temple University School of Medicine, Temple University Hospital, Philadelphia, Pennsylvania

Chapter 143

Bianca Siegel, MD

Assistant Professor, Department of Otolaryngology, Wayne State University School of Medicine, Detroit, Michigan

Children's Hospital of Michigan, Detroit, Michigan

Chapter 195

Natalie L. Silver, MD, MS, Assistant Professor, Department of Otolaryngology, University of Florida, Gainesville, Florida

Chapter 71

Alfred A. Simental Jr. MD, Chairman, Otolaryngology, Head and Neck Surgery, Loma Linda University School of Medicine, Loma Linda, California

Chapters 67, *78*, *84*

Jeffrey P. Simons, MD, Associate Professor of Otolaryngology, University of Pittsburgh School of Medicine, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, Pennsylvania

Chapters 197, *198*

Libby J. Smith, DO, Associate Professor Otolaryngology, University of Pittsburgh School of Medicine, Director, Swallowing Disorders Center, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 2, *9*, *10*

Carl H. Snyderman, MD, MBA, FACS

Professor, Departments of Otolaryngology and Neurosurgery Neurological Surgery, University of Pittsburgh School of Medicine

Co-Director, Center for Cranial Base Surgery, University of Pittsburgh

Medical Center, Pittsburgh, Pennsylvania

Chapters 38, 77, 98, 109, 116, 122, 123, 151

Arturo Solares, MD, Associate Professor, Otolaryngology, Skull Base Surgery and Neurosurgery, Emory University, Atlanta, Georgia

Chapter 120

Mario G. Solari, MD, Assistant Professor, Department of Plastic Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 164, 170

John Song, MD, Associate Professor, Director of Head and Neck Surgery, Department of Otolaryngology, University of Colorado, Aurora, Colorado

Chapter 173

Ryan Soose, MD, Assistant Professor, Department of Otolaryngology, Director, Division of Sleep Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 54, 56

Satyan B. Sreenath, MD, Department of Otolaryngology- Head and Neck Surgery, University of North Carolina, School of Medicine at Chapel Hill, Chapel Hill, North Carolina

Chapter 166

Amanda L. Stapleton, MD, Assistant Professor of Otolaryngology, Otolaryngology, University of Pittsburgh School of Medicine, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Chapter 189

Tonya Stefko, MD, Assistant Professor, Ophthalmology, Otolaryngology, and Neurological Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapters 149, 151, 154, 187

Jeffrey Steitz, MD, Resident Physician, Otolaryngology, Head and Neck Surgery, University of Louisville, Louisville, Kentucky

Chapters 27, 83

Andrew Tassler, MD

Assistant Professor, Otolaryngology, Head and Neck Surgery, Weill Cornell Medical College

Attending Otolaryngologist, Otolaryngology, Head and Neck Surgery, New York Presbyterian Hospital, New York

Chapters 48, 93

Paul A. Tennant, BS, MD, Assistant Professor, Otolaryngology, Head and Neck Surgery, University of Louisville School of Medicine, Louisville, Kentucky

Chapter 27

Adam Terella, MD, Assistant Professor, Otolaryngology, Head and Neck Surgery, University of Colorado School of Medicine, Aurora, Colorado

Chapter 173

Andrew Thamboo, MD, MHSc, Clinical Instructor, Department of Otolaryngology, Head and Neck Surgery, Stanford University, Stanford, California

Chapter 99

Apurva Thekdi, MD, Director, Texas Voice Center, Houston, Texas

Chapter 8

Brian D. Thorp, MD, Assistant Professor, Department of Otolaryngology-Head and Neck Surgery, University of North Carolina, School of Medicine at Chapel Hill, Chapel Hill, North Carolina, USA

Chapter 166

Prasad John Thottam, DO., FAAP, Director Beaumont Children's Hospital Pediatric Aerodigestive Center, Clinical Assistant Professor

Michigan State University, Michigan Pediatric Ear, Nose and Throat Associates (MPENTA), Pediatric Otolaryngology/ Head & Neck Surgery, Detroit, Michigan

Chapter 193

Elizabeth Toh, MD, MBA, Director, Balance and Hearing Implant Center, Department of Otolaryngology, Head and Neck Surgery, Lahey Hospital and Medical Center, Burlington, Massachusetts

Chapters 139, *146*

Raymond K. Tsang, MS, MBChB, FRCSEd(ORL), FHKAM(ORL), Clinical Assistant Professor, Department of Surgery, University of Hong Kong, Hong Kong

Chapter 42

Amanda J. Tschetter, MD, Micrographic Surgery and Dermatologic Oncology (Mohs) Fellow, Skin Cancer Center, Mohs Surgery and Surgical Dermatology, Zitelli & Brodland, P.C., Pittsburgh, Pennsylvania

Chapter 161

Ramachandra P. Tummala, MD, Associate Professor, Neurosurgery, University of Minnesota, Minneapolis, Minnesota

Chapter 115

Meghan T. Turner, MD, Fellow in Advanced Head and Neck Surgical Oncology, Department of Otolaryngology, University of Pittsburgh School of Medicine

Chapters 12, *79*

Kitirat Ungkanont, MD, Associate Professor, Otolaryngology, Faculty of Medicine Siriraj Hospital Mahidol University, Bangkok, Thailand

Chapter 191

Andrew C. Urquhart, MD, FACS, Attending Physician, Otolaryngology, Head and Neck Surgery, Marshfield Clinic, Marshfield, Wisconsin

Chapter 104

Allan D. Vescan, MD, MSc, FRCSC, Assistant Professor, Otolaryngology, Head and Neck Surgery, University of Toronto, Toronto, Ontario, Canada

Chapter 116

Esther X. Vivas, MD, Assistant Professor, Neurotology and skullbase surgery, Department of Otolaryngology - Head and neck surgery, Emory University, Atlanta, Georgia

Chapter 144

Peter S. Vosler, MD, PhD, Resident Physician, Otolaryngology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Chapter 32

Evan S. Walgama, MD, Clinical Instructor, Otolaryngology, Head and Neck Surgery, Stanford School of Medicine, Stanford, California

Chapters 99, 110

David D. Walker, MD, Resident, Surgery Section of Otolaryngology, Head and Neck Surgery, University of Chicago, Chicago, Illinois

Chapter 30

Jonathan Walsh, MD, Assistant Professor, Otolaryngology, Johns Hopkins, Baltimore, Maryland

Chapter 199

Rohan R. Walvekar, MD, Associate Professor, Otolaryngology, Head and Neck Surgery, LSU Health Sciences Center, New Orleans, Louisiana

Chapters 66, 88, 89

Eric W. Wang, MD, Associate Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapters 24, 113, 117, 150, 156, 184

Peter Weber, MD, MBA, Director, Ear Institute, Mt Sinai and New York Eye and Ear, New York

Chapter 146

William I. Wei, MBBS, FRCS, FACS(Hon.), Emeritus Professor, Head, Department of Surgery, Director, Li Shu Pui ENT Head and Neck Surgery Centre, Hong Kong Sanatorium & Hospital, Hong Kong SAR, China

Chapter 42

Mark Whitaker, MD, Assistant Professor, Division of Otolaryngology, Department of Surgery, University of Vermont Medical Center, Burlington, Vermont

Chapter 125

Meghan N. Wilson, MD, Fellow Physician at The Children's Hospital of Philadelphia, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Chapter 121

Todd M. Wine, MD

Assistant Professor, Otolaryngology, University of Colorado Anschutz Medical Campus

Pediatric Otolaryngologist, Division of Pediatric Otolaryngology, Children's Hospital of Colorado, Aurora, Colorado

Chapter 190

Joshua W. Wood, MD, Resident Physician, Otolaryngology, Head and Neck Surgery, University of Tennessee Health Science Center, Memphis, Tennessee

Chapter 134

Robert Yellon, MD, Professor, Department of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Chapter 208

Yu-Lan (Mary) Ying, MD, Assistant Professor, Otology and Neurotology, Otolaryngology, Rutgers, The State University of New Jersey, Newark, New Jersey

Chapter 128

† Deceased

Preface

We are extremely proud to present the Third Edition of *Operative Otolaryngology: Head and Neck Surgery*. Since the publication of the Second Edition in 2008, we have witnessed tremendous progress in our specialty driven by technological advances and scientific inquiry with the refinement of surgical techniques, the development of new surgical approaches, and the genesis of new surgical disciplines. The Third Edition recognizes these changes with new and expanded content to present the latest advances across all disciplines. While we have changed the format for easier access and reliability, we have not changed our commitment to provide an accurate and up to date description of the *hows* and *whys* of reliable surgical techniques for an international audience.

The third edition has 78 more chapters, than the second edition, with new sections on the nasopharynx, pediatrics, sialendoscopy, and sleep disorders. Sections are organized based on anatomical region and subspecialty. Within each section, chapters are arranged from the less-to-more complex. New features of each chapter include: Evidence-Based Medicine Question, Editorial Comment, and Review Questions. One of the biggest advances in head and neck surgery has been the development of robotic surgery. The third edition includes applications of robotic surgery for neoplasia of the oropharynx, nasopharynx, hypopharynx, and larynx; volumetric tongue base reduction for obstructive sleep apnea; tumors of the prestyloid parapharyngeal space; and management of the unknown primary. There are greatly expanded sections on cranial base surgery, otology, reconstruction, and thyroid/parathyroid surgery. Interesting new techniques include: balloon sinuplasty, drug-induced sedated evaluation of obstructive sleep apnea, hyoid suspension, repair of superior canal dehiscence, and implantable middle ear devices. Although surgical techniques eventually fall out of favor and risk becoming obsolete, we recognize the importance of maintaining

proficiency with classical procedures, especially in regions of the world where resources are limited or circumstances require a different philosophy of surgical management. We have retained these time-tested techniques alongside minimally invasive alternatives.

Operative Otolaryngology: Head and Neck Surgery has always been about the legacy of the Department of Otolaryngology at the School of Medicine and the University of Pittsburgh Medical Center (UPMC) under the leadership of Eugene N. Myers and Jonas T. Johnson. Collectively, the faculty has had a tremendous impact on generations of residents, fellows, and international scholars. Many of their trainees (both domestic and international) have gone on to establish their own legacy through the promulgation, around the world, of the Pittsburgh way of managing patients. The extended "Pittsburgh family" has grown since the last edition, with a pool of 196 authors and 21 section editors. We are deeply indebted to them for their contributions. All of the authors of this textbook are members of the faculty of the University of Pittsburgh School of Medicine or Dental Medicine, have received training at the University of Pittsburgh Medical Center, or have trained under a graduate of these institutions.

Acknowledgments

We gratefully acknowledge the enormous contributions of our Editorial Coordinator, Beverly Poremba, and her staff: Allison Reiber and Nancy Yim.

We also acknowledge the efficient, good-natured help, guidance, and advice from Belinda Kuhn, Senior Consultant Strategist at Elsevier, along with Sam Crowe, Content Development Specialist, Joshua Mearns, Content Development Specialist, Dr. Atiyaah Muskaan, Project Manager, and Miles Hitchen, Senior Designer, from Elsevier for making this Third Edition possible.

We are eternally indebted to Mary Jo Tutchko for her efforts over the years, on all projects big and small. Nothing would ever get done without her help.

In Memoriam

This edition is dedicated to the memory of Berrylin J. Ferguson, MD, who served as an Associate Editor for the second edition. Dr. Ferguson was Professor of Otolaryngology in the University of Pittsburgh School of Medicine and Director of the Division of Sinonasal Disorders and Allergy at the University of Pittsburgh Medical Center. She established herself as an International leader in rhinology. Her presence is greatly missed.

Volume 1

OUTLINE

Section 1. Larynx: Voice

1. Office-Based Laryngeal Procedures
2. Phonomicrosurgery for Benign Vocal Fold Lesions
3. Recurrent Respiratory Papillomatosis
4. Vocal Fold Injection via Microlaryngoscopy
5. Medialization Laryngoplasty and Arytenoid Adduction
6. Intraoperative Medialization Laryngoplasty

Section 2. Larynx: Airway

7. Excision of Laryngocele
8. Laryngeal Trauma
9. Bilateral Vocal Fold Immobility
10. Acquired Laryngeal Stenosis

Section 3. Larynx: Oncologic Surgery

11. Transoral CO2 Laser Microsurgery for Cancer of the Larynx
12. Horizontal Partial Laryngectomy
13. Vertical Partial Laryngectomy
14. Supracricoid Partial Laryngectomy

15. Supraglottic Transoral Robotic Surgery

16. Total Laryngectomy

17. Total Laryngopharyngectomy

Section 4. Trachea and Mediastinum

18. Operative Otolaryngology: Bronchoscopy

19. Open Tracheostomy

20. Percutaneous Tracheostomy

21. Operative Otolaryngology: Laryngotracheal Separation

22. Tracheal Resection

23. Management of a Tracheocutaneous Fistula and Depressed Scar

24. Stenosis of the Tracheostoma Following Total Laryngectomy

25. Voice Restoration After Total Laryngectomy

26. Closure of the Tracheoesophageal Fistula Site

Section 5. Oral Cavity

27. Cancer of the Lip

28. Partial Glossectomy

29. Total Glossectomy

30. Excision of Cancer of the Floor of the Mouth

31. Operative Otolaryngology: Excision of Buccal Carcinoma

32. Transoral Inferior Maxillectomy

Section 6. Oropharynx

33. Transoral Excision of Oropharyngeal Malignancy

34. Transoral Laser Microsurgery of the Base of the Tongue

35. Transoral and Robotic Tonsil Surgery for Cancers of the Base of the Tongue and Pharynx

36. Transoral Robotic Surgery for Neoplasms of the Base of Tongue

37. Surgery of the Soft Palate

38. Transoral Removal of Elongated Styloid Process

39. Transcervical Pharyngotomy

40. Pharyngectomy

Section 7. Nasopharynx

41. Endoscopic Nasopharyngectomy

42. Robotic-Assisted Nasopharyngectomy

43. Maxillary Swing/Transpalatal/Midface Degloving With Le Fort I Osteotomy Approach for Nasopharyngectomy

44. Facial Translocation Approach to the Nasopharynx

Section 8. Hypopharynx and Esophagus

45. Esophagoscopy and Hypopharyngoscopy

46. Dysfunction of the Upper Esophageal Sphincter

47. Penetrating Trauma to the Hypopharynx and Cervical Esophagus

48. Partial Pharyngectomy

49. Reconstruction of Hypopharyngeal Defects

50. Cancer of the Cervical Esophagus

Section 9. Surgery of Obstructive Sleep Apnea

51. Office-Based Snoring Procedures

52. Drug-Induced Sedated Endoscopy

53. Uvulopalatopharyngoplasty and Related Modifications (Traditional Uvulopalatopharyngoplasty, Uvulopalatal Flap, Anterior Palatoplasty)

54. Advanced Palatal Surgery: Expansion Sphincter Pharyngoplasty & Transpalatal Advancement Pharyngoplasty

55. Volumetric Tongue-Base Reduction (Lingual Tonsillectomy, Coblation Midline Glossectomy, Trans Oral Robotic Surgery)

56. Hypoglossal Nerve Stimulation Therapy

57. Hyoid Suspension

58. Genioglossus Advancement

59. Maxillomandibular Advancement for Obstructive Sleep Apnea

Section 10. Neck and Parapharyngeal Space

60. Office-Based Procedures: Fine-Needle Aspiration Biopsy of a Mass in the Head and Neck

61. Management of the Unknown Primary Cancer

62. Sentinel Lymph Node Biopsy

63. Superselective Neck Dissection

64. Selective Neck Dissection

65. Modified Radical Neck Dissection

66. Radical Neck Dissection

67. Central Compartment Neck Dissection

68. Retropharyngeal Neck Dissection

69. Management of Tumors in the Prestyloid Parapharyngeal Space

70. Transoral Approach to the Parapharyngeal Space

71. Posterolateral Neck Dissection

72. Excision of Neural Tumors of the Parapharyngeal Space

73. Excision of Carotid Body Tumors

74. Endoscopic and Robotic Applications to Neck Surgery

75. Management of Traumatic Soft Tissue and Vascular Injuries to the Neck

76. Deep Neck Abscesses

77. Anterior Transcervical Approach to the Cervical Spine

Section 11. Thyroid and Parathyroid

78. Open Thyroidectomy

79. Minimally Invasive Video-Assisted Thyroidectomy

80. Robotic-Assisted Thyroidectomy

81. Massive and Substernal Goiter

82. Invasive Thyroid Cancer

83. Intraoperative Parathyroid Hormone Monitoring

84. Parathyroidectomy for Primary Hyperparathyroidism and Nonlocalizing Hyperparathyroidism

85. Parathyroidectomy for Secondary Hyperparathyroidism

86. Reoperative Parathyroidectomy

Section 12. Salivary Glands

87. Office-Based Procedures

88. Salivary Endoscopy

89. Surgical Management of Ranula

90. Mass in the Buccal Space

91. Excision of the Submandibular Gland

92. Superficial Parotidectomy

93. Deep Lobe Parotidectomy

Section 13. Nasal Cavity

94. Office-Based Diagnosis of Sinonasal Disorders

95. Septoplasty—Classic and Endoscopic

96. Nasal Septal Perforation

97. Surgery of the Turbinate

98. Sphenopalatine Artery Ligation for Epistaxis

99. Operative Otolaryngology: Anterior and Posterior Ethmoid Artery Ligation for Epistaxis

100. Surgical Management of Hereditary Hemorrhagic Telangiectasia

101. Rhinectomy

Section 14. Paranasal Sinuses

102. Balloon Sinus Dilation

Office-Based Laryngeal Procedures

Priya Krishna, and Clark A. Rosen

Introduction

Office-based laryngeal procedures are quickly gaining popularity. These procedures are cost effective and provide an important alternative for patients who are not good candidates for operative direct laryngoscopy. Included are those patients with contraindications to general anesthesia or who have anatomic variations that result in poor exposure when direct laryngoscopy is attempted. Advantages of procedures performed on an awake patient in the office include the performance of intraoperative assessment of vocal quality without interference from sedation or an endotracheal tube.[1] Described in this chapter are several procedures that can be successfully and relatively easily undertaken in the office setting under local anesthesia.

Key Operative Learning Points

1. The superior arcuate line is the key landmark lateral to the vocal fold for injection augmentation of the vocal fold.

2. Proper positioning of the patient, strong endoscopy skills, adequate anesthesia, and appropriate patient selection are critical to success of an in-office laryngeal procedure.

3. It is important to know exactly where the tip of the needle is prior to injection for *any* type of injection procedure. The angle of the needle in an injection procedure is also an important consideration in ensuring success of the procedure.

4. Avoiding multiple injection sites during injection augmentation improves retention of the injected material.

Preoperative Period

History

1. History of present illness—Patients may present a variety of complaints:

   a. Hoarseness

   b. Chronic cough

   c. Shortness of breath

   d. Throat pain

   e. Difficulty swallowing

2. Past medical history

   a. Recent surgery where the recurrent laryngeal nerve was at risk

   b. Neurologic disorders (Parkinson's disease, multiple system atrophy, essential tremor)

   c. History of recent intubation

   d. Recent laryngoscopy or laryngeal surgery

   e. History of laryngopharyngeal reflux

   f. Occupational voice use, recreational voice use, or vocal misuse

   g. History of smoking

Physical Examination

1. Perceptual assessment of voice: Breathy voice in glottic insufficiency or breathy breaks with abductor spasmodic dysphonia, strained–strangled voice in case of adductor spasmodic dysphonia, strained voice in case of vocal fold granuloma

2. Raspy voice quality and/or diplophonia with paralysis, paresis, presence of vocal fold lesions of any kind

3. Oral cavity/oropharyngeal anatomy: Interincisal distance, presence, and strength of gag reflex

4. Neck anatomy: Ease of palpating thyroid and cricoid cartilage landmarks, presence of masses

5. Flexible laryngovideostroboscopy demonstrating:

   a. Vocal fold atrophy

   b. Vocal fold hypomobility or immobility

   c. Vocal fold scar demonstrating a decreased mucosal wave

   d. Benign vocal fold lesions: Polyps, cysts, Reinke edema, vocal fold granulomata, and papillomas

   e. Lesions of unknown malignant potential (leukoplakia/ hyperkeratosis)

   f. Laryngeal dystonia or tremor

Imaging

No imaging is required preprocedure, although imaging may be recommended in diagnosis of some disease processes being treated by office procedures (outside the scope of this chapter)

Indications

1. Vocal fold injection[2]

   a. Augmentation: Glottic insufficiency of any kind (due to vocal fold paralysis, paresis, atrophy, scar)

   b. Modulation of vocal fold scars (steroids) or subglottic/tracheal scar

   c. Treatment of spasmodic dysphonia

2. Biopsy

   a. Establishment of a diagnosis for a laryngeal lesion

3. Laser[3]

   a. Treatment of vascular lesions of the vocal fold (i.e., ectasias, varices)

   b. Treatment of epithelial and selected subepithelial lesions of the vocal fold (i.e., polyps, cysts, papilloma, Reinke edema, granulomata, glottic webs, leukoplakia, dysplasia)

Contraindications

1. Unstable cardiopulmonary status

2. Allergy to local anesthetics or injectable materials

3. Poor exposure of the endolarynx due to prolapsing arytenoid or severe supraglottic constriction

4. Poorly defined cervical anatomic landmarks (in case of percutaneous injection)

5. Significant tremor in the laryngopharynx

Contraindications to botulinum toxin use:

1. Pregnancy

2. Breast-feeding

3. Impaired abduction of vocal fold (in setting of posterior cricoarytenoid muscle (PCA) injection)

4. Any neuromuscular condition (i.e., myasthenia gravis)

5. Concurrent aminoglycoside treatment

Preoperative Preparation

1. Discontinue antiplatelet/anticoagulants (though no studies to show increased incidence of complications with in office injection).

2. Recommend prescribing a small dose of an anxiolytic (i.e., Xanax 0.5 mg 1 hour prior to procedure and may be repeated once 5 minutes prior to procedure if needed) for patients who know they might experience anxiety.

Operative Period

Perioperative Antibiotic Prophylaxis

1. Not required—rate of infection is very low, despite this being a clean-

contaminated surgical environment

Monitoring

No active monitoring is necessary during an in-office procedure; it is advisable to take preprocedure and postprocedure vital signs.

Anesthesia

1. Nebulizer: 5 cc 4% lidocaine delivered over 10 minutes—useful for per-oral procedures to eliminate the gag reflex

2. Flexible drip catheter: Silastic catheter guided through the channel of the flexible laryngoscope, direct application to larynx of 4% lidocaine, elicit laryngeal "gargle"

3. Percutaneous transtracheal/transcricothyroid injection of 4% lidocaine, which induces vigorous coughing

4. Anesthetize the skin with 1% lidocaine with epinephrine for percutaneous techniques (optional).

5. Be mindful of toxic limit of 7 to 8 mL (5 mg/kg; approximately 350 mg in 70-kg patient)[4].

Positioning

1. Upright position in examination chair for the majority of procedures

2. Option is supine position during electromyographic (EMG)-guided injection of the botulinum toxin

Patient Factors[5]

"the ideal patient has:"

1. Normal or minimal gag reflex

2. Ability to remain calm for 10- to 30-minute duration of procedure

3. Adequate interincisal distance of 20 mm at least (i.e., no trismus)[3]

4. Adequate intranasal airway (to pass laryngoscope, which is 3 to 4 mm in diameter, or TNE scope, which is 5 mm in diameter)

5. Absence of neurologic conditions affecting stability of the head (no torticollis or tremor)

6. Motivated to have the procedure done in the "office" and not the operating room with general anesthesia

Instruments and Equipment to Have Available

- Flexible laryngoscope with distal chip with a channel for passage of a flexible catheter for anesthetic and/or flexible needle passage and/or fiber-based laser (or rigid 70-degree telescope for a one-person approach)
- C-mount camera (attaches to the flexible or rigid laryngoscope)
- Video monitor for visualization (Fig. 1.1)
- Curved Abraham cannula for delivery of topical lidocaine and vocal fold palpation, as needed; alternative: flexible drip catheter placed inside flexible scope channel or an angiocatheter type device to fit in the working channel
- Injection device for transoral injection approach–orotracheal injector or proprietary malleable needles (Merz North America)
- 23-, 25-, or 27-gauge 1.5-inch needles for percutaneous injection (when required) or 20-gauge spinal needle for certain techniques
- Flexible fine-gauge injection needle for use with working channel in flexible laryngoscope
- Endoscopic biopsy forceps to place through working channel or per-oral type biopsy forcep
- Injectable material: Calcium hydroxylapatite, carboxymethylcellulose, hyaluronic acid, micronized dermis (for augmentation), dexamethasone, or triamcinolone
- Alcohol prep pad or topical prep solution (povidone-iodine) for

percutaneous injections

- Topical cetacaine spray (benzocaine/tetracaine)
- Topical oxymetazoline and/or 2% Pontocaine or 2% lidocaine mixture for nasal decongestion and anesthesia
- Cotton pledgets
- 4% lidocaine (topical) for drip and nebulization
- 2% lidocaine viscous
- Nebulizer
- Potassium titanyl phosphate (KTP), neodynium:yitrium aluminium garnet (Nd: YAG), or fiber-guided CO_2 lasers

Specific to Botox injection:

- EMG device—either handheld or traditional EMG apparatus
- Botulinum toxin

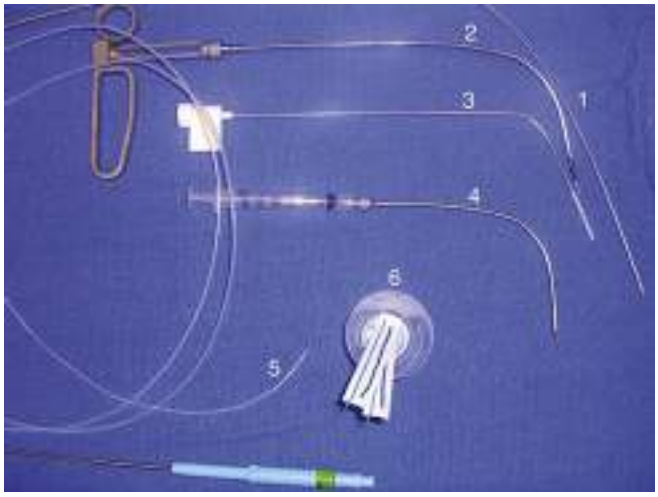

FIG. 1.1 Common equipment used for office laryngeal procedures. *1,* flexible wire sheath with 27-gauge needle; *2,* Xomed orotracheal injector device; *3,* Merz -Bioform malleable 25-gauge orotracheal needle; *4,* 3-mL syringe attached to Ab raham cannula; *5,* end of flexible endoscopic catheter for administration of topical anesthetic; *6,* nasal pledgets.

- Insulated 25- or 26-gauge needle electrode, which is also used to simultaneously administer Botox
- Local anesthetic for skin (1% lidocaine with 1:100,000 epinephrine)—optional

Key Anatomic Landmarks

1. Superior arcuate line—line starting at lateral border of vocalis and where the ventricle starts

2. Thyroid notch—for thyrohyoid technique

3. Thyroid cartilage

4. Cricothyroid membrane—for percutaneous augmentation or botulinum toxin injection

Prerequisite Skills

1. Strong skills with endoscopic procedures

2. Thorough knowledge of external and internal laryngeal anatomic landmarks

3. Laser safety training (for any laser procedure)

Operative Risks

1. Infection

2. Bleeding/hemorrhage

3. Worsening hoarseness due to misplaced injectable (if in a too superficial plane; i.e., Reinke space)

4. Airway obstruction

5. Aspiration due to residual local anesthetic

6. Anesthetic toxicity from overdose

Surgical Techniques

Percutaneous Methods

Percutaneous injection technique (two-person): Transcricothyroid (Fig. 1.2)

- Anesthetize skin with either 1% lidocaine with epinephrine or transtracheal 4% lidocaine injection.
- Bend 25-g 1.5″ needle at 45-degree angle.
- Place needle through cricothyroid space just off midline of the side to be injected.
- Assistant can use flexible laryngoscope to confirm position of the needle.
- Can visualize needle in subglottic airway, aim toward infraglottic surface of vocal fold
- Botox injection using laryngeal EMG guidance does not need visual confirmation (one-person technique).

Percutaneous injection technique (two-person): Thyrohyoid (Fig. 1.3)

- Anesthesia techniques are the same as for the transcricothyroid method.
- Use either 25-g 1.5″ needle or spinal needle.
- Enter thyrohyoid space at thyroid notch at an acute angle, nearly 90 degrees.

Percutaneous injection technique (two-person): Transthyroid cartilage

- Topical anesthesia administered similar to other percutaneous techniques
- Need an endoscopist to help confirm needle position
- Guide 20-gauge spinal needle through thyroid cartilage in perpendicular fashion, and then rotate it anteriorly and horizontal to the ground; position needle 6 to 8 mm lateral to midpoint of thyroid cartilage; spinning the needle through the cartilage like a screw eases insertion.
- Tilt needle laterally toward ipsilateral arytenoid cartilage to run needle

parallel to vocal fold; avoid puncturing the epithelium.

- Remove stylet and then attach syringe with injectate; slowly inject under direct visualization from above with laryngoscope.

Per-Oral Injection Technique (Fig. 1.4)

- Use either proprietary needle, which comes with injectable material (Merz Aesthetics), or Xomed orotracheal injector needle.
- For the orotracheal injector, load a slip tip tuberculin syringe with injectable material of choice and attach a disposable needle to the end of shaft.
- Can use nebulized 4% lidocaine (5 cc) to help with depressing gag reflex
- Place ½″ × 3″ pledgets, with a mixture of oxymetazoline and 4% lidocaine into both nasal cavities for at least 5 minutes.

FIG. 1.2 Transoral vocal fold augmentation with endoscopic guidance placement of Abraham cannula. Note positioning of patient.

FIG. 1.4 Proper placement of the needle lateral to the vocal fold for augmentation using flexible endoscopy. Reprinted with permission from Andrade FP, Carrau R, Buckmire R: Safety and cost-effectiveness of intra-office flexible video-laryngoscopy with transoral vocal fold injection in dysphagic patients. Am J Otolaryngol 27:319-322, 2006.

- Remove pledgets. Then guide flexible channel laryngoscope, to the level of the base of the tongue; then use drip catheter with 4% lidocaine to drip sequentially over the base of the tongue, epiglottis, AE folds, and laryngeal vestibule and vocal folds; you can also use Abraham cannula perorally to deliver topical anesthesia.
- Gently palpate vocal folds with the tip of the catheter to confirm adequate anesthesia.
- Apply either a small amount of additional 4% lidocaine or 20% benzocaine (HurriCane) spray to the oropharynx for additional suppression of the gag reflex.
- Have the patient hold his/her own tongue with gauze downward, and ask the patient to bring the jaw forward; alternatively, the surgeon can hold the tongue with the gauze.
- Guide the needle through the oral cavity over the base of the tongue into the endolarynx while visualizing on the monitor.
- Aim for a point just anterior and lateral to the vocal process in the superior arcuate line lateral to the bulk of the thyroarytenoid muscle, feel a "pop" or loss of resistance, and inject the desired amount based on contouring of the vocal fold. Avoid injecting too far medially, which may place a superficial deposit with a poor phonatory result (Fig. 1.5).
- Can confirm adequate closure (if done for augmentation/medialization) via stroboscopy postinjection

Transnasal Biopsy, Laser, or Injection Technique

- Anesthesia is delivered in an identical fashion as described previously, with nebulization and directed delivery of topical anesthesia.
- All instruments—biopsy forceps, laser fiber ensheathed in a metal guide, or endoscopic needle—are placed through the working channel.
- When performing a biopsy, it is important to grasp the tissue in question in the vocal fold and pull with a quick movement to avoid excessive tearing of the mucosa, which can lead to vocal fold scarring; biopsy anywhere else in the larynx requires the same quick movement.

FIG. 1.5 Thyrohyoid approach in cadaver larynx. Reprinted with permission from Getz AE, Schar J, Amin M: Thyrohyoid approach to cidofovir injection: a case study. J Voice 19:501-503, 2005.

- When using a laser, all personnel must wear protective eyewear specific for the laser type and for papilloma treatment. Use of laser mask is advisable but not required; standard KTP laser settings are 30 to 35 watts, 15 ms pulse width, and 2 pulse per second rate of fire.
- For steroid injection, the needle can be guided to a superficial location within the vocal fold in the treatment of benign lesions, if applicable.

Commons Errors in Technique

1. Multiple injection sites or superficial injection
2. Plugging of the needle in transcartilaginous methods
3. Inadequate visualization
4. Inadequate level of anesthesia
5. Misplaced Botox or diffusion of Botox into surrounding musculature
6. Excessive removal of mucosa leading to vocal fold scarring

Postoperative Period

Postoperative/Postprocedure Management

1. No eating or drinking is allowed for 1 hour after the procedure in order to avoid aspiration.

2. For injection augmentation, the patient should observe voice rest for 24 hours.

3. The patient receiving Botox injection for laryngeal dystonia should be told to not expect any effect for at least 2 to 3 days.

4. Voice rest is recommended for between 3 and 6 days for laser treatment of benign vocal fold lesions, except in the case of papilloma (which depends on the amount of mucosal free edge of vocal fold being treated).

Complications

1. Vasovagal reaction

2. Respiratory compromise

3. Misplacement of injectable into the wrong plane, resulting in adverse phonatory outcomes

4. Inadvertent surrounding tissue burns from laser use or excessive laser use, which may cause vocal fold scarring

5. Aspiration pneumonia from too large an injection of botulinum toxin into the laryngeal adductor muscles

Alternate Management Plan

For augmentation/medialization:

1. Voice therapy alone but usually both pre- and postprocedure

2. Laryngeal framework surgery

For chemodenervation (use of Botox/Xeomin)

1. Selective laryngeal adductor denervation

For benign and premalignant vocal fold lesions

1. Microsuspension direct laryngoscopy ± microflap excision ± laser treatment

2. Voice therapy

Discussion

Evidence-Based Medicine Question

Are intralesional steroid injections in the office well tolerated and beneficial in treatment of benign vocal fold lesions?

A meta-analysis of six studies performed in 2013 indicated that these procedures are well tolerated under local anesthesia and demonstrated significant improvements in both objective and subjective measures of vocal quality.

Editorial Comment

Office-based laryngeal procedures have now become the preferred modality of treatment for many otolaryngologists. Not only are they time saving but they avoid the dangers of sedation or general anesthesia. This is not to say that office-based procedures are not without complications. However, serious complications that leave a patient with long-term morbidity or mortality are exceedingly rare. Knowing where one's needle tip is at all times before an awake office-based vocal fold injection augmentation is paramount. The per-oral technique offers the ideal visualization and angle of insertion into the layered vocal fold but also has the steepest learning curve of any of the techniques. Once mastered, though, it provides an effective and predictable intervention. The percutaneous techniques can be more facile to learn and can also offer visualization of the needle tip before injection; however, the depth of insertion can be more unpredictable due to the angle of needle insertion. Indications for office KTP laser continue to grow and now include some benign subepithelial vocal fold lesions and vocal fold scarring (with the

intention of remodeling/softening the scar). Patients with chronic epithelial disease such as papilloma and dysplasia are now returning to the OR much less frequently due to office-based KTP laser "maintenance" of these lesions. Almost all of these procedures require more than one person to complete. A reliable and easily reproduceable one-man technique/device for vocal fold injection augmentation that can be performed in the office by any otolaryngologist is hopefully on the horizon.

Review Questions

1. All of these are relative contraindications for a per-oral approach, except

   a. Head tremor

   b. Trismus

   c. Anxiety

   d. **Previous head and neck cancer surgery**

2. All of these are approaches to vocal fold augmentation, except

   a. Per-oral

   b. Transcricothryoid

   c. Thyrohyoid

   d. **All of the above**

3. Vocal fold augmentation is typically done for which of the following indications?

   a. **Vocal fold paralysis**

   b. Vocal fold polyps

   c. Respiratory papillomatosis

   d. Reinke edema

Phonomicrosurgery for Benign Vocal Fold Lesions

Clark A. Rosen, and Libby J. Smith

Introduction

Patients complaining of hoarseness, vocal fatigue, diminished vocal range, strain, or other vocal issues require a complete laryngeal examination. Based on the findings of this examination, several treatments may be indicated, including surgery. Phonomicrosurgery (PMS) encompasses a variety of elective operations whose primary goal is to improve the quality of the voice. These procedures focus on precision microsurgical techniques to remove benign vocal fold lesions, while not disrupting surrounding normal tissue. Hirano's body cover theory of vocal fold vibration is paramount in the design of current microsurgical principles and surgical procedures.[1] The delicate interface between the mucosa (cover) and the deeper lamina propria layers and muscle (body) allows for the creation of a mucosal wave (Fig. 2.1). Alterations in the muscosal wave result in dysphonia. Stroboscopy, which provides vital information about the mucosal wave, is absolutely essential in the evaluation of dysphonic patients. Wound healing is optimized by preserving the mucosa whenever possible and limiting surgery to the vocal fold layers involved with pathology (staying as superficial in the vocal fold as possible). The higher content of fibroblasts in the vocal ligament may result in increased scar deposition if surgery extends to this region.[2] Fortunately, the majority of bilateral vocal fold lesions are located within the superficial lamina propria, resulting in expected better postoperative mucosal wave vibration, and thereby likely improving vocal outcomes. Our improved knowledge of vocal fold microanatomy and the use of stroboscopy have led to improved patient care and surgical advancement in PMS.

Sound is the product of subglottic airflow forcing closed vocal folds to open, thereby leading to the generation of a mucosal wave along the medial edge of the vocal fold. Closure of the vocal folds during this vibratory cycle is achieved by the inherent elastic recoil of the vocal fold and the Bernoulli effect. This is called the myoelastic aerodynamic theory of phonation. This cycle usually occurs 100 to 1200 times per second. A mass on the vocal fold can disrupt this normal process and lead to hoarseness and other vocal complaints. Therefore the use of stroboscopy, which allows visualization of the mucosal wave, is indispensable in the care of these patients. Depending on the patient's history and laryngeal examination, either flexible transnasal laryngoscopy with stroboscopy (vocal fold motion abnormalities), or rigid, per-oral, endoscopy with stroboscopy (lesions), or both may need to be performed to fully evaluate the larynx. Such laryngeal examinations will provide the surgeon with an idea of the depth and type of the lesion. Although all vocal fold lesions are sent to pathology for evaluation, it is difficult for pathologists to distinguish between various vocal fold lesions based on their histologic characteristics. Precise classification of benign vocal fold lesions is therefore based on the surgeon's evaluation in the operating room, including magnification with the operating microscope, palpation of the vocal fold, identification of the physical features of the lesion or lesions, such as a cystic or fibrous mass, and location of the pathology.[3]

Key Operative Learning Points

- The key surgical anatomy related to PMS for benign vocal fold lesions involves the layered structure of the membranous true vocal fold.
  - Major components to the layered structure of the vocal fold
    - Epithelium
    - Lamina propria
    - Muscle (thyroarytenoid-lateral cricoarytenoid)
  - The most medial aspect of the muscle that runs from the vocal process of the arytenoid to the thyroid cartilage is named the vocalis muscle.
- Excluding epithelial diseases of the vocal folds, all benign vocal fold lesions arise within the lamina propria, which can be defined as the

anatomic space between the epithelium and the muscle of the vocal fold. There are anatomically (or histologically) three distinct layers of the lamina propria.

  - Superficial layer
  - Intermediate layer
  - Deep layer
    - The intermediate and deep layers, also called the vocal ligament, are not surgically distinct.

- From a surgical perspective, there are two key operative locations within the lamina propria
  - Subepithelial space
  - Ligamentous region
- The mucosa of the vocal fold is defined as being composed of the epithelium and the superficial layer of the lamina propria.
- The majority of benign vocal fold lesions occur within the subepithelial space. The most common pathology that occurs in this region includes[4]:
  - Vocal fold nodules
  - Vocal fold polyp(s)
  - Subepithelial cyst(s)
  - Subepithelial fibrous mass(es)
  - Reinke edema
- Lesions that occur in the area of the vocal fold ligament include:
  - Ligamentous vocal fold cyst(s)
  - Ligamentous fibrous mass(es)
  - Rheumatologic lesion(s)[3]
- The majority of benign vocal fold lesions occur in the midportion of the membranous vocal fold, which is positioned halfway between the anterior commissure and the vocal process of the true vocal fold.

Types of Benign Vocal Fold Lesions[3]

• Vocal Nodules

Vocal nodules are benign bilateral lesions, not always symmetrical, located within the lamina propria, with normal overlying epithelium. The mucosal wave is normal or near-normal. They are typically located at the midpoint of the musculomembranous vocal fold. Breathy and raspy dysphonia is the result of incomplete vocal fold closure. Vocal nodules tend to occur in patients who use their voices aggressively (i.e., children, cheerleaders). After the inciting phonotraumatic behavior is eliminated and voice therapy is implemented, these lesions always resolve. Accordingly, surgery is not indicated for vocal nodules.

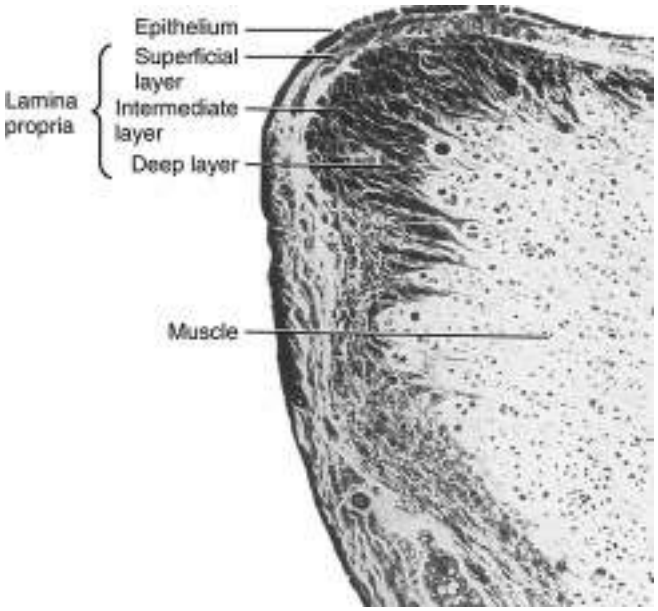

FIG. 2.1 Cross-sectional view of a vocal fold demonstrating layers of the vocal fold lamina propria. Reprinted with permission from Hirano M: Clinical Examination of Voice. New York: Springer-Verlag; 1981, p 5.

• Nonspecific Vocal Fold Lesion(s)

These vocal fold lesions are similar to vocal fold nodules. However, these lesions persist after voice therapy, despite resolution or significant improvement of the patient's dysphonia. Because the patients' dysphonia

resolves and the lesions are benign, no surgery is indicated.

• Vocal Fold Polyp

A vocal fold polyp is located in the subepithelial space, usually at the midpoint of the musculomembranous vocal fold. It is generally unilateral, sometimes with a contralateral reactive lesion. A vocal fold polyp can be sessile (broadly attached to a vocal fold) or pedunculated (hanging from a stalk). This lesion is believed to be the product of intense phonotrauma or vocal fold hemorrhage. Inflammatory agents, dehydration, hormone treatment, and anti-inflammatory medications may be predisposing factors. Truncation or microflap excision is performed for a vocal fold polyp if the voice is functionally impaired after conservative therapy.

• Vocal Fold Cyst

A vocal fold cyst, both subepithelial and ligamentous, is often unilateral and located at the edge of the midmusculomembranous portion of the vocal fold. The encapsulated structure is thought to be due to glandular duct blockage or phonotrauma or may be congenital. The mucosal wave is more reduced with a ligamentous vocal fold cyst. Proper voice use and voice therapy are often the initial treatments. If this is not adequate to meet the vocal demands of the patient, microflap excision is performed.

• Fibrous Mass

A fibrous mass is composed of irregular fibrous material without clearly defined borders. This lesion can occur in either the subepithelial space or near the ligament of the vocal fold, both with normal overlying epithelium. This mass is often located in the midmembranous vocal fold, either unilateral or bilateral, and therefore incomplete vocal fold closure is common. Unilateral lesions are frequently associated with a contralateral reactive lesion. Development of a fibrous mass is often associated with chronic phonotrauma or hemorrhage. Voice therapy is often the initial treatment. If this fails, surgical excision with a microflap technique is indicated.

Subepithelial fibrous mass(es) have a reduced mucosal wave but not usually as severely reduced as ligamentous fibrous mass(es). When deep dissection is needed to excise these lesions, there is a greater risk of

reduced postoperative voice improvement than with more subepithelial fibrous masses.[4]

- Reactive Lesion

Reactive lesions are believed to result from altered contact forces from a primary contralateral lesion, such as a polyp, cyst, or fibrous mass. Videostroboscopy will demonstrate a convex lesion (primary lesion) that fits into a concave reactive lesion (secondary lesion). This lesion can be surgically removed at the same time the primary lesion is removed or left to resolve during the postoperative period. This decision is based on the surgeon's preference and experience.

- Reinke Edema (Polypoid Degeneration, Diffuse Polyposis, Chronic Polypoid Corditis)

Reinke edema involves the deposition of gelatinous material within the subepithelial space. It is usually bilateral but may be asymmetrical or unilateral. These patients' voices are lower in pitch and dysphonic. Clinically, women are affected more often by Reinke edema; however, this may be due to selection bias because women are more bothered by lower vocal pitch and roughness and thus are more prone to seek treatment. The largest risk factor is smoking, followed by reflux and phonotrauma. When the pathologic accumulation is severe, airway obstruction can occur. Primary treatment is to remove the offending agents that led to the development of Reinke edema. Smoking cessation is vital. Voice therapy can occasionally be helpful if the probable cause is phonotrauma. Only after several months of compliance with smoking cessation and other conservative treatments (acid suppression and voice therapy) should surgery be considered, except in the case of airway obstruction. Conservative removal of a portion of the gelatinous material is achieved through a lateral cordotomy on the superior aspect of the vocal fold, followed by suctioning and/or near complete removal of material from the subepithelial space and excision of redundant tissue. Care must be taken because overly aggressive removal of redundant superficial lamina propria will lead to scarring and permanent hoarseness. Laser treatment with the potassium titanyl phosphate (KTP) laser may be a reasonable alternative treatment option.[5]

Preoperative Period

History

- Dysphonia
  - Speaking voice
  - Singing voice
- Vocal fatigue
  - Speaking voice
  - Singing voice
- Diminished singing range
  - Upper
  - Lower
  - Passaggio (transition from chest to head voice)
- Vocal strain
- Increased effort
  - Speaking voice
  - Singing voice
- Voice use history and demands
  - Speaking voice
  - Singing voice

Physical Examination

- Examination of the head and neck
- Specialized examination of the larynx
  - Flexible laryngoscopy ± rigid laryngoscopy
  - Stroboscopy
    - Evaluation of the vibratory margin so that the vibratory effects of the lesion(s) can be determined. Alteration or diminution of the mucosal wave (vibration along the medial/vibratory margin) leads

to dysphonia.

- This view also allows the clinician to look for associated vocal fold scar(s), which may be an important comorbidity and negatively impact surgical outcome.

Imaging

- Radiologic imaging is very rarely indicated.

Indications

- PMS is an elective procedure. The risks and benefits of surgery should be clearly explained to the patient.
- The patient's vocal limitations (speaking and singing) should be thoroughly reviewed, especially in relation to the vocal requirements of occupational, avocational, and social demands.
- This review process is often conducted over a period of several weeks and involves the patient, the family, a speech therapist, and possibly a singing voice specialist.
- After all nonsurgical therapies (when appropriate) have been exhausted and still more is required of the patient's voice, only then is it appropriate to proceed with PMS.

Contraindications

- Poor patient compliance with voice therapy and/or future healthy voice use
- Inadequate time postoperatively for voice rest and reduced voice use
- Severe comorbidities

Preoperative Preparation

- Preoperative voice therapy is very important in preparing the patient for surgery. One to two sessions are often scheduled if the patient did

not receive voice therapy before the decision to undergo surgery.

- Anticoagulant medications should be avoided preoperatively if medically possible.
- Smoking cessation is critical for improved postoperative healing.
- The patient should avoid vocal abuse and misuse preoperatively. These guidelines will prepare the patient and vocal folds for surgery.
- The need for an absolute voice rest (approximately 7 days) and reduced voice use (additional 7 to 10 days) after surgery should be discussed with the patient preoperatively. The amount of voice rest and restricted voice use is determined by the extent of surgery along the vibratory margin of the vocal fold (the medial portion of the vocal fold that makes contact with the other vocal fold during vibration).
- The patient should make the appropriate schedule changes to comply with the prescribed postoperative voice restrictions.
- If the patient has any laryngopharyngeal reflux symptoms (globus, throat clearing, excessive mucus, cough, heartburn[4]), proper acid suppression medications should be started several weeks before surgery. This may decrease the risk for postoperative wound-healing complications.
- Discussion of consent for PMS should include the risks associated with general anesthesia, infection, bleeding, dental injury, injury to the temporomandibular joint, and injury to the lingual nerve.[6]
  - A serious discussion between the patient and surgeon involving the small but real risk of no voice improvement or worsening of vocal function must take place before surgery.
  - Keeping in mind the elective nature of these surgeries, the patient must accept these risks.[7]

Operative Period

Anesthesia

- Close communication between the surgeon and the anesthesia team is

important for successful PMS.

- These procedures require general anesthesia, with complete relaxation of the patient throughout the procedure.
- Preoperative medications
  - Steroids (intravenous [IV])
  - Glycopyrrolate (Robinul) (unless contraindicated) will improve the surgical environment by minimizing swelling and secretions.
  - Acetominophen (IV)
  - Antiemetic agent if indicated
  - A small endotracheal tube (size 5.0 to 5.5) should be placed without the aid of a stylet.
    - Not only does the smaller tube improve visualization for the surgeon, but it also diminishes the chance of injury to the vocal folds during intubation.
    - If a vocal fold(s) is injured during intubation, the planned surgery may need to be postponed.
    - Stressing the importance of careful intubation is often facilitated by discussing the planned surgery with the anesthesia team before the procedure and by the surgeon being present during intubation.
    - If an endotracheal tube will obscure adequate visualization, jet ventilation can be used. Tracheal jet ventilation is preferred over supraglottic jet ventilation because there is no vibration of the operative site nor desiccation of the vocal fold tissues.

Positioning

- Patient positioning is critical to obtain the best visualization of the larynx.
- The optimal position is supine with the neck flexed and the head extended (Fig. 2.2).
  - Obese patients may require "ramping" to place their head and neck in an optimal position of large-bore laryngoscope placement.

- This can be done with the use of a troop pillow (works best with taller patients).
- Shorter patients who need "ramping" require multiple rolls of blankets under the shoulders and head to achieve body positioning so that the tragus is on an equal level with the sternal notch.

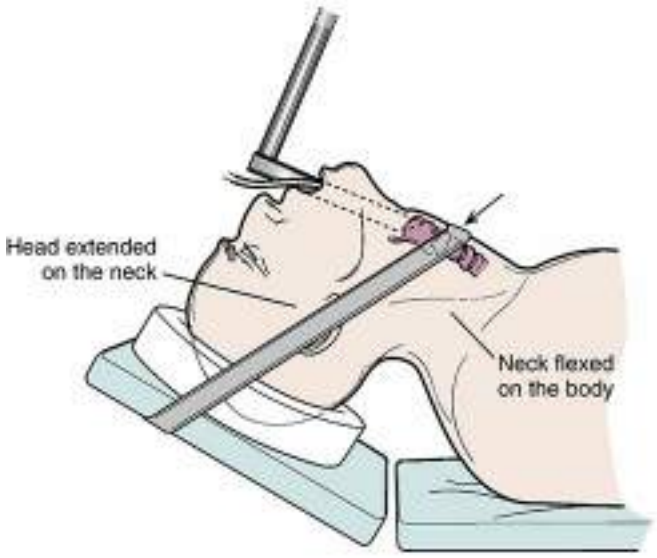

FIG. 2.2 Patient positioning for microsuspension laryngoscopy: neck flexion and head extension. "Arrows shows anterior neck pressure applied to enhance anterior commissure exposure".

Perioperative Antibiotic Prophylaxis

- Required only for mucosal surgery associated with a heart or orthopedic implant

Monitoring

- It is wise to assess for excess tongue pressure from the suspended laryngoscope and consider intermittent release from suspension.
- Persistent complete or near-complete muscle relaxation throughout the procedure is helpful, and thus intermittent monitoring of this is wise.

Instruments and Equipment to Have Available

- A chair for the surgeon that has support for the arms is essential. This chair should be able to be adjusted for height of the base, arm support, and back support. Frequently these types of surgical chairs can be found being used by ophthalmologists.
- Dental guard, standard athletic mouthpiece or custom made by patient's dentist
- Variety of different sizes and shapes of laryngoscopes
  - Large-bore laryngoscopes are vital for precise, detailed, and controlled microsurgery of the vocal folds.
  - Specialized laryngoscopes aid with visualization for patients with "difficult" laryngeal anatomy or when specific areas of the larynx are to be viewed for surgery (posterior commissure, subglottis).
- Laryngoscope suspension device: gallows or rotation/fulcrum. We feel that the former is superior because the vector of force is more advantageous than a rotation/fulcrum device (Lewy or chest holder), which allows a larger laryngoscope to be used with less risk of laryngoscope-related dental injury.
- 0-, 30-, and 70-degree (Fig. 2.3) rigid telescopes (5-mm diameter, approximately 22-cm length)
- A high-quality operating microscope with adjustable eye pieces
- Specialized PMS instruments that include very small scissors, forceps, knife, retratctors (triangular), suctions, and elevators. The working end of these instruments is usually between 1 and 2 mm in diameter.
- A video tower/camera connected to the telescopes and microscope not only aids in student teaching but also allows the operating room staff to know what the surgeon is doing.
- Lasers are of limited use in PMS. There is no distinct advantage to using a laser over a "cold steel" technique, especially in view of the risk of thermal injury and the cost of using a laser.

Key Anatomic Landmarks

- This subepithelial plane is where most benign vocal fold pathology is found, and working in this plane can minimize postoperative scar formation that occurs from dissection in the deeper aspect of the vocal fold layered structure.
- Subligament area is near or within the vocal ligament. Fibrous masses or cysts can occur here and represent a greater chance of postoperative scar tissue from extensive dissection in this area.

Prerequisite Skills

- Able to perform binocular, high-power microscopy
- Bimanual surgery

Operative Risks

1. Intubation injury: Close collaboration with the anesthesia team is needed. Intubation with a small endotracheal tube (i.e., 5.0 or 5.5, designed specifically for microlaryngoscopy) should be carefully placed under direct visualization to avoid inadvertent injury to the vocal folds. Not only can this type of injury be deleterious to the treatment of the lesion but more importantly with severe injuries can be catastrophic to long-term voice outcome.

2. Dental injury: Although rare, major dental injury (i.e., broken tooth) is ameliorated by proper dental protection. It must be noted if the patient has poor dentition, multiple missing teeth, or caps, because these situations increase the risk of sustaining dental injury.

3. Laser airway fire: In situations when a laser is used in treatment of a benign vocal fold lesion (papilloma, Reinke, leukoplakia), all laser safety precautions must be followed at all times: FiO_2 <40%, bulb syringe of saline within reach of the surgeon, wet towels over the patient's head, use of a laser-resistant endotracheal tube, moist pledget over the endotracheal tube cuff, and proper staff eye protection. All operating room staff must be trained in what to do in case of airway fire: turn off

oxygen while removing the endotracheal tube, placement of saline into the airway, bronchoscopy to evaluate for injury, and then re-intubate.

Surgical Technique

- The teeth and alveolar ridge are protected with dental protection.
- The largest laryngoscope that can be accommodated should be placed because this allows the surgeon the best exposure while operating on the vocal folds.
- Suspension of the laryngoscope allows the surgeon to operate with both hands, which improves the level of precision achieved. Several suspension devices are currently available: gallows or rotation.
- Velcro or tape can be applied to the anterior aspect of the neck at the level of the cricoid or trachea to improve exposure.[8] Placement of anterior pressure on the thyroid cartilage should be avoided because it will reduce tension on the vocal folds, thereby making PMS more difficult.

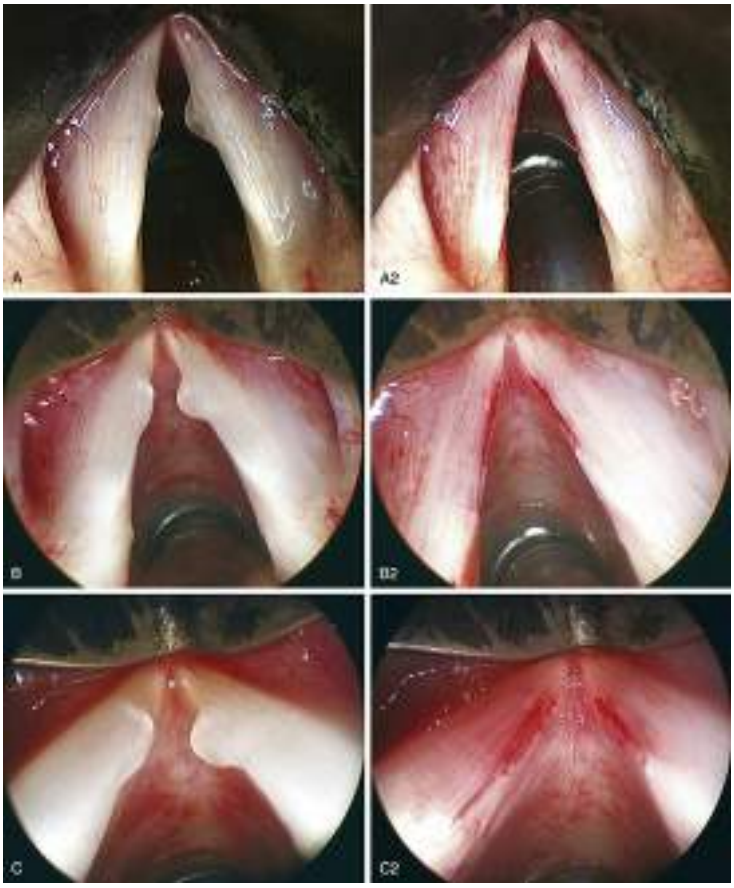

FIG. 2.3 Comparisons of preoperative views of the lesion and postoperative views after microflap surgery with 0-, 30-, and 70-degree telescopes. **A,** Preoperative view with a 0-degree scope. **A2,** Postoperative view with a 0-degree scope. **B,** Preoperative view with a 30-degree scope. **B2,** Postoperative view with a 30-degree scope. **C,** Preoperative view with a 70-degree scope. **C2,** Postoperative view with a 70-degree scope.

Surgeon Ergonomics

- After the patient and laryngoscope are in the operative position, attention should be made to address surgeon ergonomics during surgery.
- Taking a moment to achieve this, which usually requires the operating table to be placed into Trendelenburg position and the alteration of the height of the surgeon's chair, results in fewer musculoskeletal complaints from the surgeon and may improve surgical precision.

- Studies have shown that a favorable ergonomic position includes:
  - Laryngoscope angle of approximately 40 degrees from the horizon
  - Neutral surgeon neck position
  - Forearm stabilization and foot placement on the floor or stationary step[9]

Microflap

- The microflap technique historically involved an incision along the lateral aspect of the superior surface of the vocal fold, with subsequent medial dissection to the lesion. The lesion was then carefully dissected and removed, and the large, medially based microflap was put back into position. Scarring, denoted by decreased mucosal wave seen on stroboscopy, was found in the area of dissection. This observation led to modification of the procedure, with less scarring beyond the confines of the lesion. This new procedure was termed the mini microflap or medial microflap.[2,10]
- This modern microflap involves starting the dissection immediately lateral to the lesion and avoiding unnecessary dissection in healthy tissue. The term *microflap technique* will be used from here on to denote this newer, and more focused, procedure.
- The three guiding principles of microflap excision of subepithelial pathology are as follows:
  - Make the epithelial incision as close to the submucosal pathology (lateral) as possible.
  - Do not disrupt normal tissue surrounding the vocal fold pathology.
  - Stay in as superficial a plane as possible.
- Epinephrine (1:10,000 concentration) is often injected at the base of the lesion before making the incision to ensure hemostasis and to achieve hydrodissection for better identification of the proper surgical plane (submucosal plane).
- The incision, using a sickle or straight knife, is made through the mucosa over, or immediately lateral to, the lesion (Fig. 2.4). This diminishes damage to surrounding normal tissue.

- A small curved elevator is then used to develop the plane between the mucosal microflap and the pathology. It is often easier to develop this plane anterior or posterior to the lesion and then extend it over the lesion itself (Fig. 2.5).
  - This is the most difficult maneuver of microflap surgery and must be done with great patience and caution.
  - In situations with significant epithelial attenuation, such as with polyps, not all the epithelium can be preserved. In these cases, preservation of as much healthy epithelium as possible is attempted.
  - Development of a plane between the submucosal pathology and vocal ligament is often easier, except with vocal fold cyst(s) and fibrous mass(es) involving the vocal ligament.
- Small curved microscissors may be necessary to release fibrous bands between the microflap and submucosal pathology or between the submucosal pathology and the underlying vocal ligament. Once the submucosal pathology has been dissected, it is carefully removed and sent for pathologic examination (Fig. 2.6).

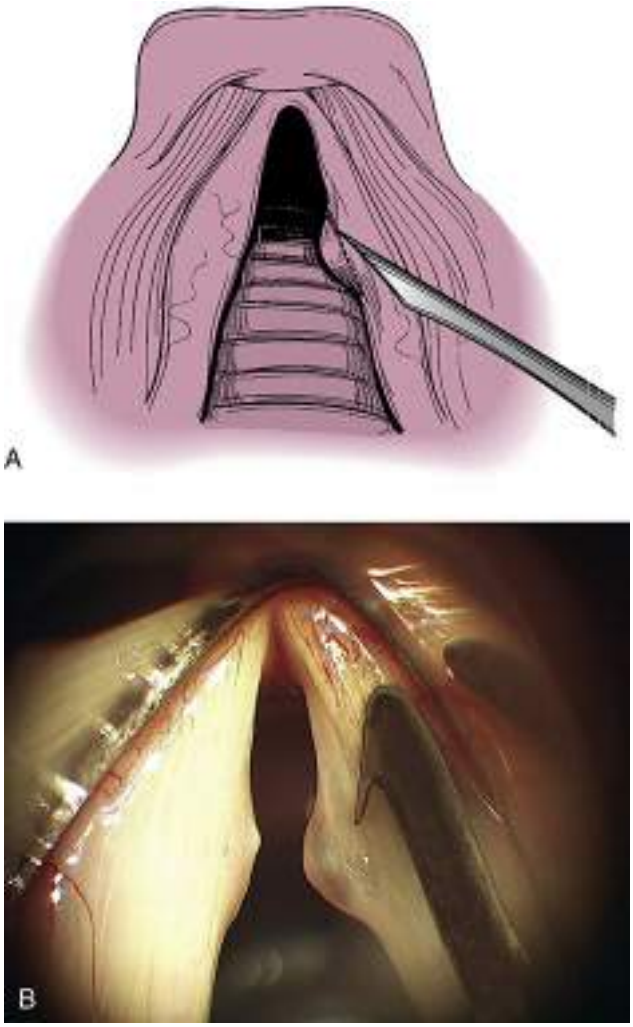

FIG. 2.4 **A,** Mucosal incision at the junction of vocal fold pathology and the superior surface of the vocal fold. **B,** Cordotomy at the lateral aspect of the lesion with a sickle knife.

- After removal of the primary lesion, the microflap should be retracted medially, and visual inspection of the operative site should be performed to make sure no other abnormal tissue is present.
- The microflap is then redraped (Fig. 2.7). Upon completion of the microflap excision, the free edge of the vocal fold (leading edge, medial edge) should be palpated and visually completely straight, without concavities or mucosal tags (see Fig. 2.3).
- Hemostasis is achieved by injecting epinephrine (1:10,000) at the surgical site before incision and placing epinephrine-soaked pledgets during and after surgical removal of the lesion.

Surgical Technique—Truncation

- Truncation (excision) of a vocal fold polyp is occasionally applicable. The lesion must be pedunculated. Indication for truncation versus microflap is severely abnormal epithelium surrounding the vocal fold lesion that would not be of any value to preserve with a microflap technique.
- Submucosal injection for hydrodissection is not recommended before truncation because it will obscure the desired excision location.

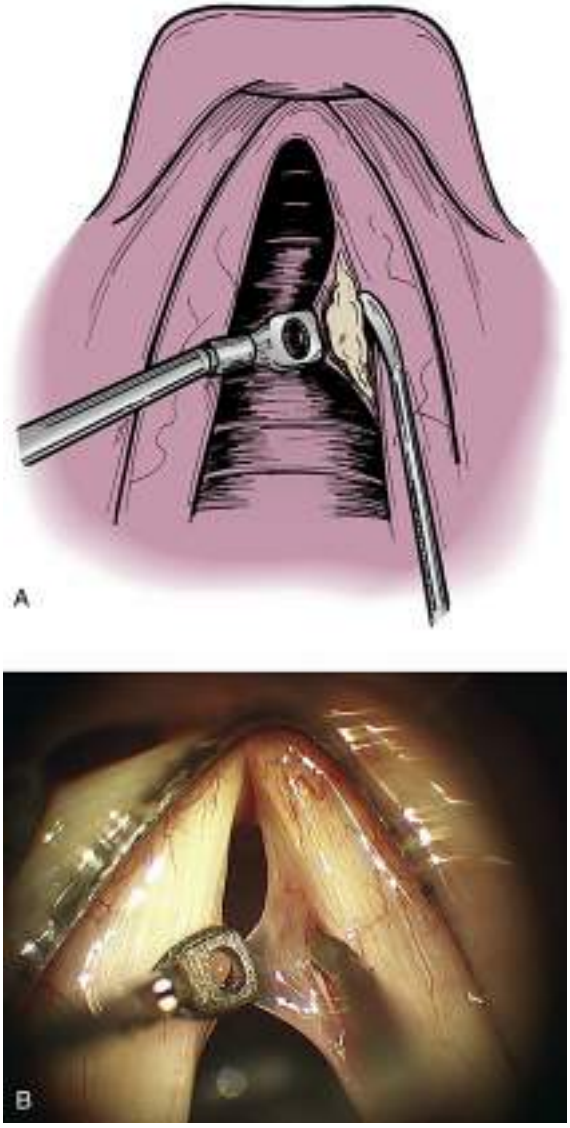

FIG. 2.5 **A** and **B,** Developing a plane with a blunt dissector between the lesion and deeper tissues.

- The pathology is grasped and gently retracted medially, and the stalk is cut at the level of the vocal fold mucosa (Fig. 2.8). A small epithelial defect will be produced.
- Great care should be taken to make sure that the truncation incision is precisely at the junction of the vocal fold pathology and the normal vocal fold free edge. Great care should be taken to not cut into the deeper aspect of the vocal fold during the truncation procedure.
- Hemostasis is achieved with pledgets soaked in epinephrine.

Common Errors in Technique

- Placing a small-bore laryngoscope resulting in suboptimal glottal exposure, which will negatively impact the precision of PMS
- Excessive resection of epithelium
- Placing the microflap incision too far lateral

FIG. 2.6 Removal of the lesion and redundant mucosa.

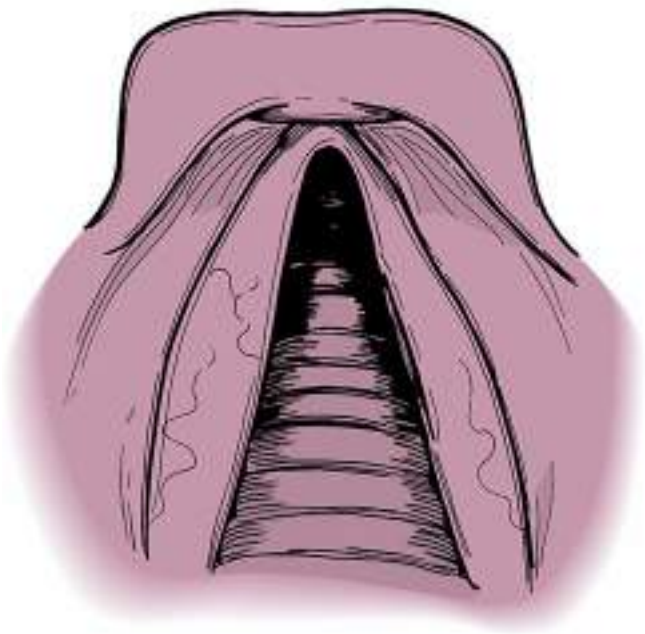

FIG. 2.7 Microflap redraped over the operative site.

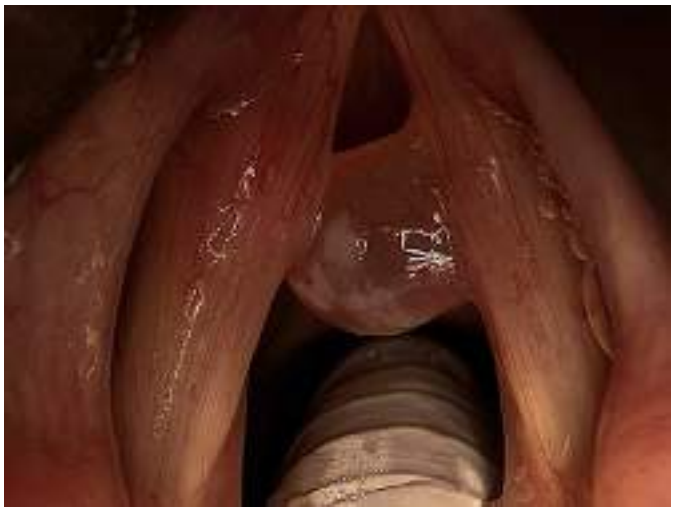

FIG. 2.8 Truncation of a vocal fold polyp *(dashed line).*

- Dissection deep to the lesion before performing the subepithelial dissection. This reduces the countertension that the surgeon relies on to perform the subepithelial dissection.
- Making the microflap incision too short, limiting exposure

Postoperative Period

Postoperative Management

- Voice rest is a component of almost every phonomicrosurgical procedure. Absolute (strict) voice rest can range from as short as 2 days to as long as 14 days. The length of absolute voice rest depends on the extent of surgery, patient compliance, and the surgeon's philosophy and past experience.
- Absolute voice rest consists of restrictions on the following activities: talking, whispering, whistling, straining, Valsalva maneuvers, coughing, and sneezing.
- Upon completion of strict voice rest, stroboscopy should be performed to evaluate the level of healing of the vocal fold surgical site. If there is adequate epithelial coverage, the patient is transitioned to light voice use (relative voice rest), usually defined as 5 to 10 minutes of breathy, "airy" voicing per hour. The quantity of voice use is then increased over the subsequent weeks, often with the help of a speech-language pathologist.
- Patients should continue taking acid suspension medications after surgery to aid in the healing process.
- Proper hydration is strongly recommended.
- Continued smoking cessation after surgery is important for maximal healing.
- Postoperative voice therapy is indicated in the majority of PMS patients, to not only optimize final voice quality outcome but to also reduce the chances of return to phonotraumatic behaviors that likely resulted in formation of the initial benign vocal fold lesion.

Complications

- Outcomes of PMS for benign vocal fold lesions are generally extremely good.[2] Akbulut et al. demonstrated that the majority of midmembranous benign vocal fold lesions have an excellent prognosis for patient-perceived improvement in voice. Following PMS, the majority of patients report perceived voice handicaps within the normal range except for ligamentous fibrous mass lesions of the vocal

fold.[4] The incidence of restoring the individual to a normal Voice Handicap Index-10 (VHI-10) after surgical excision of the majority of benign midmembranous lesions, except for ligamentous fibrous masses, ranges from 50% to 67%. In addition, the mean postoperative VHI-10 for all of the midmembranous vocal fold lesions (except for ligamentous fibrous masses) surgically treated is less than 11, which suggests a normal perception of voice handicap as patients without voice complaints. Overall, voice outcomes are typically very favorable after PMS; however, it is important that individual responses may vary from the overall core responses referenced previously.

- The factors that determine the level of success following surgical treatment for benign vocal fold lesions typically include:
  - Proper preoperative care,
  - Patient compliance,
  - Surgical precision,
  - Postoperative patient wound healing factors, and
  - Postoperative voice therapy.
- Complications of PMS range from the actions taken to achieve adequate exposure, to technical surgical points, to untoward vocal outcomes.
- The potential for injury to the teeth increases when the patient has poor dentition or multiple missing teeth and when difficulty is encountered in obtaining proper exposure of the larynx. Frequently, these patients can be detected before surgery. Use of reinforced plastic dental guards or firm, moldable splint (i.e., Aquaplast) may mitigate the risk of dental injury.
- Injury to the lingual nerve (numbness of the tongue, change in taste sensation) occurs in approximately 10% to 20% of patients. This is due to pressure from the laryngoscope, which usually resolves within 4 weeks.[6]
- There is a 1% to 2% risk of no voice improvement after PMS, in addition to a 1% to 2% risk of the voice becoming worse after surgery.
  - This is often due to poor wound healing with scar formation and/or comorbid vocal fold scar associated with the vocal fold lesion.

- If surgery requires deeper dissection into the vocal ligament, scar formation is likely.
- There is currently no cure for vocal fold scarring, so inadvertent disruption of tissues deep to the superficial lamina propria is discouraged unless mandated by the pathology.
- If the microflap is not appropriately draped over the surgical wound and therefore does not adhere to the vocal fold, epithelial ingrowth deep to the microflap may occur. Surgical excision of the microflap is then required.
- Microflap necrosis and flap death can occur with excessive edema and trauma. Accordingly, the flap must always be treated with great care.
- If necrosis of the microflap occurs, vocal fold healing on its own will take longer.

- Significant postoperative stiffness (scarring) can be treated with several monthly submucosal steroid injections, performed typically under local anesthesia, in an attempt to modify the wound-healing process.

Alternative Management Plan

1. Continued observation is an alternative choice of treatment for benign vocal fold lesions. This is a viable option for patients who are not bothered by their voice quality or it does not adversely affect their quality of life. Often serial, recorded examinations can be used to ensure that there is no progression of disease over time if no surgery is to be performed.

2. Prolonged voice rest is NOT a viable alternative management plan. Rather, it is critical to optimize the laryngeal mechanics of voicing to reduce adverse forces/tension during phonation. This is achieved through voice therapy and compliance on part of the patient. Voice therapy should be done by a dedicated speech-language pathologist who specializes in voice disorders.

Discussion

Evidence-Based Medicine Question

Is there a voice-related treatment outcome difference between ligamentous fibrous mass lesions compared with other subepithelial benign midmembranous vocal fold lesion(s) (subepithelial fibrous mass, vocal fold polyp, vocal nodules, etc.)?

Yes.

Akbulut et al. found that the treatment outcomes for patients with a ligamentous fibrous mass were worse compared with other benign subepithelial midmembranous vocal fold lesions.[4] The difference in treatment outcome most likely occurs from the more extensive surgical dissection in and near the vocal ligament and the nature of the pathology of the lesion.

Editorial Comment

Laryngeal examination with videostroboscopy provides essential information about the possible type and depth of benign vocal fold lesion(s) and is a core aspect to the evaluation and treatment of patients with benign vocal fold lesions. Preoperative voice care in the form of voice therapy and counseling for surgery is required for most patients and establishes a platform for success after surgery. Worsening of the voice after surgery or no voice improvement (1% to 2% of patients for each) is a real risk and must be discussed with the patient preoperatively. Rushing a patient to surgery before thorough evaluations by a physician and speech therapist is a disservice to the ultimate care of the patient and may downgrade the outcome of the procedure.

A clear understanding of vocal fold anatomy is needed to perform precise microflap surgical dissection. Close collaboration with the anesthesia team, proper patient and surgeon positioning, adequate laryngeal exposure, and proper instrumentation are vital for success.

Imprecise dissection into the deeper layers of the vocal fold (vocal ligament and muscle) will lead to scar formation and thus worse vocal outcomes. Dental injuries do occur, often as a result of poor dentition or improper placement of the laryngoscope. The gallows suspension is superior to a rotation/fulcrum suspension device in both exposure and

minimizing dental injury.

Review Questions

1. Select which are not principles of good ergonomics for phonomicrosurgery:

   a. Neck and spine are aligned perpendicular to the floor

   b. Establish a solid base by having the feet supported.

   c. **Keeping the arms near shoulder height**

   d. Using adjustable eye pieces of the microscope, which are designed to minimize neck flexion or extension

   e. Placing the proximal aspect of the laryngoscope near the height of the surgeon's umbilicus

2. Select which is not an indication for phonomicrosurgery:

   a. Significant speaking voice limitations after maximum amount of nonsurgical therapy

   b. **The patient's desire to have "straight edges" of the vocal folds**

   c. Significant singing voice limitations after maximum amount of nonsurgical therapy

   d. Decreased pitch and roughness to the voice in a patient with Reinke edema

   e. Frequent voice loss due to a vocal fold lesion despite voice therapy

3. Select statements that apply to microflap surgery of the vocal fold:

   a. Care should be taken to conserve adjacent normal tissue.

   b. The most common plane of dissection is in the subepithelial space.

   c. Dissection deep to the vocal ligament is usually required.

   d. **Answers a & b**

e. Answers a, b, & c

4. Appropriate surgical approach for vocal fold cysts and fibrous lesions includes which of the following?

   a. Vocal fold stripping

   b. Partial cordotomy

   c. **Microflap**

   d. Open lateral approach

5. With surgical excision of a vocal fold cyst, which of the following statements is correct?

   a. Deep dissection to remove the cyst and surrounding cuff of muscle is most appropriate to prevent recurrence.

   b. Stripping of the entire epithelial lining should be done first to better expose the cyst.

   c. Purposeful puncture and drainage of the cyst are helpful for dissection.

   d. **Dissection of the superficial epithelium from the cyst prior to deeper dissection is easier and helps to prevent inadvertent tearing of the epithelium.**

6. Which of the following patient-positioning techniques is NOT helpful for direct laryngoscopy?

   a. Head extension relative to the neck

   b. Neck flexion

   c. **Neck extension with shoulder roll**

   d. Patient with head positioned at the end of the bed with the articulated head board of the operating table

7. Which of the following is NOT a key component of phonomicrosurgery?

   a. **Wide local excision for prevention of recurrence**

   b. Conservative removal of submucosal pathology with preservation of overlying epithelium

c. Use of high-powered visualization with a microscope

d. Specialized microinstruments designed for the precision required to preserve the architecture of the vocal folds

8. A 36-year-old male has a left vocal fold exophytic lesion with normal overlying epithelium on examination with no other symptoms and no concerns with his voice or dyspnea. How would you manage this patient?

a. Surgical removal with microflap

b. **Observation**

c. Surgical removal with wide local excision

d. In-office biopsy

Recurrent Respiratory Papillomatosis

Thomas L. Carroll, and Anju Patel

Introduction

Recurrent respiratory papillomatosis (RRP) is a rare viral-induced disease of the upper aerodigestive tract characterized by epithelial lesions. Caused by human papillomavirus (HPV), this disease presents in both children and adults.[1] RRP is considered a benign neoplastic process; however, the disease can lead to significant morbidity and fatal complications, and there is a risk for RRP to transform into an epithelial malignancy (Fig. 3.1).[2]

The prevalence of RRP is approximately 4 in 100,000, with nearly 2000 pediatric cases diagnosed yearly.[1] Juvenile-onset RRP is typically diagnosed prior to age 5 and is considered more "aggressive" than adult-onset RRP, due to the significant impact the RRP lesions can have on the small pediatric airway.[2] In the United States, affected children may undergo more than four procedures yearly and on average nearly 20 in their lifetime.[1] Adult-onset RRP presents most commonly between 20 and 40 years of age (although it can present at any age), with a higher propensity in men. It also typically has a more indolent course with high remission rates.[3]

There are more than 100 HPV subtypes, though HPV 6 and 11 are most commonly associated with RRP. HPV 11 is typically more aggressive in disease progression. Less frequently, HPV 16 and 18 have been linked to RRP, though there is a higher rate of malignant transformation noted with these subtypes.[2] Vertical transmission is seen in juvenile-onset RRP. The route of transmission is not clearly known. Arguments have been made for hematogenous, intrauterine, and direct contact in the birth canal, as patients with juvenile-onset RRP are typically first born and vaginally delivered. Adult onset is associated with reactivation of

pediatric disease or secondary to a sexually transmitted disease.[1]

It is theorized that microtears in the epithelium or co-infection with other microbes allows entry of HPV into the body. For example, increased cervical HPV rates are associated with concurrent *Trichomonas vaginalis* infections. These infections are believed to weaken the tight junctions of epithelial cells.[3] Phonotrauma has been speculated as the etiology for entry into the vocal folds. After this occurs, an immune response is formed, and most individuals are able to clear the infection over the span of 2 years.[3] Five percent of the population has HPV DNA identified in the larynx, though significantly fewer actually display findings consistent with RRP. The mechanism behind this remains unclear.[3] Various factors including epidermal growth factor receptor, cyclooxygenase-2, and prostaglandins are overexpressed in papillomas, and this is currently an area of research for further treatment.[3]

FIG. 3.1 Recurrent respiratory papillomatosis (RRP) of supraglottis and true vocal folds. Notice the frondlike appearance of a typical RRP lesion in this operative view.

Spread beyond the larynx is associated with increased morbidity and mortality and found in 30% of children and 16% of adults with RRP.[1] The most common sites of extralaryngeal spread include the oral cavity, trachea, and bronchi. Development of pulmonary RRP is linked to high mortality, despite aggressive medical and surgical management.[3]

Key Operative Learning Points

1. Potassium titanyl-phosphate (KTP) laser offers lesion excision, which is especially advantageous for awake, in-office treatment approaches but is also highly effective when used in the operating room (OR).

2. CO_2 laser and cold knife excision can be employed.

3. Office-based KTP laser is an effective method of removing the lesions and restoration of the voice.

4. Microdébriders can be used for bulky disease in the operative setting but should be used less preferentially in the supraglottis and/or subglottis.

Preoperative Period

History

1. Hoarseness without periods of clarity

2. Progressive stridor, cough, dyspnea

3. Recurrent pneumonia may be an indicator of pulmonary involvement.

4. Maternal or paternal history of genital warts

5. Immunization history

Physical Examination

1. Voice evaluation

   a. Voice evaluation by a speech language pathologist (SLP) can establish a baseline from which to improve. The patient may require voice therapy after or between surgical procedures, and input from an SLP on the initial visit is helpful. However, voice therapy during active treatment is not usually helpful.

2. Vocal tract endoscopy

   a. Endoscopy, either through a flexible laryngoscope or 70-degree

Hopkins rod, can delineate the extent of disease. Flexible endoscopy affords a view of the nasopharynx, which can often demonstrate concurrent RRP lesions on the pharyngeal surface of the soft palate. Laryngovideostroboscopy can be used as an adjunct to identify more sessile lesions or early recurrences. Chip tip flexible endoscopy can offer better visualization of vascularity and surface contours that often accompany RRP. This technology uses charge-coupled device chips to create digitally based images for endoscopy. Light filters can be employed diagnostically or as an adjunct to office-based KTP laser ablation of RRP.

3. Tracheoscopy

   a. In-office evaluation for extralaryngeal disease can be helpful for preoperative planning. Intubation may not be the best choice if subglottic lesions exist, and jet ventilation would need to be pursued.

4. Auscultation of the lungs

Imaging

Chest radiograph: Not typically indicated but could be used to identify pulmonary disease secondary to obstructive RRP lesions in the lower airways

Computed tomography: Not usually performed unless there is a concern for pulmonary involvement

Additional Testing

1. Pulmonary function tests (PFTs) if there is a concern for pulmonary involvement. Flow loops may be helpful, if there is stridor or dyspnea but no visualized laryngeal disease. It would be used as an adjunct to laryngoscopy and tracheobronchoscopy in cases of more extensive disease.

Indications

1. Dyspnea

2. Dysphonia

3. Globus sensation

Contraindications

None necessary

Preoperative Preparation

1. Discontinue anticoagulant and antiplatelet drugs for 1 week, if possible.

2. Consent for complications: Worsened voice, persistent dyspnea, need for further surgery, infection, injuries associated with suspension laryngoscopy (dental injury, mucosal injury, taste change; see Chapter 2)

Operative Period

Anesthesia

OR: General, 5.0 microlaryngoscopy endotracheal tube (start with a laser-safe tube if planning on using a laser). This affords good airway control while providing unobstructed visualization of the glottis (see Chapter 2).

Office: Topical 4% lidocaine (techniques includes oxymetazoline-lidocaine spray to bilateral nares, insertion of cotton pledgets soaked with 4% lidocaine, nebulizer treatment with 4% lidocaine, topical drip of 4% lidocaine through a channel scope or with an Abraham cannula (see Chapter 1).

Positioning

OR: Supine, small round headrest, no shoulder roll, neck flexion may be useful if the larynx is very anterior

Office: Sniffing position, which has the patient rest his or her elbows on thighs, chin out, and nose out as if sniffing a flower

Perioperative Antibiotic Prophylaxis

None necessary

Monitoring

OR: Per anesthesia protocol

Office: Preprocedure vital signs. Brief monitoring for 15 to 20 minutes postprocedure in the waiting room is acceptable; no formal postprocedural monitoring or intraprocedure monitoring is used.

Instruments and Equipment to Have Available

1. KTP laser (or CO_2 laser with pattern generator)
2. Laser precaution equipment
3. Microdébrider (OR)
4. Microlaryngeal instruments
5. Suspension microlaryngoscopy setup
6. Microscope with 400 mm lens
7. Operating chair
8. Laryngotracheal anesthesia
9. Channel flexible laryngoscope (office procedure)

Key Anatomic Landmarks

Anterior commissure: Should be visualized at the time of surgery to evaluate for RRP and also monitor and minimize trauma

Prerequisite Skills

1. Flexible laryngoscopy

2. Direct laryngoscopy

Operative Risks

1. Injury to normal laryngeal structures

2. Intraoperative airway fire

3. Suspension laryngoscopy: Dental injury, mucosal injury, metallic taste. Numbness of the tongue may occur and typically resolves spontaneously over 2 to 6 weeks.[4]

Surgical Technique

- OR: Turn the bed 90 degrees. Keep the bed level with a headrest under the head. Apply a tooth guard to protect the maxillary dentition. All exposed facial and upper body skin are covered with wet towels if a laser is to be used. Airway evaluation should now be performed with examination of the oral cavity, oropharynx, hypopharynx, endolarynx, subglottis, and trachea to accurately stage the sites and extent of disease. Use the largest laryngoscope possible. Advance the laryngoscope until optimal exposure of the endolarynx is achieved. Suspend the laryngoscope. Use angled telescopes in 0, 30, and 70 degrees to (1) map out all RRP disease locations and nature, and (2) take photographic documentation. This helps in visualizing the locations of the lesions. The ventricle, undersurface of the vocal folds and anterior and posterior commissures are best visualized with 30- and 70-degree telescopes. The operating microscope is then brought in to further visualize the affected regions. A ½-by 3-inch pledget soaked in saline is placed in the subglottis above the endotracheal tube cuff if the CO_2 laser is to be used. A small amount of papilloma is excised with cold instruments and sent for biopsy. The remaining papillomas are now removed using the surgeon's method of choice:

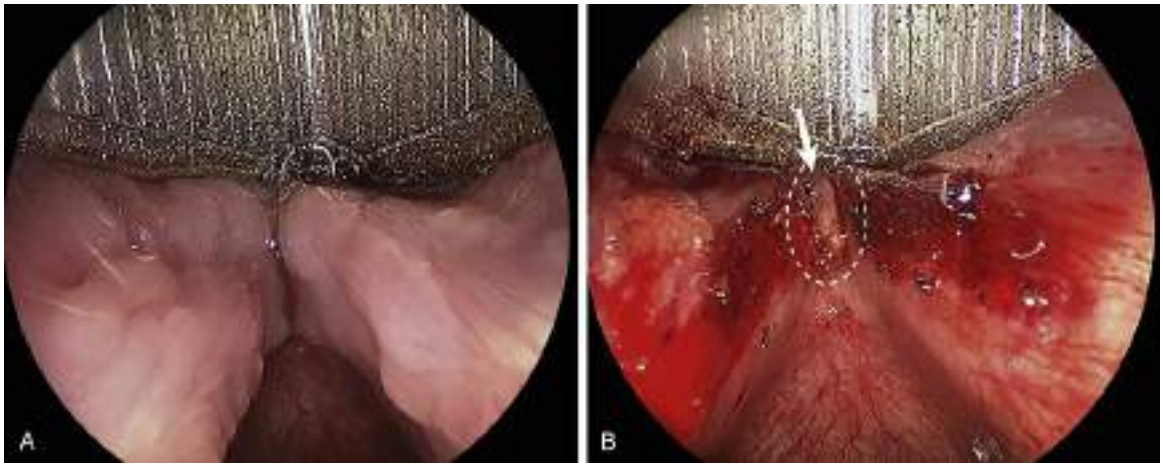

FIG. 3.2 Staging of recurrent respiratory papilloma (RRP) removal from the anterior commissure. **A,** Intraoperative photograph before RRP removal. Notice bilateral anterior commissure lesions. **B,** After right-sided RRP removal. Lesions are intentionally not removed from the left anterior commissure to prevent formation of an anterior glottic web (*arrow* and *circled area*).

- KTP laser removal of RRP can be done in several methods.[5]

1) KTP removal of RRP (outside-in)

To minimize the risk of thermal injury to the vocal fold while using the KTP laser for removal of RRP, the KTP laser is fired directly at the RRP, with the laser energy and working distance adjusted to result in a "blanching" effect on the RRP with the KTP laser energy. If the surgeon feels that this treatment effect, KTP-1, will be adequate, then the KTP treatment is done. Additional KTP laser energy can be applied to the operative site, which will cause small epithelial "craters" (i.e., disruption of the epithelium of the RRP tissue). Often this KTP-2 treatment effect will be sufficient for successful RRP treatment. If the RRP is bulky, additional KTP laser energy can be applied (often with laser fiber direct contact), resulting in a KTP-3 treatment effect. If the surgeon's goal is complete removal of the RRP at the time of surgery, after the entire area of RRP has been "blanched" from a conservative and minimal KTP laser energy delivery approach, a suction (5 or 7 French) is used to remove the treated RRP surface. If there is additional RRP present after the treated

disease has been removed by suction or cup forceps, the same use of the KTP laser can be employed until there is no gross RRP present at the operative site (KTP-4).

2) KTP removal of RRP (inside-out)

Working within the plane between the papilloma and the normal underlying true vocal fold tissue, the lesions can be removed in their entirety while staying as superficial as possible. The KTP laser is often used for areas of minimal disease and can be time consuming if used in an angiolytic fashion. Alternatively, it can be used to remove bulky lesions via a dissection technique that seeks to achieve KTP-4 laser effects.[5] This focuses on ablation of the interface between the normal vocal fold and RRP: Use settings of approximately 30 to 35 watts, 15 millisecond pulse width, and 2 to 3 pulses per second. Beginning at an area of transition between RRP and normal epithelium, the laser can be used to blanch this area until it can be sloughed off with another tool such as suction. Once this plane is established, dissection of the tissue can be performed along the entirety of the undersurface of the lesion (see Video 3.1).

- "Cold steel" may be used to dissect just below the epithelium and remove the RRP lesion, trying to preserve as much lamina propria as possible.
- CO_2 laser with pattern generator may also be considered when available and used to ablate the lesions.
- The microdébrider can be employed to remove bulky lesions and especially above and below the true vocal folds; however, it is not recommended to be used aggressively on the true vocal fold. Often the microdébrider is employed to debulk, and the KTP laser or cold steel can resect the lesions on the true vocal fold tissue.
- Oxymetazoline or 1:10,000 epinephrine-soaked pledgets are used for hemostasis. At the end of the procedure, laryngotracheal anesthesia is sprayed into the endolarynx for topical anesthesia.
- Care must be taken at the anterior commissure of the vocal folds. Leaving some residual RRP on one side and staging the surgery into two parts is often employed to avoid a laryngeal web. Alternatively,

when using KTP or CO_2 laser, a small amount of RRP can be blanched but left in place (not suctioned off) on one side of the anterior commissure to slough on its own (Fig. 3.2).

- Office: Fig. 3.3 and Video 3.2. Apply anesthetic as instructed previously. (It is optional to place a 14-French nasogastric tube through one nostril and attach it to suction to remove plume during surgery if the patient can tolerate it.) Laser safety precautions should be taken. Thread KTP laser fiber through channel scope. Using a setting of 30 to 35 watts, 2 pulses per second, and a 15 millisecond pulse width, ablate papillomas as tolerated from a patient standpoint. Ideally this technique is used for recurrent lesions or as a staged procedure after the initial biopsy or total surgical removal or for very limited initial lesions.
  - KTP laser treatment effects are described using a five-point classification system[5]:
    - KTP V, noncontact angiolysis
    - KTP 1, epithelial blanching
    - KTP 2, epithelial disruption
    - KTP 3, contact epithelial ablation
    - KTP 4, contact epithelial ablation with tissue removal

FIG. 3.3 In-office potassium titanyl-phosphate (KTP) laser use. The availability of office-based treatments of recurrent respiratory papilloma with KTP laser has

revolutionized the management of this disease. The patient can be seated comfortably and be given topical anesthesia, and the surgeon can accomplish in 5 minutes what typically would take an hour or more in the operating room.

Common Errors in Technique

1. Suboptimal exposure due to incorrect placement of the laryngoscope: Ensure that the head and neck are in good placement (neck flexion, head extension), adjust the laryngoscope to the optimal depth such that the anterior commissure can be visualized, and use adhesive tape to apply anterior cricoid pressure if needed.

2. Deep dissection: Deep, cold knife dissection or aggressive CO_2 laser used in a cutting rather than ablative fashion can lead to poor voice outcomes, especially after multiple surgeries due to scar formation in the lamina propria. With the advent of new technologies and techniques, RRP surgery can preserve the voice. Injury from laser heat (i.e., depth of penetration of laser energy) must be considered; the voice may suffer with delayed recovery of lamina propria vibration and possibly permanent scar tissue formation.

3. Patient tolerance of awake, unsedated KTP laser procedure: Nasal anesthesia is most important. Allow the cotton pledgets soaked in lidocaine to remain in the nose for at least 5 minutes. Confirming laryngeal anesthesia by touching areas to be treated with a drip catheter or scope before starting to use the laser helps reassure the clinician of appropriate topical anesthesia. The patient will feel the laser if the surgeon works for too long in one area. The surgeon should change locations to another area of RRP if the patient is uncomfortable during the laser procedure.

Postoperative Period

Postoperative Management

1. Initial 4- to 6-week postoperative follow-up

2. Office-based KTP laser procedures for recurrences to avoid another OR procedure

3. Adjust frequency of visits based on recurrence rate or if the location of the disease is impacting voice or breathing.

Complications

1. Worsened voice or breathing due to glottic or subglottic stenosis: May require further surgery to address the area of scarring, though this is a very difficult problem to treat, especially in the setting of active RRP. Anterior glottic webs are the most common scars to form as a result of aggressive, anterior, and bilateral resection with any of the previously listed methods, including KTP laser. This can be prevented by leaving a small area on one side of the anterior commissure with untreated RRP (with a plan to remove on "staged" second look in OR or in office) or ablated/blanched RRP but not removing it or sloughing it off with the suction.

Alternative Management Plan

1. Cidofovir: Antiviral medication that is an adjunct treatment to surgery. It is injected intralesionally and used in an off-label manner. It selectively inhibits viral DNA polymerase and stops viral replication. This medication gained popularity in the 1990s because it increases time intervals between treatments. Patients should be informed that studies in rats with very high-dose exposure have demonstrated an increased rate of malignant transformation. The RRP Task Force indications for cidofovir use include the need for six or more surgeries yearly, increasing frequency of surgeries, and extralaryngeal spread.[6] The recommended dose is approximately 2 mL in children and 4 mL in adults of a 5 mg/mL solution every 2 to 4 weeks, for a trial of 3 to 5 injections.[2] Minimal medication is noted in the serum during and after the procedure.

2. Interferon: Nonspecific regulatory proteins that have antiviral, antiproliferative, and immunomodulating activities. This is a systemic therapy given via subcutaneous injection. Side effects include neuropsychiatric changes and bone marrow suppression. Altered hormone levels may lead to infertility. Effective therapy has been

documented; however, a rebound effect occurs once therapy is stopped.[7]

3. Bevacizumab (Avastin): An adjunct treatment to surgery. It is a chemotherapeutic agent that consists of recombinant humanized monoclonal immunoglobulin G1 antibodies that inhibits endothelial growth factor, also injected intralesionally.[8]

4. Indole 3-carbinol (I3C): Compound derived from cruciferous vegetables such as broccoli, brussel sprouts, cabbage, and cauliflower. I3C can also be found as an over-the-counter supplement. It affects cytochrome P450-regulated estrogen metabolism and, as a consequence, inhibits estrogen-dependent growth of papilloma tissue.[7]

5. HPV quadrivalent vaccine: This vaccine uses virus-like particles to produce an antibody response against subtypes 6, 11, 16, and 18. These subtypes are associated with RRP; therefore, it is critical to discuss this topic with patients and their families. This is not a therapeutic vaccine and thus has no role for patients with active disease. However, widespread pre-HPV-exposure vaccination will lead to the eradication of RRP. The eventual elimination of this disease could be achieved with widespread vaccinations and herd immunity.[7]

Discussion

1. The use of the KTP laser has become more commonplace, often replacing a pulse dyed laser with similar or possibly better tissue interaction.

2. The key to successful voice outcomes is preservation of the lamina propria and conservative surgery.

3. Follow up in office for surveillance and for KTP laser procedures for recurrences.

4. Adjunctive treatments can be helpful in the setting of severe disease, frequent recurrence, or recurrences that are in suboptimal position for voicing.

5. From a preventative standpoint the HPV vaccine offers the strongest potential for eliminating RRP in the future.

Evidence-Based Medicine Question

How is adult-onset RRP transmitted?

Two methods of disease acquisition are postulated in the literature. The first occurs by vertical transmission from mother to child. Patients may be infected with the HPV but do not become symptomatic until later in life. Literature has described increased risk in first-born individuals, delivered vaginally in teenage mothers. However, this is controversial, as Ruiz et al. did not show differences in RRP patients compared with control patients suggesting another mode of transmission is more likely.

The second method is through sexual contact. Having multiple sexual partners has been associated with HPV-related oropharyngeal squamous cell carcinoma and has been considered in other disease processes. Ruiz et al. observed a possible association between RRP and increased number of lifetime vaginal/anal sex partners. There was no association between RRP and the number of oral sex partners noted. They suspect that RRP is not correlated with orogenital contact but rather mouth-to-mouth contact. Therefore, any intimate oral contact could be associated with spread of the disease. Further studies will be needed to evaluate the RRP population more closely and on a greater scale.

Editorial Comment

The diagnosis of true vocal fold RRP is no longer a vocal "death sentence." The implementation of photangiolytic lasers such as pulsed dye and KTP affords the user the ability to remove RRP lesions above the level of the lamina propria in their entirety, preserving vibration and voice. Office-based KTP laser ablation of RRP has afforded patients the ability to avoid multiple missed days from work for both the procedure and the recovery. Adjunctive therapies such as cidofovir continue to have a role in the treatment of RRP, and newer adjuncts such as bevacizumab show promise.

Review Questions

1. Which of the following is an indication for cidofovir use according to the RRP Task Force?

   a. Age less than 10 at diagnosis

   b. Age greater than 50 at diagnosis

   c. **Need for 6 or more surgeries yearly**

   d. High-risk HPV subtype

   e. RRP that reoccurs on an annual basis

2. Which HPV subtype is most commonly associated with RRP?

   a. HPV 6 and 18

   b. **HPV 6 and 11**

   c. HPV 11 and 16

   d. HPV 16 and 18

   e. HPV 22 and 27

3. Who is the HPV vaccine currently offered to?

   a. All individuals

   b. Only women over the age of 11 and under age 27

   c. **All individuals over the age of 11 and under age 27**

   d. All individuals under age 27

   e. Individuals with the recent diagnosis of RRP

Vocal Fold Injection via Microlaryngoscopy

Vyvy Young

Introduction

The term *vocal fold injection* (VFI) typically refers to global vocal fold augmentation for purposes of addressing glottic insufficiency,[1] although superficial injection into the lamina propria is performed occasionally (e.g., steroids, as for the treatment of vocal fold scar). In situations where the impact of global augmentation on symptoms is unpredictable, a trial VFI with a temporary material may also be beneficial.[2] Many options for augmentation material are currently available, with variable advantages, disadvantages, and durations of benefit. Advances in technology and techniques now allow Otolaryngologists to perform VFI under either local or general anesthesia.[1] This chapter focuses on VFI via microlaryngoscopy under general anesthesia.

Selection of injection material, type of anesthesia, and location of procedure (e.g., office, operating room, or endoscopy/procedure suite) should be determined on a case-by-case basis. Factors to consider include the patient's medical comorbidities and candidacy for the procedure, patient and/or surgeon preference, expected duration of symptoms/vocal fold motion abnormality (i.e., immediate postoperative period following surgery with high hopes for spontaneous recovery of motion vs. underlying malignancy), need or preference for hemodynamic monitoring, goal of the procedure (e.g., symptom treatment vs. trial), and insurance-related considerations.

VFI via microlaryngoscopy remains an important tool in the care of patients with symptomatic glottic insufficiency. Key advantages of this technique include immobility of the vocal folds and improved precision of injection material placement, complete airway control, and more

detailed investigation of the vocal folds (including direct palpation to assess for vocal fold scar or cricoarytenoid joint fixation). Results of VFI are typically excellent in patients with glottic insufficiency related to vocal fold immobility/paralysis; outcomes of VFI for other laryngeal conditions such as vocal fold atrophy or scar tend to be more variable.

Key Operative Learning Points

1. Adequate laryngeal exposure is critical.

2. Familiarity with different types of laryngoscopes

3. Familiarity with different injection material options

4. Typically the goal is global augmentation. (It is important to know when to use superficial injection.)

5. Superficial injection is to be avoided when global augmentation is the goal.

Preoperative Period

History

1. History of present illness

   a. Voice

      1) Characteristics: breathy, raspy, decreased volume/projection, increased effort, vocal fatigue, vocal strain, tightness, pain with speaking

      2) Aggravating or alleviating factors

         a) For example, voice rest versus prolonged speaking, change in weather/temperature/humidity, stress, medications

   b. Swallowing

      1) Characteristics: dysphagia to liquids versus solids versus pills, coughing or choking episodes, need for Heimlich maneuver, weight loss, change in diet

2) Aggravating or alleviating factors

a) Impact of compensatory strategies: head turn, chin tuck, double swallow, liquid wash

3) Asking about history of recent pneumonia is of critical importance.

c. Breathing

1) Characteristics: dyspnea with speaking versus exertion versus rest

2) Aggravating or alleviating factors

d. Precipitating factors

1) Surgery

a) Thyroid

b) Cervical spine

c) Lung

d) Esophagus

2) Intubation

a) Size of endotracheal tube

b) Duration of intubation

3) Upper respiratory infection

4) Accident/trauma

5) None identifiable

e. Other associated symptoms

1) Cough

2) Globus sensation

3) Throat clearing

4) Mucus

5) Other symptoms including reflux-related (e.g., heartburn, burning sensation in nose/mouth/throat, or bitter/sour taste)

2. Past medical history

a. Prior treatment and its efficacy

1) Surgery

2) Speech therapy

3) Over-the-counter (OTC) medications (mucolytics, antihistamines, throat sprays, lozenges)

4) Voice rest

5) Steroids

6) Antibiotics

7) Gargling

8) Increased fluids (e.g., water, tea)

b. Medical history

1) General assessment regarding candidacy for surgical procedure

c. Surgery

1) Especially important to include cervical spine, other neck, and/or chest surgery

d. Family history: usually not helpful

e. Medications

1) Antiplatelet drugs

a) Not a specific contraindication. Important to make sure that patient is counseled appropriately about risk of hemorrhage and even airway compromise.

f. Social history

1) Tobacco use

a) Active tobacco use can increase the risk of postoperative coughing (at extubation and in the early postoperative period), which may increase the risk of premature implant extrusion.

2) Occupation and associated vocal demands (e.g., teacher, cashier, call center worker, attorney, social worker, waiter/bartender)

Physical Examination

1. Examination of the head and neck with focused areas as listed here
2. Examination of the neck
   a. Evidence of prior surgery (e.g., scars) or trauma
   b. Degree of cervical range of motion and any restrictions (flexion or extension); this may affect ease of intubation and/or exposure with the laryngoscope
3. Oral cavity
   a. Evaluate for trismus.
   b. Assess status of patient's dentition. Pay particular attention to the presence of any of the following: caps, crowns, partial dentures, bridges, missing/loose/broken teeth.
   c. Look for torus mandibularis (may require a smaller laryngoscope).
4. Flexible laryngoscopy
   a. Flexible laryngoscopy is critical in the evaluation of patients with voice, swallowing, or breathing symptoms.
   b. Flexible laryngoscopy is superior to rigid oral laryngoscopy in the assessment of vocal fold motion. The use of a rigid Hopkins rod telescope or high-definition chip-tip flexible laryngoscope may allow improved magnification and visualization of specific vocal fold abnormalities (e.g., vocal fold scar, lesions, sulcus vocalis).
   c. Specific task: repeated alternating sniff-/i/ maneuvers are especially useful for assessing vocal fold ABDuction (opening) and ADDuction (closing).

Imaging

1. Typically imaging is indicated only in cases of vocal fold immobility of uncertain etiology.

2. Computed tomography (CT) of the neck can serve to evaluate the course of the recurrent laryngeal nerve.

a. CT may not be indicated if the history is strongly suggestive of an etiology of vocal fold immobility/paralysis (e.g., anterior cervical diskectomy and fusion (ACDF), thyroidectomy, esophagectomy, lung surgery).

3. Modified barium swallow if indicated to evaluate dysphagia

a. MBS may be useful in situations where the surgeon is trying to decide whether to proceed with VFI versus continuing with observation alone; the presence of aspiration is a strong indication to proceed. If there is no aspiration, observation may be a reasonable alternative.

Indications

1. Symptomatic glottic insufficiency (which may be due to vocal fold immobility, paresis, atrophy)[1]

a. Voice

b. Swallowing

c. Breathing

d. Some combination of these symptoms

2. *Trial* VFI[2]

a. In some cases it is not obvious whether vocal fold augmentation alone will improve voice symptoms. In these patients, the use of a temporary augmentation material as a "trial" VFI may be helpful in clarifying the degree of benefit that may be achieved after vocal fold augmentation.

b. Examples of situations in which trial VFI may be helpful: vocal fold scar, atrophy, paresis, or concurrent neurologic disease (e.g., causing dysarthria)

Contraindications

1. Patients with medical comorbidities that carry an increased risk for general anesthesia need to carefully weigh the potential risks versus benefits of VFI. The presence of such a risk is not an absolute

contraindication, but in such patients VFI under local anesthesia may be a good alternative option. The reader is referred to Chapter 94 and also item 3 under Additional Resources at the end of this chapter.

2. Although not an absolute contraindication, it is strongly suggested that VFI be considered with great caution in cases of a unilateral vocal fold immobility, which is associated with a contralateral vocal fold hypomobility, as these patients will have a baseline decrease in glottic airway size. Further vocal fold augmentation (either unilateral or bilateral) may additionally narrow this already restricted airway and should be undertaken with extreme care.

a. It is uncommon that the benefits would outweigh the risks in patients with these vocal fold motion abnormalities. (An example might be a patient with documented aspiration who refuses a tracheostomy.) This issue should be considered in depth prior to proceeding.

b. Extensive counseling of all parties including the patient, his or her family, and other associated services (e.g., Thoracic Surgery) is critical. It is particularly important to discuss the risk of airway compromise and the possibility of requiring urgent intubation and/or tracheostomy.

c. If VFI is pursued, this should be performed very conservatively, as anteriorly as possible, and under as carefully controlled circumstances as possible.

Preoperative Preparation

1. Flexible laryngoscopy is imperative; additionally, *stroboscopy* is strongly recommended.

a. Know which side to augment (critical in cases of planned unilateral injection).

b. Know the size of the glottic gap (helps to guide the degree of augmentation to be performed).

c. Evaluate the presence of vocal fold height mismatch. This may guide the location of injection material in an attempt to improve "matching" up of vocal fold levels.

d. Flexible stroboscopy is superior to laryngoscopy alone for the assessment of vocal fold closure, size of the glottic gap, and the presence of vocal fold height mismatch.

2. Counseling to establish expectations (for both patient and family)

a. The goal is to recover the patient's normal voice, but it is possible that the patient's symptoms may be improved or even resolved without a complete return to "normal." Use of patient self-report questionnaires (i.e., Voice Handicap Index [VHI], VHI-10, Voice Related Quality of Life [VRQOL]) may be helpful in monitoring the patient's degree of symptomatology and response to treatment. I assess pre- and postinjection VHI-10 scores in all patients.

b. The patient is advised about the potential need for additional procedures. This may be especially appropriate in cases of temporary VFI (such as following acute-onset vocal fold immobility), but it may even be needed following long-term augmentation, as with adipose tissue.

c. In cases of trial VFI, the patient is counseled that voice symptoms may improve, decline, or remain unchanged.

3. Discontinue antiplatelet drugs if possible.

Operative Period

Anesthesia

1. VFI is traditionally performed under general endotracheal anesthesia (GETA). More recent techniques to perform VFI under local anesthesia have been described; the reader is referred to Chapter 1 for further details. This chapter focuses on VFI under GETA.

2. Use as small an endotracheal tube as possible to permit maximal visualization of the vocal folds during laryngoscopy. I prefer a 5.0 microlaryngoscopy tube (MLT) for all laryngeal surgery. This should be taped to the oral commissure, preferably along the upper lip. Taping to the lower lip can sometimes affect oral opening and thus laryngoscopic exposure. Moving the "tube tree" or endotracheal tube holder further down the body (not immediately next to the head and neck) is helpful for

keeping the anesthesia circuit out of the way.

3. Perioperative medications: one-time dosing at the start of the case

   a. Dexamethasone (Decadron)—decreases laryngeal edema

   b. Ondansetron (Zofran)—decreases nausea and associated risk for postoperative emesis

   c. Glycopyrrolate—decreases secretions and facilitates visualization during laryngoscopy

4. Laryngotracheal anesthesia (plain lidocaine, either 4% or 2%, based on availability and/or surgeon preference. I prefer 4% spray).

   a. Administered once at intubation (can be done by anesthesia)

   b. Administered a second time at the end of the procedure prior to extubation—decreases risk of laryngospasm and coughing upon extubation

5. A short-duration muscle relaxant is helpful during the procedure.

Positioning

1. Supine

2. No shoulder roll—it would place the patient in a suboptimal position for laryngoscopy

3. It is helpful to have an adjustable headboard to allow neck flexion if needed. Having the operative bed backward can allow this.

Perioperative Antibiotic Prophylaxis

Not indicated

Monitoring

1. Routine anesthesia monitoring

2. Short-duration muscle relaxant

Instruments and Equipment to Have Available

1. Multiple sizes and types of laryngoscopes
   a. Small-caliber laryngoscopes
   b. Longer laryngoscopes
   c. Laryngoscope with anterior "lip"
2. Small-caliber suction (5, 6, or 7 Fr)
3. Head light box depending on the type of light source
4. Reinforced dental guard to prevent injury to the teeth
5. Rigid telescope(s) versus microscope
   a. With camera equipment and monitor—especially helpful in teaching situations

Key Anatomic Landmarks:

1. Superior arcuate line Fig. 4.1
2. Vocal process

Prerequisite Skills

1. Laryngoscopy

Operative Risks

1. Airway compromise
   a. May result from bleeding, overaugmentation, or laryngospasm
2. Vocal fold hemorrhage
3. Poor injection (i.e., too superficial, too anterior, inadequate quantity) resulting in worsening or no change in symptoms
4. Injury to teeth/gums/lips

5. Tongue—numbness or change in taste
    a. Avoid by timely completion of surgery and/or releasing suspension during prolonged cases

Surgical Technique

- Ensure adequate anesthesia/relaxation.
- Eye protection. Drape head for laryngoscopy—this also protects the eyes.
- Reinforce a plastic dental guard with several layers of tape; this provides an easy, convenient, and inexpensive additional layer of protection. Place this reinforced guard over the maxillary dentition. For edentulous patients, a foam pad or moistened gauze may be used to protect the alveolar ridge.
- Pass the laryngoscope by mouth and advance to the larynx under direct visualization.
    - Keep the laryngoscope in the midline—this decreases pressure on the tongue.
    - Attempt to keep the epiglottis in the normal anatomic position as the laryngoscope slides underneath.(Exception: The Lindholm laryngoscope is designed to be placed into the vallecula and so does not pass under the epiglottis.) Folding over of the epiglottis can increase the difficulty of achieving an adequate laryngoscopic view of the vocal folds.
    - Flex the head if necessary.
    - Do not use a shoulder roll.
    - Maintain good direction of pull on the laryngoscope, primarily up and away. Avoid rocking back on the teeth.
- Special note on the choice of laryngoscope:
    - I prefer to use the laryngoscope with the largest possible distal aperture to allow full visualization of both true vocal folds simultaneously. My preference is to start with the largest-caliber universal modular glottiscope or the Dedo, depending on

availability. If adequate visualization cannot be achieved in this way, a smaller laryngoscope may be substituted.

- I prefer the use of the slotted anterior commissure scope when VFI is performed using telescopic guidance (as opposed to microscopic guidance).The slot facilitates manipulation of both a telescope and the needle within the confines of a small-diameter scope.

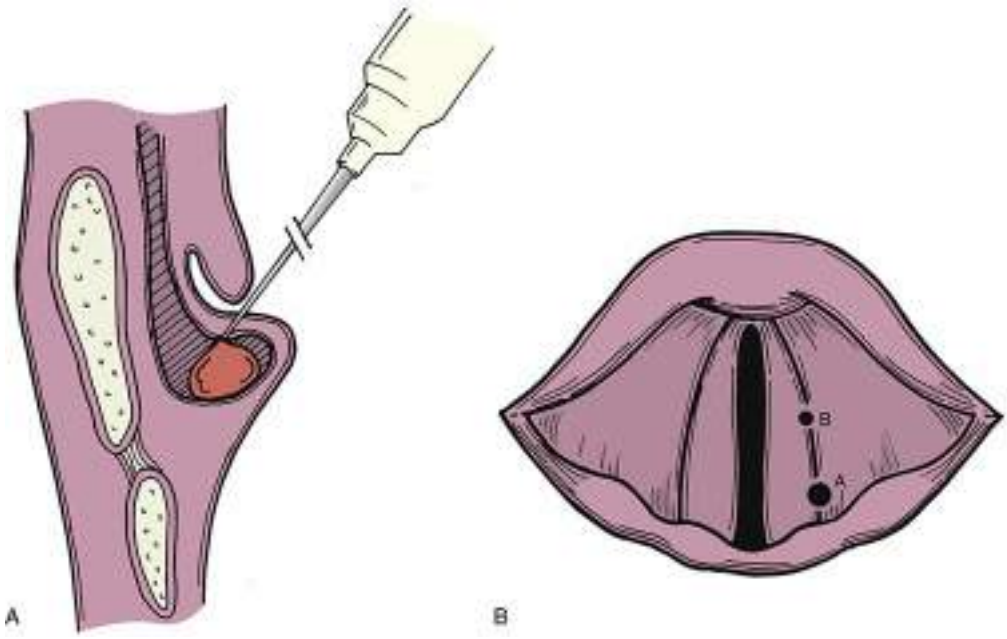

FIG. 4.1 Diagram of the ideal location for deep vocal fold injection, including coronal **(A)** and axial **(B)** views. In 4.1B, Point A represents the intersection between the longitudinal superior arcuate line and the vocal process and is the preferred initial injection site. If needed, additional augmentation can be performed at a secondary site (point B) at the mid-portion of the vocal fold along the superior arcuate line.

- Be prepared to use different laryngoscopes if adequate visualization cannot be achieved. Check the reinforced dental guard frequently and change it often if there is any evidence of wear or damage to the dental guard. I routinely change to a new reinforced dental guard after two manipulations or changes of laryngoscopes.

- Place the laryngoscope into suspension.
  - I strongly advocate the use of a suspension system that attaches

directly to the operating table. This provides maximal stability and minimizes risk to the patient (including dislodgement of the suspension system).

- Use of alternative suspension systems (such as a Lewy arm) resting on a Mayo stand is acceptable, but strong caution is advocated in these respects:
  - Place patient in optimal position for microscopic visualization prior to placing in suspension. This usually involves ensuring that the operating table is low enough. Trendelenburg positioning of the patient may also be helpful.
  - Remind all OR personnel that once in suspension, the Mayo stand cannot be touched. Have all cameras, light cords, and suction cords appropriately placed before suspension. This avoids inadvertent jostling of the stand with manipulation of any of these cords/lines.
- Use of alternative suspension systems which rest on the patient's chest are strongly discouraged due to inherent instability of that type of suspension.

- Ensure adequate visualization of the true vocal folds.
  - The goal is simultaneous visualization from the anterior commissure to the vocal processes bilaterally.
  - This may require anterior cricoid pressure, which can be applied with Velcro straps, adhesive tape, or manual pressure (this last option is not recommended but is feasible if no other option exists).
- Magnified examination of the true vocal folds
  - I like to use 5-mm rigid telescopes at various angles (0, 30, and 70 degrees) to fully evaluate the true vocal folds. This allows thorough inspection of the anterior commissure, ventricle, and infraglottic aspect of the vocal folds as well as the mid-membranous portion of the true vocal folds.
  - VFI can be performed using telescopic guidance if needed/preferred (I recommend a 0- or 30-degree telescope for this purpose). I suggest the use of the operating microscope when possible to maximize visualization and precise placement of the VFI.

- Palpation of the true vocal folds
  - Assess the status of cricoarytenoid joint motion by placing an instrument against the vocal process and displacing it laterally. This can be done with a curved blunt laryngeal elevator or a laryngeal suction (not attached to suction tubing).
  - Palpate the true vocal folds themselves to assess for lesions or stiffness suggestive of scar tissue.
- Identify proper location for the VFI.
  - Superficial injection—purposeful placement of injection material (e.g., dexamethasone) into the superficial lamina propria. The reader is referred to item 3 under Additional Resources, at the end of this chapter, for further details.
  - Deep injection
    - Proper placement is at the intersection of the superior arcuate line and the vocal process (see Fig. 4.1B, point A).
    - If needed, a secondary site can be injected in the midportion of the true vocal fold along the superior arcuate line (see Fig. 4.1B, point B). I prefer to avoid this, when possible, to avoid extrusion of the injection material through the initial injection site.

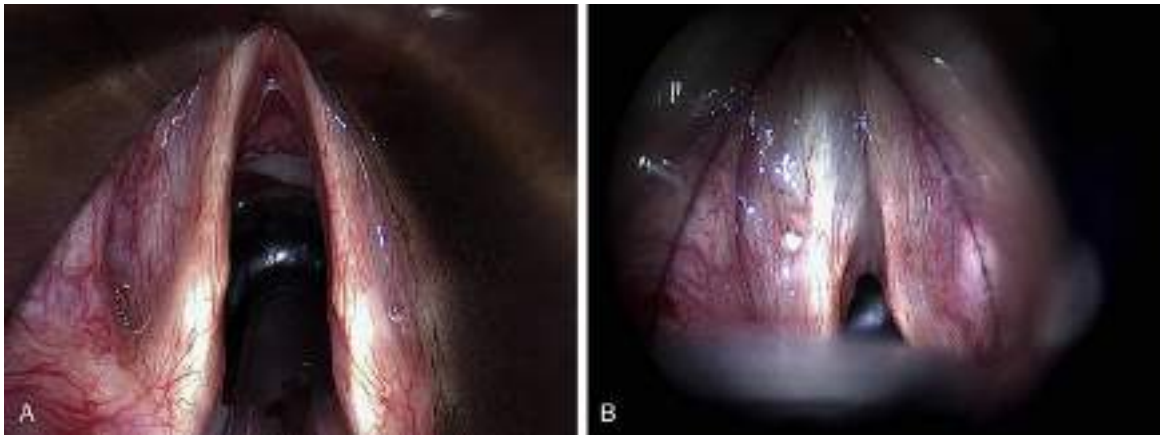

FIG. 4.2 Preoperative, **A,** and postoperative, **B,** photographs of a patient with right vocal fold paralysis who underwent bilateral deep vocal fold injection.

- Preparation of injection material

- This depends on type of injection material
- Prefabricated materials such as Prolaryn or Renu—follow directions in packaging
- Collagen products such as Cymetra—follow directions in packaging
- Adipose tissue
  - Briefly, abdominal adipose tissue is typically harvested (either via liposuction or through open harvest) for this purpose.
  - Prior to injection, I rinse the adipose tissue with 2 L of sterile lactated Ringer's solution and then soak it in an insulin bath for 5 minutes.
  - The reader is referred to items 3 and 4 under Additional Resources, at the end of this chapter, for further details.
- Options
  - Xomed orotracheal injector needle (27 Ga)
  - Needle (24 Ga) is included with prefab package—could be Prolaryn or Renu.
  - Lipoinjection device (e.g. Instrumentarium) (14 to 16 Ga) for adipose tissue

- Slow, steady deployment of injection material
  - Look for infraglottic augmentation first.
  - This augmentation should then move "up" to the medial aspect of the true vocal cord (TVF).
  - The end result should be global augmentation (Fig. 4.2).
- Gently suction any extruded material from the opening.
- Any bleeding typically resolves spontaneously. However, if necessary, control bleeding with an epinephrine-soaked cottonoid pledget. I use epinephrine 1:10,000 and a ½- by 3-inch pledget.
- Laryngotracheal anesthesia (4% or 2% plain lidocaine spray)
- Orogastric tube suctioning of gastric contents if desired. I recommend this to decrease the risk of postoperative emesis.

- Remove laryngoscope, check teeth, and check tongue.
- Communicate with anesthesia personnel regarding the importance of quiet emergence and extubation. This type of direct communication is critically important and cannot be overemphasized.

Common Errors in Technique

1. Inadequate visualization of larynx/vocal folds
   a. Too much false vocal fold "show"
   b. Epiglottis flopped down
2. Superficial injection when deep augmentation is desired
3. "Bubbling up" of the superior surface of the TVF—seen particularly with patients with vocal fold atrophy
4. Injecting too far laterally—material going into the paraglottic space is wasted because it does not improve vocal fold augmentation and closure. Avoid this by checking to see in which direction the bevel of the needle is pointed—medial or anterior is better.
5. Injecting too far anteriorly—the goal is global augmentation

Postoperative Period

Postoperative Management

1. I counsel patients to undergo a period of voice rest after deep VFI. For lipoinjection, 3 days; for other materials, 24 hours
2. Same-day surgery—routine surveillance in the postanesthesia care unit (PACU), after which the patient is discharged to home as appropriate. Overnight observation will rarely be required.
3. No narcotics necessary. Acetaminophen (Tylenol, extra-strength) is permitted as needed.
   a. Caveat: patients may have abdominal discomfort and/or bruising after liposuction in cases of lipoinjection. These patients typically do not require narcotics but are more likely to require acetaminophen to

address their discomfort. It is important to counsel patients regarding the possibility of postoperative abdominal pain related to the harvesting of adipose tissue.

4. No restrictions on eating/drinking once the patient has been cleared after anesthesia

5. Anticoagulant/antiplatelet drugs can usually be resumed the next day.

Complications

1. Inadequate augmentation versus premature extrusion of injection material

   a. Reassess symptoms, particularly dysphagia. Modified barium swallow if indicated

   b. Consider repeat injection if indicated.

   c. Consider evaluation for adjunctive treatments (swallowing therapy, voice therapy) to optimize symptoms in the event that a repeat injection is not desired.

2. Superficial injection

   a. Typically causes decreased vibration and can worsen voice quality

   b. Keep in mind that even temporary materials may have longer duration when injected superficially.

   c. Depends on material

      1) Calcium hydroxylaptite (CaHA)—typically results in a visible white mass under the epithelium (often described as a "chiclet" because of its resemblance to the small piece of candy-coated chewing gum)—may require surgical removal (typically microflap incision with removal vs. suction)[3]

      2) Clear materials (Prolaryn gel, Restylane) are difficult to visualize and therefore are typically not removed.

3. Too much augmentation

   a. Observation—some cases are associated with natural resorption initially (e.g., adipose tissue). Otherwise all temporary materials will resorb over time.

b. If the patient is symptomatic from this, surgical excision and removal of excess material can be considered (degree of difficulty depends on the material).[4,5]

4. Persistent symptoms

a. Look for underlying reason for persistent symptoms.

b. Other measures may be required to address this.

1) Voice therapy

2) Swallowing therapy

3) Respiratory retraining therapy

4) Restructuring of patient expectations

5. Vocal fold hemorrhage

a. Typically self-limited

b. Additional voice rest may be helpful.

6. Airway compromise

a. Look for underlying etiology.

1) Laryngospasm

a) Lidocaine IV push

b) Positive pressure ventilation

c) Reintubation—if this must be done, use as small a tube as possible. Often the patient may be observed in the recovery room for a short period of time (e.g., 1 hour) and then can often be extubated successfully. Less commonly, overnight intubation/observation may be required.

d) Low-dose succinylcholine

2) Edema of the airway

a) Try to avoid this with an intraoperative dose of intravenous steroids.

3) Overaugmentation

a) If identified in the immediate postoperative period and causing airway symptoms, reintubation is an option.

b) Surgical removal of excess material if necessary

4) Anxiety

a) The anesthetist may be able to administer anxiolytic medication.

7. Injury to the teeth

a. Refer to family dentist or appropriate dental specialist.

b. Prevention is key.

8. Temporomandibular joint dysfunction

a. Soft diet, anti-inflammatory medication; a dental guard may help

b. Expectant management

9. Tongue dysgeusia/numbness

a. Conservative measures: passage of time and reassurance

Alternative Management Plan

1. VFI under local anesthesia
2. Evaluation of patient's candidacy for other treatments

a. Voice therapy

b. Swallowing therapy

3. Compensatory strategies to address dysphagia

a. Head turn, chin tuck

Discussion

Evidence-Based Medicine Question

What is the utility of trial VFI?

Initially described in 2010, trial VFI attempts to determine the degree of voice improvement that can be achieved following vocal fold augmentation when the anticipated results are not clear or predictable.

Carroll and Rosen presented a cohort of 25 patients with vocal fold atrophy and/or paresis who underwent temporary vocal fold augmentation.[2] In their study, 76% (19/25) of the patient cohort had improvement and 24% (6/25) did not. Furthermore, 10 of these patients underwent further permanent augmentation and all had good results. These authors suggest that trial VFI may be helpful in situations where expectations following vocal fold augmentation are not clear, as in the case of vocal fold atrophy, paresis, scar, or combined communication difficulties (e.g., concurrent dysarthria).

In 2015, Young and colleagues sought to compare voice outcomes after trial VFI and long-term augmentation in patients with vocal fold atrophy.[6] They reviewed 19 patients and found that 42% (8/19) had a good response and 58% (11/19) had poor response to trial VFI. Among those with a good response, 75% (6/8) also had a good response to long-term treatment. Among those with a poor response to trial VFI, 55% (6/11) also had a poor response to long-term treatment. However, interestingly, 45% (5/11) of patients with poor response to trial VFI then went on to have a good response after long-term augmentation. The authors concluded that a good response to trial VFI appears to be predictive of a similar good response to long-term treatment. However, poor results following trial VFI are not necessarily suggestive of poor response following long-term augmentation and should be interpreted by the Otolaryngologist and patient with caution.

Based on these data, the predictive ability of trial VFI remains unclear, but trial VFI may still be useful in certain situations, such as those involving vocal fold atrophy, paresis, or scar. Appropriate expectations about the utility of results following trial VFI are critically important.

Editorial Comment

This chapter provides a very thorough discussion of a very important laryngologic procedure designed to reestablish vocal fold closure in cases of vocal fold paralysis, atrophy, paresis, or scar. In patients with vocal fold immobility, possibly due to paralysis versus cricoarytenoid joint pathology, cricoarytenoid joint palpation during microlaryngoscopy is extremely important. If mobilization is a major goal of the procedure, it is recommended that the surgeon perform cricoarytenoid joint palpation

without endotracheal tube intubation at the start of general anesthesia and without suspending microlaryngoscopy. This avoids any confounding variables affecting assessment of the motion of the cricoarytenoid joint. For this aspect of the procedure, it is recommended that the patient undergo general anesthesia and then direct laryngoscopy with cricoarytenoid palpation, as in Chapter 5 describing the laryngoscope being purposely suspended manually high in the endolarynx, followed by a careful assessment of vocal fold motion when the vocal process of the arytenoid cartilage is displaced laterally.

When a patient with vocal fold paralysis causing dysphonia as well as dysphagia is considered for microlaryngoscopy and injection of the vocal fold, it may be prudent to proceed with vocal fold augmentation prior to a formal swallowing evaluation, given that history has demonstrated significant improvement of dysphagia following vocal fold augmentation. If dysphagia persists postoperatively, then proper swallowing evaluation is warranted.

Regarding intraoperative medication for microlaryngoscopy and vocal fold augmentation, it is important to note that intravenous steroid administration should be done with the patient sedated or in a very slow, controlled fashion to prevent a genital sensation from the IV push of the steroids. In addition, intravenous acetaminophen and intramuscular ketorolac are often very helpful for postoperative pain control. For individuals undergoing microlaryngoscopy with impaired dentition or dentition that has poor alignment, often a customized dental guard made by a dentist or one fabricated intraoperatively using nasal splint material (e.g., Aquaplast) can be very helpful in preventing dental injury in the face of pre-existing dental pathology.

It is important to note that overaugmentation of the vocal fold anteriorly will result in a severely strained voice and an unhappy patient; thus great care should be taken to avoid excessive augmentation of the anterior vocal fold.

Review Questions

1. Reasons for persistent symptoms after VFI include all of the following *except*

   a. Insufficient augmentation

   b. Improperly placed augmentation

   c. **Incorrect choice of augmentation material**

   d. Underlying etiology of symptoms not addressed by VFI

2. The longest-lasting injection material is

   a. Calcium hydroxyapatite

   b. Hyaluronic acid

   c. Carboxymethylcellulose

   d. **Autologous adipose tissue**

3. The best landmarks to determine the location for VFI are the

   a. Superior arcuate line and anterior commissure

   b. **Superior arcuate line and vocal process**

   c. Intersection of vocal ligament and midpoint of membranous vocal fold

   d. Intersection of vocal ligament and vocal process

Medialization Laryngoplasty and Arytenoid Adduction

R. Jun Lin, and Clark A. Rosen

Introduction

Medialization laryngoplasty (type I thyroplasty) and arytenoid adduction are excellent surgical options for rehabilitation of the voice in patients suffering from glottic insufficiency. These are great options for surgical therapy to augment and reposition the vocal folds to improve vocal fold closure and thereby improve vocal function.[1,2] Glottic insufficiency may be caused by any combination of the following: vocal fold atrophy (presbylarynges), vocal fold scar, vocal fold paresis, or vocal fold paralysis. These procedures can also be used to address soft tissue deficits of the vocal folds after surgery or trauma.[3]

A variety of implant materials have been used to medialize the vocal folds in medialization laryngoplasty, including Silastic, hydroxylapatite block, and Gore-Tex. This chapter discusses the general approach to medialization laryngoplasty and does not discuss the different implants or the design of the shape of the implant, given that these are very personal choices for each surgeon and that medialization laryngoplasty can be done successfully with any of the aforementioned implant materials.

If the patient's dysphonia and/or dysphagia is related to a severe posterior glottic insufficiency, arytenoid adduction should be strongly considered because it is the only operation that consistently corrects glottic insufficiency in the posterior aspect of the glottis.[4-6] Neither injection laryngoplasty nor medialization laryngoplasty can address clinical issues related to posterior glottic insufficiency. Arytenoid adduction simulates the contraction of the lateral cricoarytenoid muscle by placing a suture in the muscular process of the arytenoid to rotate the

arytenoid cartilage. This helps to medialize the posterior portion of the vocal fold, lengthen the vocal fold, close the posterior glottic gap, and change the height mismatch of vocal folds.[6,7]

Key Operative Learning Points

- Identification of the entire aspect of the muscular tubercle located on the inferior border of the thyroid cartilage ala
- Slight overmedialization should be done during medialization laryngoplasty to account for intraoperative edema of the vocal fold and prevent undermedialization of the vocal fold postoperatively.
- Adjustment of implant based on findings of voice quality, vocal fold appearance, and vocal fold closure pattern. Intraoperative end results should include a slightly strained voice, medial augmentation of vocal fold, and complete glottal closure.

Preoperative Period

History

1. History of presenting illness

- Acute or gradual onset of hoarseness
- Precipitating events such as surgery, endotracheal intubation, or upper respiratory infection
- Voice quality weak, breathy, and effortful
- Dyspnea with speaking
- Coughing and choking, especially with drinking liquids
- History of aspiration pneumonia

2. Pertinent past medical history

- History of neck surgery (e.g., thyroid, parathyroid, carotid), cervical spine surgery, or thoracic/mediastinal surgery
- History of malignancy (e.g., head and neck, thyroid, esophagus, lung)

- History of cerebrovascular accidents
- Underlying pulmonary disease (e.g., chronic obstructive pulmonary disease [COPD])—These patients have a smaller pulmonary reserve and thus will require more urgent intervention for vocal fold paralysis.

Physical Examination

- Complete examination of the head and neck
- Examination of the cranial nerves
- Transnasal flexible laryngoscopy to evaluate vocal fold motion, including mobility of the contralateral vocal fold, and overall airway status
- Stroboscopy to assess glottic closure pattern and vocal fold levels

Imaging

- Computed tomography (CT) or magnetic resonance imaging (MRI) scan from skull base to aortic arch (along the course of the recurrent laryngeal nerve) with contrast in vocal fold paralysis with no clear precipitating events

Indications

- Symptomatic glottic insufficiency (dysphonia, dyspnea on phonation, aspiration), especially if there is little or no chance of return of vocal fold motion

Contraindications

- Coagulopathy (relative)
- Malignancy involving the laryngotracheal complex
- Poor abduction of the contralateral vocal fold due to airway concern
- Presence of vocal fold lesions

- Intact vocal fold mobility (for arytenoid adduction)

Preoperative Preparation

- Review the patient's laryngeal examination.
- Counsel patients to stop anticoagulation agents, such as nonsteroidal anti-inflammatory medications (e.g., ibuprofen), Coumadin, antiplatelet agents (e.g., clopidogrel), and factor Xa inhibitors (e.g., rivaroxaban, apixaban, dabigatran). Management of patient's anticoagulants may be coordinated with his/her cardiologists and/or hematologists.
- Discuss with the patient regarding the environment in the operating room, given that the patient will be awake and only slightly sedated. It is best to prepare patients psychologically while they are awake for having surgery on their neck.
- Counsel the patient that there may be a need for a bilateral procedure and the addition of an arytenoid adduction procedure pending the intraoperative results of the medialization laryngoplasty. Often with experience, surgeons can determine preoperatively, based on the laryngeal examination and the patient's voice quality, whether he or she will require a unilateral or bilateral medialization laryngoplasty. However, certain situations do occur intraoperatively in which voice quality is only marginally improved with a medialization laryngoplasty, and it is determined that the patient would benefit significantly from a simultaneous arytenoid adduction.

Operative Period

Anesthesia

- Before the patient comes into the operating room, nebulization of a 50:50 mixture of 4% lidocaine (2 mg/kg) and 1% tetracaine (0.5 mg/kg) is performed to provide topical anesthesia to the upper aerodigestive tract, which facilitates the patient tolerating the flexible laryngoscopy during the procedure.

- Robinul, an anticholinergic medication, should be administered, unless medically contraindicated, to minimize laryngeal secretions during the procedure.
- The patient will then undergo the procedure under monitored anesthesia care (MAC), which includes local anesthesia with sedation and analgesia.

Positioning

- Once in the operating room, the patient is placed in a supine position with a conservative shoulder roll to provide extension of the neck. Care should be taken to ensure that the patient is comfortable.

Perioperative Medications

- A prophylactic dose of intravenous antibiotics is given approximately 30 to 45 minutes before the skin incision, as per surgical prophylaxis guidelines.
- One dose of dexamethasone (10 mg) is given to minimize airway edema.

Monitoring

- The patient will be monitored by the anesthesia health care provider as per standard of practice.

Instruments and Equipment to Have Available

- Standard head and neck soft tissue set
- Cottle or Freer elevator
- Measuring caliper
- Drill with a 1- to 2-mm cutting burr
- Flexible laryngoscope

- C-mount camera with video tower/monitor
- Surgeon's preferred implant material
  - For Gore-Tex implants, select middle ear instruments (e.g., middle ear alligator, annulus elevator, middle ear curette), Woodson elevator, Kerrison rongeus (1- to 3-mm tips)
  - For Silastic implants, Netterville medialization set (Medtronic ENT, Jacksonville, FL), Silastic block
- For arytenoid adduction, 4-0 monofilament permanent suture (e.g., Mersilene by Ethicon, Medline Industries. Inc, Northfield, IL) and Kitner dissector (peanut)

Key Anatomic Landmarks

1. Medialization laryngoplasty
   - Inferior border of the thyroid cartilage
   - The entire aspect of the muscular tubercle located on the inferior border of the thyroid cartilage ala because the angulation of this process can cause incorrect orientation of the medialization window
2. Arytenoid adduction
   - Posterior border of the thyroid cartilage
   - Posterior lamina of the cricoid cartilage
   - Cricopharyngeus muscle
   - Posterior cricoarytenoid (PCA) muscle
   - Muscular process of the arytenoid, seen as "a grain of rice"

Prerequisite Skills

- Good understanding of laryngotracheal anatomy
- Basic soft tissue handling skills

Operative Risks

- Infection
- Bleeding/neck hematoma
- Violation of the pyriform sinus (arytenoid adduction)
- Implant migration
- Implant extrusion
- Airway obstruction
- Persistent dysphonia after surgery requiring revision surgery. Reasons for suboptimal results include persistent posterior glottic gap, undermedialization, implant malposition (anteriorly and/or superiorly), vocal fold height mismatch.

Surgical Technique

Medialization Laryngoplasty (Type I Thyroplasty)

- Cotton pledgets soaked with 4% lidocaine and oxymetazoline decongestant are applied to the most patent nasal cavity.
- After intravenous sedation is obtained, 1% lidocaine with 1:100,000 epinephrine can be injected both superficially and deep in the area of the thyroid ala on the proposed side or sides of surgery. A superior laryngeal nerve block in the thyrohyoid space should be performed if arytenoid adduction is planned.
- A 4- to 5-cm incision is made in a curvilinear fashion along a normal skin crease near the inferior border of the thyroid ala. The incision is made on the side of the medialization laryngoplasty and may cross over the midline by approximately 1 cm.
- The platysma muscle is incised and subplatysmal flaps are elevated superiorly and inferiorly to approximately the level of the hyoid bone and the cricoid cartilage, respectively.
- The midline raphae is divided between the strap muscles, exposing the thyroid cartilage.

- Two self-retaining retractors or multiple fishhooks are used to retract the skin and the strap muscles to optimize exposure of the thyroid cartilage.
- The outer perichondrium of the thyroid cartilage is incised longitudinally along the midline. Subperichondrial elevation should be done widely to expose the thyroid ala approximately 5 mm posterior to the muscular tubercle. This is imperative because the posterior aspect of the muscular tubercle of the inferior aspect of the thyroid ala will identify the true inferior border of the thyroid cartilage, which determines the plane of the vocal fold and location of the thyroplasty implant.
- A caliper is used to measure approximately 5 to 7 mm posterior to the midline of the thyroid cartilage and 3 mm above the inferior border of the thyroid cartilage. This is the area where the proposed thyroplasty window will be made (Fig. 5.1).

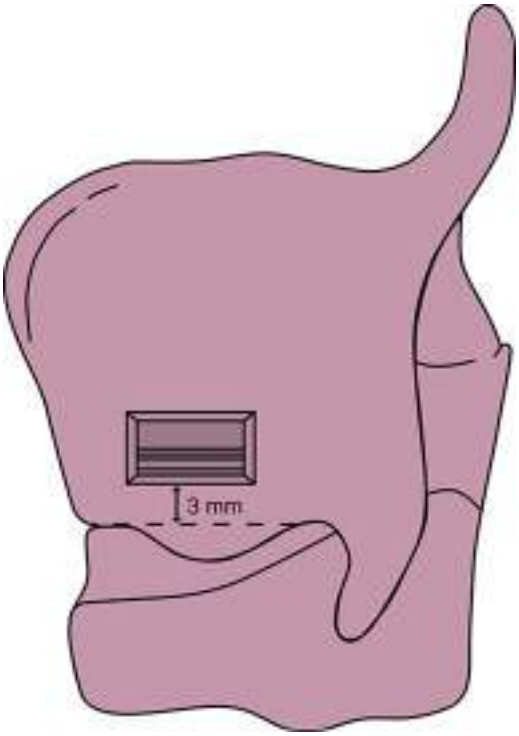

FIG. 5.1 Location of medialization laryngoplasty window.

- A 25-gauge needle can be placed through the thyroid cartilage in this area, confirming with simultaneous flexible laryngoscopy that the

proposed thyroplasty window is appropriately positioned immediately lateral to the vocal fold and is not too posterior, anterior, or superior. If the thyroid ala is too ossified for the 25-gauge needle to pass through, a small hole can be drilled using a 1- to 2-mm cutting burr in the approximate location of the thyroplasty window, and a blunt instrument, such as the annulus elevator, can be passed through to confirm the position of the proposed window with flexible laryngoscopy.

- If a Gore-Tex medialization laryngoplasty is planned, then a window of 3 × 3 mm^2 at the previously determined optimal site can be made with a drill (if the thyroid cartilage is ossified) or with a no. 15 scalpel blade or a beaver blade.[8] For a Silastic medialization laryngoplasty, the thyroplasty window is typically 6 × 13 mm^2 in dimension and can be created with either a drill or a scalpel.
- After the thyroid cartilage has been removed from the window, it is wise to incise the perichondrium superiorly, posteriorly, and inferiorly, creating an anteriorly based inner perichondrium flap. The paraglottic space can then be elevated posteriorly and inferiorly in preparation for placement of the medialization laryngoplasty implant. Simultaneous flexible laryngoscopy and evaluation of the voice during the elevation of this pocket will determine the size, location, and nature of the implant and is extremely important to the success of the operation. Surgeons should take great care to avoid overmedialization of the vocal fold anteriorly and superiorly. These are the two most common mistakes made by surgeons doing medialization laryngoplasty. The implant is then inserted through the thyroplasty window with simultaneous flexible laryngoscopy monitoring and assessment of the patient's voice quality (Fig. 5.2).
- After the voice quality and vocal fold position are optimized, the implant can be secured to the adjacent thyroid cartilage with a permanent 4-0 Prolene suture. Hemostasis should be obtained, and a small drain, although not always necessary, may be placed in the dependent portion of the wound.

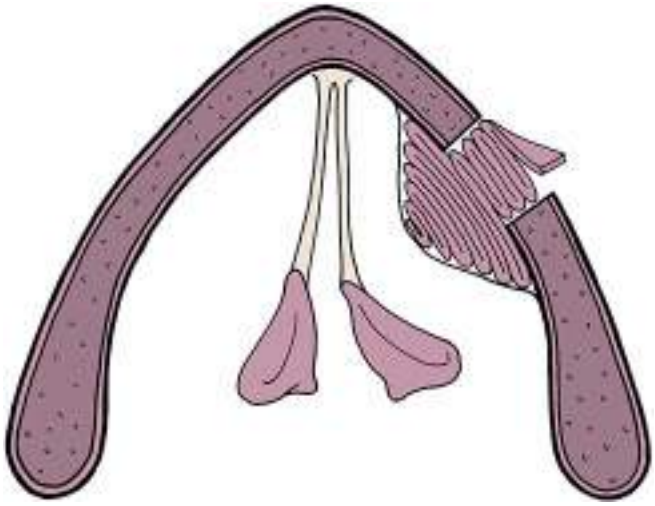

FIG. 5.2 Placement of Gore-Tex into paraglottic space to medialize the vocal fold.

- The perichondrium should be laid back over the thyroplasty window, and the strap muscles should be re-approximated in the midline. Finally, skin closure should include both dermal and epidermal closures to maximize the cosmetic results of the operative site.

Arytenoid Adduction

- The surgical approach to arytenoid adduction is the same as described earlier for medialization laryngoplasty.
- Approximately 1 cm of the medial aspect of the sternohyoid muscle is transected below its insertion onto the hyoid. This helps to improve posterior exposure for arytenoid adduction.
- After elevating the perichondrium off the anterior two-thirds of the thyroid ala as described for medialization laryngoplasty, the elevation should be continued to the posterior border, specifically skeletonizing the inferior cornu of the thyroid cartilage.
- Careful dissection around the posterior border of the thyroid ala from the inferior cornu superiorly up toward the greater cornu is then done, taking great care to adhere to the thyroid cartilage to avoid entering the pyriform sinus.
- For further exposure and rotation of the larynx, a hook can be placed on the greater cornu to rotate the larynx medially and expose its

posterior aspect.

- Bipolar cautery can then be used to release the superior portion of the cricopharyngeus muscle as it attaches to the inferior cornu. This allows exposure of the pyriform sinus.
- The pyriform sinus lies directly over the posterior lamina of the cricoid cartilage, which is the location of the PCA muscle and is the main anatomic landmark for the surgical dissection. To fully evaluate the location of the pyriform sinus throughout this portion of the dissection, it is wise to have patients intermittently "puff out" their cheeks, which will inflate the pyriform sinus and outline its boundaries.
- Dissection of the pyriform sinus off of the cricoid cartilage should then be done in an inferolateral to superomedial direction until the PCA muscle is identified. The PCA muscle can be identified by the direction of the muscle fibers running from a medial-inferior to the lateral-superior direction and ending at the muscular process of the arytenoid cartilage.
- Following retraction of the inferior portion of the pyriform sinus, the PCA muscle is usually clearly identified and can be traced up to identify the ridge on the arytenoid cartilage, which is the muscular process of the arytenoid cartilage (Fig. 5.3).

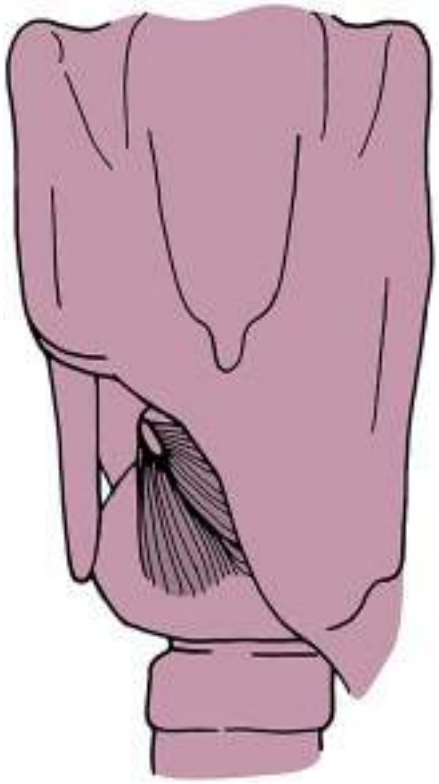

FIG. 5.3 Identification of the muscular process of the arytenoid cartilage.

- A small portion of the posterior border of the thyroid cartilage (a posterior thyroplasty window) can be removed with a rongeur to assist in finding and suturing the muscular process of the arytenoid cartilage (Fig. 5.4).
- After the muscular process of the arytenoid cartilage is identified, a figure-of-eight suture, using a 4.0 nonabsorbable suture (e.g., Mersilene), is placed through the arytenoid cartilage.
- Confirmation of proper placement of this suture is done with simultaneous flexible laryngoscopy. Control and manipulation of the arytenoid are now possible via the suture placed through the muscular process of the arytenoid cartilage.
- If the medialization laryngoplasty window has not yet been made, the two arms of the suture placed through the muscular process of the arytenoid cartilage can be clamped, and the larynx can be placed back into its anatomic location for creation of the medialization laryngoplasty window as described earlier.

- After the medialization laryngoplasty window is created, lateral paraglottic dissection posterior to the window can be done with an elevator to develop a tract that extends from the muscular process of the arytenoid cartilage to the medialization laryngoplasty window.
- After this path has been created, a middle ear alligator can be passed from the window posteriorly to the posterior aspect of the larynx and bring both arms of the arytenoid adduction suture forward through the window.
- After the sutures have been drawn forward, one suture can be placed anterior and inferior to the window through the cricothyroid membrane, and the second suture can be placed immediately anterior through the medialization laryngoplasty window through the thyroid cartilage. Gentle tension on this suture will rotate the arytenoid into an adducted position and significantly improve the vocal fold length and position of the paralyzed vocal fold.

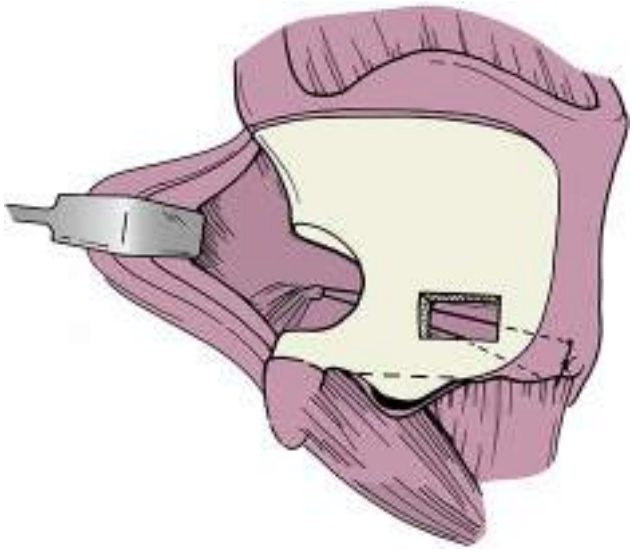

FIG. 5.4 A small portion of the posterior border of the thyroid cartilage can be removed with a rongeur to assist in finding and suturing the muscular process of the arytenoid cartilage.

- With gentle tension on the arytenoid adduction sutures and simulated medialization through the medialization laryngoplasty window, voice quality and vocal fold position can be evaluated via simultaneous

flexible laryngoscopy to determine optimal suture tension and amount of medialization required (see Fig. 5.4).

- When medialization laryngoplasty is done in conjunction with arytenoid adduction, typically less medialization is required, and it is very rare that a significant amount of tension needs to be applied to the arytenoid adduction suture for optimal phonatory function.
- After the arytenoid adduction suture has been placed, the medialization laryngoplasty can be completed as described earlier. A small drain is placed in the dependent portion of the wound, and the wound can be closed the same way as the medialization laryngoplasty procedure (Video 5.1).

Common Errors in Technique

- Medialization laryngoplasty and arytenoid adduction should not be done when the preoperative airway is compromised with poor contralateral vocal fold abduction.
- Position of the implant is the key to successful medialization laryngoplasty, and great care should be taken to ensure that the implant is not placed too superior or too anterior.
- Great care should be taken not to violate the airway during placement of the implant (medialization laryngoplasty) and during elevation of the pyriform sinus (arytenoid adduction).
- A clear path must be created for the arytenoid adduction suture from the muscular process of the arytenoid to the medialization laryngoplasty window to ensure proper rotation of the arytenoid.
- Excessive tension on the arytenoid adduction suture can cause overrotation of the arytenoid and poor voice outcome.

Postoperative Period

Postoperative Management

- Same-day surgery or overnight 23-hour observation (for arytenoid

adduction) depending on the patient's coexisting medical comorbidities

- Pain management
- Intravenous steroids at 8-hour intervals for 24 hours (Decadron 6 to 8 mg) if the patient is observed overnight
- If the patient had an arytenoid adduction, he or she should be discharged on a Medrol pack with a 6-day tapering dose.
- Elevation of the head of the bed
- No voice rest
- No empiric antibiotic therapy
- Follow up in clinic in approximately 4 weeks because it takes approximately 3 to 4 weeks for the edema of the vocal folds and the surrounding tissues to resolve before making a repeat laryngeal examination valid.

Complications

1. Medialization laryngoplasty

- Implant malposition.[9] The implant can be inappropriately located in a variety of dimensions, although the most common implant malpositions include (1) too much medialization of the vocal fold by the implant and (2) too superior positioning of the implant.[5,10] The latter problem causes a ventricular prolapse and medialization of the false vocal fold, which impairs normal voice production. In addition, as mentioned earlier, excessive medialization of the vocal fold anteriorly can cause a pressed or strained voice quality.
- Undermedialization of the vocal fold. This is often due to failure to account for intraoperative edema that occurs within the vocal fold throughout the surgical procedure and/or failure to recognize the need for contralateral augmentation. For this reason, the implant should be designed to induce a very slight amount of strain within the voice at the end of the procedure, knowing that a small amount of the strain in the voice is due to edema of the vocal fold. As the edema resolves in 2 to 3 weeks after surgery, the voice quality will be excellent.

- Implant extrusion. Implants can extrude medially into the airway or laterally out into the skin. The former complication is severe and can become an airway emergency. This is believed to occur due to an unrecognized violation of the mucosa, usually of the ventricle, during placement of the implant.

2. Arytenoid adduction

- Pharyngocutaneous fistula. This occurs from violation of the pyriform sinus during the dissection to identify the PCA muscle. If violation is identified intraoperatively, careful oversewing of the opening in the pyriform sinus is warranted.
- Overrotation of the arytenoid cartilage. This can come from excessive tension placed on the arytenoid adduction suture. This is usually identified and corrected during the procedure and thus occurs rarely. It is important to note that excessive tension is rarely required for the arytenoid adduction procedure. The suture placed on the arytenoid cartilage is only to guide the arytenoid into a more favorable position for phonation and to keep it there; thus excessive tension on the suture is usually not required.

Alternative Management Plan

1. Observation alone if patient does not have vocal complaints and does not have dysphagia

2. Injection laryngoplasty with a long-term injectable material (e.g., calcium hydroxylapatite)

3. Injection laryngoplasty with autologous adipose tissue

Discussion

Evidence-Based Medicine Question

1. Is medialization laryngoplasty safe in patients with previous neck radiation?

- Studies have shown that there is no significant difference in subjective voice parameters and complications after medialization laryngoplasty

in radiated versus nonradiated patients.

Editorial Comment

Medialization laryngoplasty is the most popular procedure of otolaryngologists treating glottal incompetence, especially due to vocal fold paralysis. Dr. Isshiki is honored for having reintroduced the procedure into the medical culture in 1974. Since then, there have been refinements to the procedure, but the concept remains the same: move the paralyzed vocal fold to a midline position so the mobile vocal fold can contact it.

The position of the thyroid ala window for placement of whatever type of implant the surgeon chooses is critical to the success of vocal fold medialization. If placing a solid block implant, the angle and position of the window is critical. If placing a Gore-Tex strip, it is important to keep the dissection within the inner perichondrium in the area where the implant will be placed. Aggressive undermining in these cases is not recommended because it could lead to migration of the implant to a less favorable position.

The addition of arytenoid adduction often varies upon surgeon training but can be critical in improving the patient's voice if there is a large posterior glottal gap, a foreshortened vocal fold (with decreased tension), or significant vertical height mismatch of the vocal folds. The arytenoid adduction procedure helps to correct these anatomic findings, resulting in increased generation of subglottic air pressure and therefore vocal intensity.

A different way to approach the arytenoid was conceived by Dr. Zietels et al., first described in 1998. This technique focuses on repositioning the arytenoid posteriorly, superiorly, and medially on the cricoid. Depending upon training, a clinician may feel more comfortable with one or the other of these two arytenoid repositioning techniques.[11,12]

Review Questions

1. How does the position of the thyroplasty window differ in males and females?

   a. Anterior border of the thyroplasty window is more anterior in males

   b. **Anterior border of the thyroplasty window is more posterior in males**

   c. Superior border of the thyroplasty window is more superior in males

   d. Superior border of the thyroplasty window is more inferior in males

2. What are the indications for arytenoid adduction?

   a. Large posterior glottic gap

   b. Vocal fold level mismatch

   c. Reposition the arytenoid

   d. **All of the above**

3. The direction of vocal fold augmentation that can be achieved with thyroplasty is:

   a. **Medial**

   b. Anterior

   c. Posterior

   d. Superior

Intraoperative Medialization Laryngoplasty

Ricardo L. Carrau

Keywords

laryngoplasty; thyroplasty; vocal cord paralysis; glottic insufficiency

Introduction

Medialization laryngoplasty or thyroplasty type I was first described and later popularized by Ishiki during the 1970s. Netterville first reported on the immediate medialization of the true vocal fold following skull base or head and neck surgeries involving the sacrifice of the vagus or recurrent laryngeal nerves.

- Glottic insufficiency affects all laryngeal functions and may be caused by vocal fold:
  - Atrophy (i.e., presbylarynx, neuromuscular degenerative disease)
  - Weakness (i.e., paresis)
  - Paralysis
- Glottic insufficiency impairs the function of the laryngeal sphincter leading to[1-5]:
  - Poor protection of the tracheobronchial airways during swallowing (i.e., aspiration)
  - Reduction of efficiency and strength of the cough reflex
  - Elimination of physiologic positive pressure on expiration (helps to inflate the lungs)
  - Wide range of dysphonia and vocal fatigue

- Decrease in the efficiency of a Valsalva maneuver; thus patients may exhibit problems splinting the thoracoabdominal muscles, which help with lifting and facilitating bowel movements

- An immediate intraoperative thyroplasty is based on an empirical medialization of the true vocal fold. The patient's true functional deficit cannot be assessed reliably under general anesthesia; thus the need for a subsequent revision is higher than a secondary thyroplasty performed under awake sedation.
- The vast majority of patients will enjoy a satisfactory outcome resulting in adequate protection of the tracheobronchial tree against aspiration and normal or near-normal voice (vocal fatigue may be a persistent problem).
- Professional voice performers may require adjunctive procedures, such as arytenoid repositioning, to reach an optimal result.
- A seemingly adequate postoperative result may deteriorate in time due to re-accommodation of the implant (i.e., GOR-TEX strip) or vocal fold atrophy (more common in patients with a high-vagal lesion).
- Surgical medialization of a paralyzed cord displaces the affected vocal fold toward the midline and augments its bulk to improve the glottic closure (it facilitates neuromuscular compensation by the unaffected contralateral side).[1-10]

Key Operative Learning Points

- A medialization laryngoplasty or thyroplasty type I involves the medialization of a paralyzed or paretic true vocal fold by the insertion of a paraglottic implant such as[1-7]:
  - Silicone (premade and custom implants)
  - Polytetrafluoroethylene (GOR-TEX; W.L. Gore and Associates, Newark, DE)
  - Titanium alloy
  - Hydroxyapatite
  - Cartilage

  - Fascia
  - Acellular dermis
  - Adjustable balloon
- Most frequently, an intraoperative thyroplasty involves implantation without the benefit of being able to be certain of the position of the window with respect to the position of the vocal fold or the immediate effect of the implantation upon the quality and strength of the voice or cough.[2,4,5,8]
- The surgeon creates a window in the thyroid cartilage and medializes the vocal cord using dimensions that have been determined to yield adequate results for most patients operated in the traditional way (Fig. 6.1A).
- 20%–30% of patients will require revision surgery.[4-6,8]

Preoperative Period

History

This procedure may be planned preoperatively in the patient with a history of having a tumor originating in the vagus nerve (i.e., vagal schwannoma or a glomus vagale requiring removal of the vagus nerve) or requiring the sacrifice of the vagus nerve in removing an adjacent tumor (i.e., carotid body tumor). In such situations, this procedure must be discussed with the patient. There are also instances in which the need for intraoperative thyroplasty may not be anticipated, such as accidental transection of the recurrent laryngeal nerve during thyroid surgery in which the patient may not have been prepared for this additional procedure.

Physical Examination

- Examination of the neck must rule out the presence of masses, scars, or excessive subcutaneous adipose tissue, all of which may affect the choice and difficulty of the exposure.

- A preoperative flexible fiberoptic laryngoscopy ascertains:
  - The position of the vocal fold (VFs) and arytenoids (horizontal and vertical planes) during normal and forced ventilation, vocalization, and cough
  - The muscle tone of the vocal folds
  - The bulk of the vocal folds
  - The integrity of the mucosa
- Functional assessment of all lower cranial nerves is critical.

Imaging

Not necessary.

Indications

- The decision to perform an immediate intraoperative thyroplasty is multifactorial and includes such variables as the needs and desires of the patient (e.g., profession, fitness, hobbies and interests), age, premorbid laryngeal and pulmonary function, and presence of other cranial nerve deficits.
- An immediate intraoperative thyroplasty is indicated in patients who:

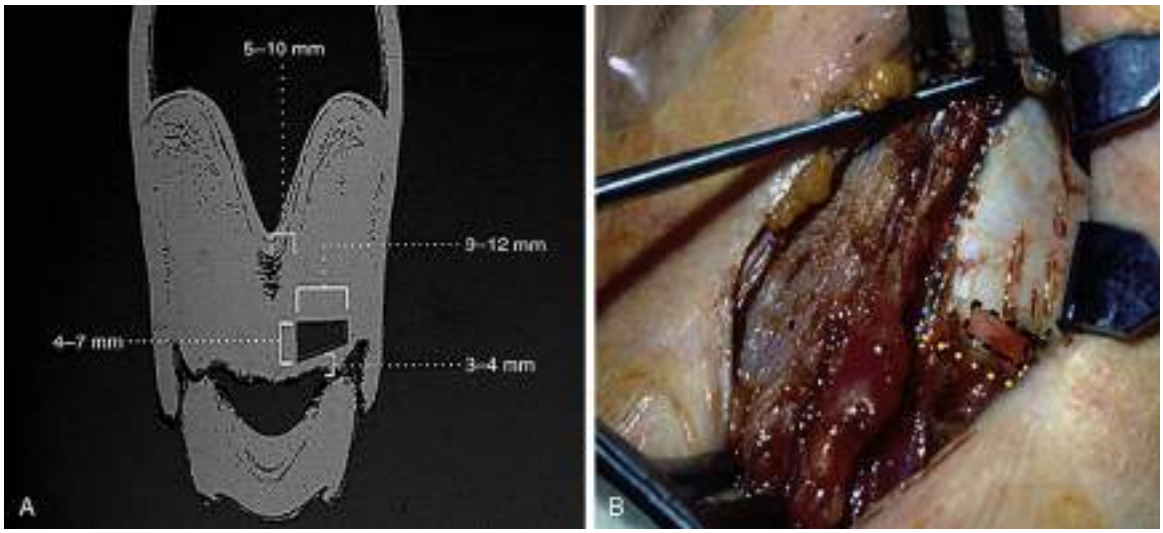

FIG. 6.1 **A,** Approximate dimensions and position of the thyroplasty window. During an immediate thyroplasty, the window is opened as close to the inferior edge of the thyroid ala as possible while still preserving an inferior strut. **B,** The strap muscles and the perichondrium of the thyroid cartilage were divided at the midline and are being retracted from the thyroid ala en bloc. Stabilization of the larynx with a single or double hook greatly facilitates this dissection and opening of the window.

- Undergo sacrifice of the vagus or recurrent laryngeal nerve during an oncologic resection
- Suffered iatrogenic or penetrating trauma to the neck with injury to the vagus or recurrent laryngeal nerves

Contraindications

- An immediate intraoperative thyroplasty is contraindicated in patients who show:
  - Glottic airway stenosis due to edema or abductor paralysis (or paresis) of the contralateral true vocal cord
  - Presence of a congenital or acquired coagulopathy (relative contraindication)
  - Strong aversion to accept the risks of the surgery or the possibility of needing a secondary revised procedure

Preoperative Preparation

- If the possibility of an intraoperative medialization is anticipated, the surgeon must ascertain the function of the contralateral vocal fold by indirect mirror or flexible laryngoscopy.

Operative Period

Anesthesia

- Continue the type of anesthesia established by the primary procedure.

Positioning

- Position the neck in a neutral position or slightly extended. Type of anesthesia, neck positioning, and placement of the incision during an immediate intraoperative thyroplasty may be dictated by the needs of the oncologic surgery or the need to control the great vessels of the neck.

Perioperative Antibiotic Prophylaxis

- Administer broad-spectrum perioperative prophylactic antibiotics and systemic corticosteroids.

Monitoring

- Continue standard anesthesia monitoring.

Instruments and Equipment to Have Available

- Flexible laryngoscope
- Unipolar electrocautery with insulated tip
- Insulated bipolar electrocautery
- Single hook retractor
- Double hook retractor
- Senn retractor (dull)
- High-speed drill
- 2-mm cutting or hybrid burr
- 1- and 2-mm bone curettes
- Cottle or Freer periosteal elevator

- Duckbill elevator
- Medical grade silicone block (medium density) or premade silicone implant
- 0.4-mm thickness GOR-TEX patch (alternate)

Key Anatomic Landmarks

- Notch and midline of thyroid cartilage
- Inferior border of the thyroid ala

Prerequisite Skills

- Experience with laryngeal framework surgery

Operative Risks

- Airway compromise
- Misplacement of the prosthesis

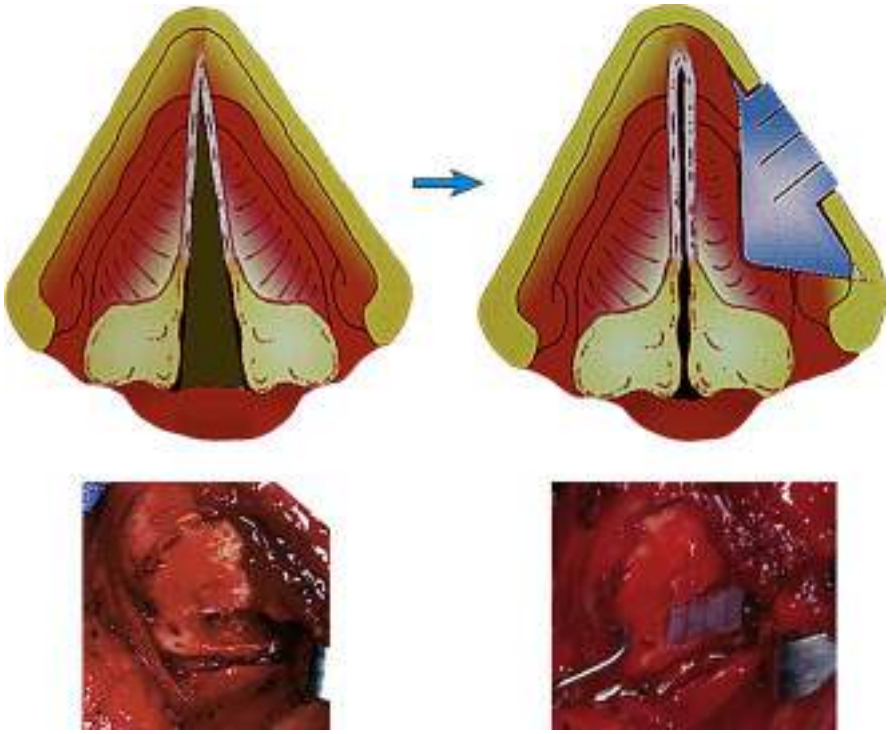

FIG. 6.2 Artistic representation of the effects of a paraglottic silicone implant medializing the vocal process and vocal fold and intraoperative photograph of the window before and after implantation. The implant adds bulk to the vocal fold and, in some cases, displaces the arytenoid posteriorly. The implant is adjustable, partially reversible, and associated with a relatively low degree of technical difficulty and low morbidity.

- Overcorrection or undercorrection
- Extrusion
- Dysphonia

Surgical Technique

- The intraoperative thyroplasty is usually accomplished through the oncologic incision or an extension.
- Divide the strap muscles and perichondrium of the thyroid cartilage at the midline.
- Stabilize the laryngotracheal complex using a single or double hook lodged at the inferior or superior border of the thyroid cartilage. This also facilitates the rotation of the thyroid cartilage, better exposing the thyroid ala. Elevate the ipsilateral strap muscles and perichondrium of the thyroid cartilage to expose its ala.
- Retract the perichondrium and strap muscles with a Senn retractor to expose the cartilage of the thyroid ala (see Fig. 6.1B).
- Transect the insertion of the sternothyroid muscle using a bipolar electrocautery, thus exposing the entire inferior border of the thyroid ala.
- The dimensions of the window vary according to the dimensions of the thyroid ala (in turn vary with height, gender, and age):
  - Ranges between 4 × 8 mm to 5 × 10 mm
  - Position the window 3 to 4 mm above the inferior border of the ala and 5 to 10 mm posterior to midline (for women and men

respectively) (see Fig. 6.1A).

- A window may be opened with a 67 Beaver blade (for cartilage) or a high-speed drill with a 2-mm coarse diamond or hybrid burr (for calcified cartilage).
  - The latter is most commonly used because most adults have undergone some ossification of the inferior aspect of the thyroid ala.
  - Drill out the window at perpendicular angles (i.e., avoiding "saucerization") until the inner cortex of the thyroid ala is thin enough to be eggshell fractured, thus allowing its removal with a 1- to 2-mm bone curette.
  - When the cartilage is soft, it can be transected with a #67 Beaver blade and elevated with a middle ear spatula or Cottle elevator.
  - One must avoid saucerization or thinning of the lower strut, which could lead to fracturing and will destabilize the implant.
- Following exposure of the inner perichondrium, a bone curette, Cottle, or duckbill elevator is inserted between the alar cartilage and the inner perichondrium to widely dissect this space.
- Incise the inner perichondrium along the axis of the window.
  - This incision allows the implant to medialize just the area corresponding to the vocalis muscle (as opposed to medializing the entire inner perichondrium).
  - A small artery is commonly encountered at the posterior aspect of this incision, requiring control with a bipolar electrocautery.
- Choice of implant material is surgeon dependent; however, carving an implant from a medium-density medical grade silicone block allows customization, does not suffer compression like the polytetrafluoroethylene strip, and is more cost effective.
- Implants are carved so they are wider and longer than the window, thus avoiding extrusion of the implant through the window.
  - A "peg" that protrudes through the window prevents migration of the implant in the coronal or sagittal planes (Fig. 6.2**).**
- Extension of the implant for 4 to 6 mm posterior to the window places the point of maximal medialization (4 to 5 mm deep) close to the vocal

process of the arytenoid cartilage, thus avoiding and sometimes correcting its anterior subluxation.

- Vertical incisions through the "peg," following the coronal plane and extending halfway into the implant, allow bending the silicone implant, thus facilitating its insertion (see Fig. 6.2).
- Re-approximate the strap muscles and perichondrium with interrupted absorbable sutures.
- Achieve complete hemostasis.
- Close the skin using a multilayer technique.

Common Errors in Technique

- Stabilization of the larynx with a hook retractor facilitates the completion of the alar window, as well as the insertion of the implant.
- Implantation must be as inferior on the thyroid ala as possible.
- A high-speed drill with a 2-mm burr is most effective in creating the window.
- Incising the inner perichondrium avoids medializing the entire hemilarynx; however, one must be cognizant of an artery that runs medial to the inner perichondrium close to the posterior aspect of the window.
- Point of maximal medialization should be as posterior as possible (close to the vocal process)
- Aim for absolute hemostasis.
- Beware of fracturing the remaining inferior strut.
  - A fracture can be repaired using wire or a 1.5-mm titanium adaptation plate.

Postoperative Period[1,6,9,10]

Postoperative Management

- Patients are advised to rest their voice as much as possible for 72 hours and to avoid activities that may require a Valsalva maneuver.
- Provide stool softeners.
- If needed, proton pump inhibitors or H_2 blockers may be prescribed to control gastroesophageal reflux (GER).
- Antitussive medications and humidified air can be provided as needed.
- Systemic corticosteroids may be continued for 24 to 48 hours (empirical).

Complications

- Common complications of an intraoperative thyroplasty type I are related to misplacement or misalignment of the implant.
  - Overmedialization or undermedialization of the vocal fold will fail to correct the glottic gap.
  - Similarly, inappropriate placement of the implant, either too high into the ventricle (or false cord) or too low into the subglottis, will result in an insufficient glottis.
  - Placement that is too anterior will lead to early contact and a very strained voice with increase of the posterior gap (i.e., greater risk of aspiration).
- Extrusion of the implant may occur if it is placed at, or if it migrates into, the ventricle.
- Infection and airway compromise are uncommon complications.

Alternative Management Plan

- An alternative to a medialization laryngoplasty is medialization by injecting the vocal fold with carboxymethylcellulose, hyaluronic acid, acellular dermis, or calcium hydroxyapatite.
- Doing a secondary laryngoplasty or injection if necessary

Evidence-Based Medicine Question

What is the value of medializing a paralyzed vocal fold?

Multiple studies have demonstrated the positive effects of a medialization laryngoplasty in correcting dysphonia and diminishing dysphagia. Cates et al. recently reported their experience with 44 patients with unilateral vocal fold paralysis, who significantly improved on their Eating Assessment Tool (EAT-10) scores after medialization. Similarly, Asik et al. noted statistically significant improvements in the maximum phonation time and in their dyspnea scales in 19 patients with unilateral vocal fold paralysis treated with medialization. In his seminal study, Netterville suggested that these effects are obtained immediately in patients undergoing an intraoperative medialization laryngoplasty, findings that we have encountered in our own experience.[2,3] Therefore, and considering the low morbidity of a medialization laryngoplasty, intraoperative implantation brings immediate benefits that helps the patient's recovery and avoids complications related to respiratory and swallowing deficits caused by glottic insufficiency.

Editorial Comment

Intraoperative medialization laryngoplasty can often provide a significant benefit to the oncologic patient who is undergoing a resection that includes the vagus and/or recurrent laryngeal nerve due to the oncologic resection. This procedure will provide significant, immediate improvement for the patient's pulmonary toilet and voice quality, which is a major safety and quality of life issue. Consent should include the elevated and increased need for revision of the medialization laryngoplasty, given that the procedure is done under general anesthesia. Furthermore, the surgeon planning the intraoperative medialization laryngoplasty should confirm, preoperatively, that the contralateral vocal fold has normal abduction. If this is not done, the patient could have significant airway embarrassment postoperatively due to the lack of preoperative identification of the contralateral vocal fold's decreased abduction. An alternative technique to intraoperative medialization laryngoplasty is to perform a temporary augmentation injection of the vocal fold using a material that will provide 1 to 3 months of vocal fold augmentation. This alternative surgical procedure can be done at the same time as the oncologic resection via direct laryngoscopy with a microscope, or a magnified endoscope, using a temporary vocal fold

injection material, such as a collagen-based material, hyaluronic acid, or carboxymethylcellulose. This alternative option provides effective postoperative glottic closure to enhance voice quality and pulmonary toilet. Furthermore, after the temporary material is absorbed, the patient can undergo customized vocal fold closure rehabilitation, if necessary, using a more durable or permanent vocal fold augmentation material (adipose tissue or calcium hydroxyapatite) or undergo medialization laryngoplasty with or without arytenoid adduction.

Review Questions

1. Dysfunction of the vocal fold may lead to
   a. Poor protection of the tracheobronchial airways during swallowing (i.e., aspiration)
   b. Reduction of efficiency and strength of the cough reflex
   c. Elimination of physiologic positive pressure on expiration (helps to inflate the lungs)
   d. Dysphonia and vocal fatigue
   e. **All of the above**
2. An intraoperative medialization laryngoplasty strives to
   a. Displace the affected vocal fold toward midline
   b. Augment its bulk
   c. Improve glottic closure
   d. Facilitate neuromuscular compensation
   e. **All of the above**
3. A medialization laryngoplasty involves
   a. The medialization of the true vocal fold by the insertion of a paraglottic implant
   b. Implantation without being able to ascertain the immediate effect of

the implantation upon the quality and strength of the voice or cough

c. Opening a window and medialization of the true vocal fold the cord using empirical dimensions

d. Revision surgery in 20%–30% of patients

e. **All of the above**

4. Contraindications for an intraoperative medialization laryngoplasty include

a. Glottic airway stenosis due to edema or abductor paralysis (or paresis) of the contralateral true vocal fold (TVF)

b. Congenital or acquired coagulopathy

c. Tongue paralysis

d. All of the above

e. **a and b**

5. The most common complication of an intraoperative medialization laryngoplasty is

a. Hematoma

b. Airway obstruction

c. **Overmedialization or undermedialization**

d. Wound infection

e. Extrusion of the implant

Excision of Laryngocele

Tack-Kyun Kwon

Introduction

The ventricle ends in a blind pouch anteriorly called the sacculus or saccule, which is variously known as the appendix ventriculi larynges or Hilton's sac. Laryngocele refers to a pathologic cystic dilation and enlargement of the saccule of the laryngeal ventricle.[1] It is a rare and benign lesion of the larynx that may present with hoarseness, dyspnea, or dysphagia, depending on its size.

Laryngoceles are classified into three groups: the internal, external, and mixed type. In the internal type, the swelling is confined within the larynx. This may be seen as a swelling of the ventricle, hiding the true cord of the same side, and even extending across the midline to compromise the airway. The internal type may extend to the aryepiglottic fold and even to the base of the tongue, completely filling one vallecula.

The external type appears as a swelling in the neck, usually at about the level of the hyoid bone and just anterior to the sternocleidomastoid muscle, but can be found almost anywhere in the neck. The sacculus extends and perforates the thyrohyoid membrane where the superior laryngeal neurovascular bundle passes. This seems to be the weakest point of the membrane. In the mixed or combined type, the internal and external portions are joined by an isthmus that gives an hourglass appearance.[1]

DeSanto classified benign cystic lesions derived from the saccule into laryngocele, laryngeal mucocele, large saccules, and laryngeal saccular cyst, depending on the size of the saccule, the presence of a communication between the saccule and the laryngeal lumen, the presence of inflammation, and the presence of symptom.[2] They

concluded that these lesions have a common pathology but show different manifestations in a developmental spectrum.

Surgical excision is indicated when the patient has apparent symptoms and a differential diagnosis is needed. A key issue is whether complete excision can be achieved without complications.

The author describes various approaches for safe surgical excision of laryngoceles.

Key Operative Learning Points

- Diagnosis and differential diagnosis are critical.
- Identification of coexisting pathology is necessary.
- Airway compromise should be avoided.
- Temporary tracheostomy may be needed to prevent postoperative airway compromise.
- Care should be taken to prevent injury to the superior laryngeal neurovascular bundle.
- Careful selection of patients is important, as the surgical approach can vary according to the size and location of the laryngocele.

Preoperative Period

It is important to know that not all laryngoceles induce symptoms and not all laryngoceles should be surgically removed. Most laryngoceles are asymptomatic at onset and do not produce symptoms until they are quite large. The most common symptom is hoarseness, but the patients may also present with dyspnea or dysphagia, depending on the size of the laryngocele, or may present with a mass in the neck depending upon the location of the external laryngocele.[1]

An asymptomatic laryngocele incidentally found on radiographic studies is not an indication for surgical treatment.[3] Office laryngoscopy is necessary to reveal a unilateral or bilateral bulge of the false vocal fold and/or aryepiglottic fold (Fig. 7.1). Examination of the ventricle is also necessary to identify synchronous pathologies that might have caused

the laryngocele, but this is almost impossible to do in an office visit because the ventricular cavity is obscured by the laryngocele.

Several imaging techniques can be used to diagnose a laryngocele. Computed tomography (CT) is the gold standard, as it allows the visualization of the air-filled saccule and its anatomic relations (Fig. 7.2). CT scan has proven to be the most accurate imaging method in defining the spatial relationship between the laryngocele and the laryngeal structures and extralaryngeal soft tissues, in differentiating the laryngocele from other cystic formations, and in identifying the coexistence of a laryngeal cancer.[4]

FIG. 7.1 Laryngoscopic view of internal laryngocele (black arrow).

FIG. 7.2 A coronal computed tomography scan showing an internal laryngocele.

History

1. History of present illness
   a. Occupations: Trumpet/trombone player, glass blower, street hawker, and singer
   b. Risk factors for laryngeal cancer: Smoking, alcohol, human papilloma virus (HPV) infection
   c. Symptoms indicating the laryngocele status: Dyspnea, dysphonia, dysphagia, fever, pain, mass in the neck
2. Past medical history
   a. Previous surgical procedures on the larynx and neck
   b. Previous history of chronic laryngeal inflammation, such as tuberculosis and amyloidosis
   c. Previous history of trauma to the larynx or neck
3. Prior treatment of larynx or neck
   a. Previous endoscopic excision of a laryngeal mass

b. Previous surgery for a mass in the neck

4. Medical illness
   a. Cardiopulmonary diseases
   b. Infectious diseases
   c. Immunosuppression, e.g., AIDS
   d. Alcoholism and/or other substance abuse
5. Medications
   a. Anticoagulants
   b. Alcohol (risk of perioperative alcohol withdrawal syndrome)
   c. Allergies to antibiotics
6. Mental and social status
   a. Ability to give informed consent
   b. Cosmetic consideration

Physical Examination

1. Neck
   a. Palpate both sides of the neck for the presence of a cervical mass.
   b. Identify external component of pathology
      1) Vertical location
         a) Cricothyroid area
         b) Thyrohyoid area
      2) Valsalva maneuver
         a) Observe size increase with/without a hissing noise.
      3) Gentle manual palpation over the mass
         b) Observe reduction in size with/without a hissing noise.
   c. Identify any evidence of previous surgery.
2. Laryngeal endoscopic examination

a. Location of a bulging mass

1) Unilateral/bilateral

2) False vocal fold, ventricle, aryepiglottic fold

b. Coexisting pathology

1) Ventricular/vocal fold mass

2) Signs of inflammation

c. Vocal fold movement/mucosal lesions

3. General health

a. Cardiovascular

b. Respiratory

c. Mental

Imaging

1. Chest radiograph

a. Synchronous lung pathology

b. Pulmonary and cardiac status

2. Esophagography: Only if dysphagia is present

3. Ultrasonography

a. Useful method for screening

b. Initial diagnostic method for a mass in the neck, differentiating the contents and location of cystic masses

4. CT scan

a. Gold standard for diagnosis and differential diagnosis

b. Confirms diagnosis and type of laryngocele

c. Differential diagnosis from other cystic benign mass and neoplasm

5. Magnetic resonance imaging (MRI)

a. Rarely indicated

b. Offers detailed information on the boundaries of laryngoceles:

Indicated for those cases associated with a tumor of the larynx

Indications

- Progressively symptomatic laryngocele
  - Hoarseness/breathing difficulties/swallowing difficulties
  - Frequent infection
  - Mass in the neck: Cosmetic concern
- Coexisting causative pathology, suspicious for malignancy

Contraindications

1. Patient factors
   a. Medically unfit for general anesthesia
   b. Inability to give informed consent
2. Disease factors
   a. Acute infection and inflammation
   b. Asymptomatic laryngocele found incidentally on radiography

Preoperative Preparation

1. Evaluations by
   a. Speech and swallowing therapist
   b. Anesthesiology
2. Discontinue antiplatelet drugs if possible.
3. Tracheostomy if patient has progressive dyspnea
4. Informed consent should include the possibility of a temporary tracheostomy.
   a. If endotracheal intubation fails
   b. For airway obstruction

Operative Period

Anesthesia

- If endoscopic laser surgery is planned, ask the anesthesiologists to intubate the patient with a small (5 for female and 5.5 for male) laser-safe endotracheal tube.
- The surgeon should always be present during induction of anesthesia, as a large internal laryngocele may occlude the airway, and it may be difficult or impossible for the anesthesiologist to intubate the patient.
- Should the anesthesiologist be unable to intubate the larynx, the surgeon may have to intubate through an operating laryngoscope or do an emergency cricothyrotomy or tracheostomy.
- A temporary tracheostomy may be required for patients with a large internal laryngocele to prevent postoperative airway compromise due to edema.
- A large-bore suction device should be prepared during the intubation procedure to suction out fluid when a laryngocele with fluid content is accidentally ruptured.

Positioning

- For the endoscopic approach, the position of the patient is the same as with endoscopic laser surgery with suspension laryngoscopy. Suspension laryngoscopy is also necessary prior to an external approach.
- For the external approach, after suspension laryngoscopic examination, the patient is placed in the supine position with the patient's neck extended by placing a shoulder roll with the head rotated to the side opposite the lesion.

Perioperative Antibiotic Prophylaxis

- Clean contaminated surgery

- Antibiotics are administered during induction of anesthesia and continued for 24 hours.
- Choices
  - Clindamycin
  - Amoxicillin-clavulanate
  - Cephalosporin and metronidazole

Monitoring

- Routine anesthetic monitoring, including pulse oximetry

Operative Risks

- Infection
- Airway obstruction
- Injury to superior laryngeal nerve

Instruments and Equipment to Have Available

- Laser equipment
  - CO_2 laser
  - Micromanipulator with coupling device between microscope and laser
  - Proper laser safety precautions (i.e., endotracheal tube protection, oxygen content adjustment, and eye protection for patient and staff)
- Microsuspension laryngoscopy
  - High-quality operating microscope with 400 mm lens
  - Rigid laryngoscope with large caliber and suction channel
  - Hopkins telescope (0, 30, and 70 degree)
  - Suspension system

    - Operating chair with arm supports
    - Microscopic endolaryngeal surgical instruments
    - Electrocautery suction tip and vascular clip set
- Resection and neck dissections
    - Standard head and neck set
    - Powered drill (used for thyrotomy on calcified thyroid cartilage)
    - Tracheostomy tubes and anesthetic tubing

Key Anatomic Landmarks

- Endoscopic laser surgery
    - True vocal fold/false vocal fold
    - Ventricle/saccule
    - Aryepiglottic fold
    - Pharyngoepiglottic fold (superior laryngeal neurovascular bundle)
    - Pyriform sinus
- Lateral thyrotomy approach
    - Subplatysmal skin flap
    - Sternohyoid muscles
    - Thyrohyoid muscles
    - Thyrohyoid membrane
    - Superior laryngeal neurovascular bundle
    - Thyroid cartilage
    - Paraglottic space

Prerequisite Skills

- Microsuspension laryngoscopy
- Laser microlaryngoscopic surgery

- Lateral thyrotomy
- Tracheostomy

Surgical Technique

- *Microsuspension laryngoscopy*
  - Microscopic and endoscopic evaluation of the larynx should be performed prior to either endoscopic laser excision or external approach.
  - Evaluation of the ventricle using angled telescopes (30 and 70 degree)
  - Careful examination of the ventricle to identify any coexisting ventricular pathology
- *Endoscopic laser excision*
  - Using a large-diameter laryngoscope, such as the Lindholm or Werda type laryngoscope, expose the entire extent of the laryngocele, if possible.
  - The lower airway should be covered with saline-soaked cottonoids to prevent laser injury and aspiration of the contents of the laryngocele.
  - Using a focused laser beam, make an incision in the most prominent false vocal fold mucosa overlying the laryngocele (Fig. 7.3).
  - The incision is extended to the deeper layer until the surface of the laryngocele is reached. To identify the neck of the sac in the ventricle, a part of the false vocal fold mucosa can be resected with the sac.
  - With gentle retraction using forceps or suction, the sac is carefully dissected from the surrounding soft tissues using a microdissector or suction tip.
  - During dissection, minor bleeding can be controlled with a defocused laser, but electrocautery or vascular clips can be used if further hemostasis is needed.
  - During the laser procedure, great care should be taken to protect the

underlying true vocal fold from laser injury.

- After the laryngocele is removed, the redundant false vocal fold mucosa may be sutured or trimmed to prevent airway compromise.

- *External approach with thyrotomy*
  - A horizontal incision is made in a skin crease; the skin flaps are elevated in the subplatysmal plane down to the inferior border of the thyroid cartilage and superiorly to the hyoid bone.
  - The level of the horizontal skin incision depends upon the location and size of the external component of the laryngocele.
  - The strap muscle is divided in the midline, and the thyroid cartilage is exposed.
  - If necessary, the superior aspect of the sternothyroid, omohyoid, and thyrohyoid muscles may be divided along the inferior border of the hyoid bone for better exposure of the laryngocele.
  - The external component of the laryngocele is identified and carefully dissected off of the surrounding soft tissues up to the thyrohyoid area. The laryngocele may be retracted with forceps and dissected carefully to avoid injury to the superior laryngeal neurovascular bundle.
  - After identification of the superior laryngeal neurovascular bundle, the thyrohyoid membrane is sectioned along the superior border of the thyroid cartilage. The superior aspect of the internal laryngocele is now visualized through this incision.

FIG. 7.3 An incision is made using a CO_2 laser during endoscopic excision of a laryngocele. Note the suction is being used for dissection.

- Although several thyrotomy incisions have been reported, I prefer a lateral thyrotomy approach. This consists of a vertical incision at the junction of anterior and the middle third of the thyroid cartilage, splitting it in half, and retracting both sides for exposure of the paraglottis (Fig. 7.4A). Thome et al. reported V-shaped cuts in the superior half of the thyroid lamina, creating a triangular window through the thyroid cartilage.[5] Having made the thyrotomy incision, the laryngocele is dissected under direct vision through this incision (see Fig. 7.4B).
- The thyrotomy incision can be made using #15 blade, but a power drill or oscillating saw is necessary when the thyroid cartilage is ossified.
- After further dissection along the internal compartment of the sac, the most inferior limit of the laryngocele at the anterior aspect of the ventricle and its entry into the larynx is sutured in a figure-eight fashion with absorbable suture and the laryngocele is excised. If the base of the laryngocele is not clearly identified, the most inferior limit of the laryngocele may be clamped and ligated with silk ligature.
- If a lateral thyrotomy incision has been made, the thyrotomy incision is approximated with 4-0 nylon suture. No reconstruction is needed after a V-shaped resection of the thyroid cartilage.
- The strap muscles are anchored in their original position on the hyoid bone. After thorough irrigation, the skin incision is closed in layers over a closed suction drain.
- A tracheostomy may be performed if postoperative edema of the airway is anticipated.

Common Errors in Technique

- When a lateral thyrotomy incision is made, be careful not to elevate the perichondrium off of the thyroid cartilage along the incision. Without

perichondrial attachment to the thyroid cartilage, the cartilage tends to break easily during approximation with sutures.

- Laryngoceles are lined by thin respiratory mucosa. Soft tissue dissection around the laryngocele should be made until a glistening capsule is clearly seen to prevent unwanted injury to the surrounding structures.
- During dissection around the thyrohyoid membrane, great care should be taken not to injure the superior laryngeal neurovascular bundle.

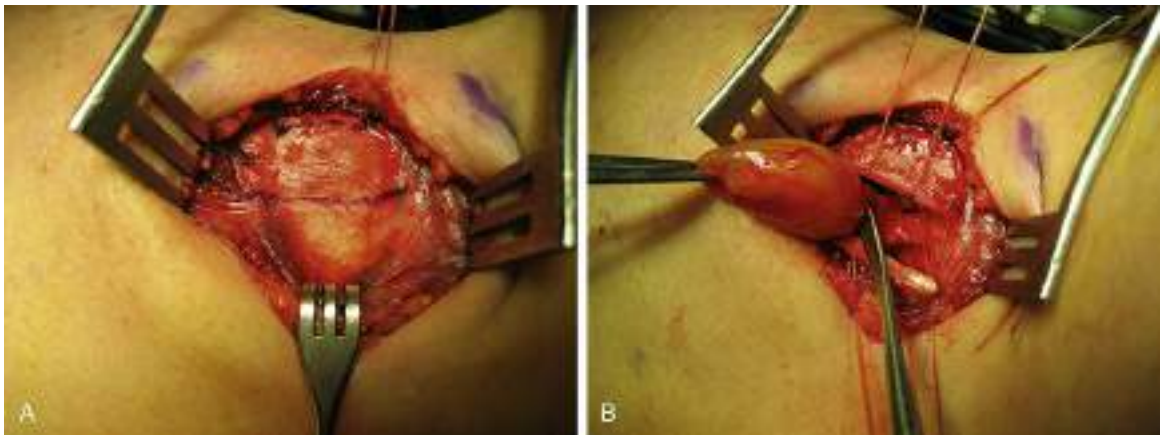

FIG. 7.4 **A,** A lateral thyrotomy incision is made at the junction of the anterior and the middle third of the thyroid cartilage. **B,** The laryngocele is retracted laterally and dissected free of the surrounding tissue.

- Incomplete excision of a laryngocele may result in recurrence; therefore the base of the saccule must be resected if possible.
- Without preoperative imaging studies, the external component of the laryngocele may be neglected, resulting in recurrence in the neck.

Postoperative Period

- The patient must be hospitalized overnight for observation for airway obstruction.

Postoperative Management

- Perioperative antibiotics
- Routine intravenous steroid administration, intra- and postoperatively, every 8 hours for 24 hours
- Tracheostomy tube can be removed once follow-up examination reveals a patent airway
- Diet as tolerated

Complications

- Postoperative airway compromise due to edema in the wound, redundant mucosa, or hematoma
- Injury to the superior laryngeal nerve resulting in aspiration and dysphagia
- Bleeding
- Recurrence of the laryngocele

Alternative Management Plan

Selected patients in poor general condition for general anesthesia may be operated under local anesthesia. Asymptomatic patients with a small to moderate size laryngocele may just be observed.

Discussion

Evidence-Based Medicine Questions

What is the function of the saccule and how does a laryngocele develop?

The laryngeal ventricle is a normal finding in man and is found only in mammals. It is a small elliptical recess located between the false vocal folds above and the true vocal folds below.[1] The laryngeal ventricle was first described by Galen; however, Morgagni described the anatomic features more completely, so it is also called the sinus of Morgagni.

In the roof anteriorly the ventricle ends in a blind pouch called the sacculus or saccule, which is variously known as the appendix ventriculi larynges or Hilton's sac.

Embryologically, the ventricle is formed by the thyroarytenoid sphincter splitting and forming the lower internal true vocal folds and the upper external false vocal folds. The recess left between them is the ventricle. Toward the end of the second month of intrauterine development, the saccule takes form and at birth is of relatively large size; this remains large until it begins to regress at the end of the sixth year.[6]

Laryngeal air sacs are normal anatomic findings in many animals. In some mammals, the air sacs extend out into the neck, even over the pectoral muscle onto the anterior chest wall. The purpose of such large sacs is to serve as a breathing apparatus, enabling the animal to hold its breath longer.[7]

Several factors contribute to the formation of a laryngocele. The two most common factors seem to be a prolonged increase in intraglottic pressure and associated long saccule.

The laryngeal mechanics of increased intraglottic pressure are as follows: Strenuous expiratory effort causes closure of the sphincters of the false cords and prevents air from escaping. The sphincters are the thyroarytenoid, thyroepiglottic, and aryepiglottic muscles. The true cords also close, but with any additional increase in pressure, air will escape through the true cords but not through the false cords. This causes a great increase in pressure in the ventricle and saccule, thereby causing dilatation of the saccule and the formation of a laryngocele in those who are predisposed. This is the reason why laryngoceles are not uncommonly seen in brass players and glassblowers.

It has also been reported that external laryngeal trauma, infectious diseases such as tuberculosis and syphilis, and tumors are associated with laryngoceles.[1]

Is laryngeal cancer correlated with laryngocele and how?

Many papers reported the correlation between laryngeal cancer and laryngocele.[5] Three possible explanations for this correlation have been proposed. The first theory is that distortion of the saccule may create a one-way valve with subsequent inflation and distention of the saccule.

The second theory is that cancer may preferentially arise in the epithelium of the saccule. The third theory is that the cancer mass can alter laryngeal physiology and increase intralaryngeal pressure, resulting in dilation of the saccule.

The first theory does not explain the existence of contralateral or bilateral laryngocele, and the second theory provides no obvious scientific evidence to support it. The third theory is thought to be the most reliable so far.[5]

Editorial Comment

The presence of cancer in a laryngocele in North America is truly unusual. We cannot explain the relationship between cancer and a laryngocele based on our experience.

Review Questions

1. Which of the following statements about laryngocele is TRUE?

   a. Laryngocele is the most common benign cystic lesion in the larynx.

   b. Laryngocele should be surgically removed if found in radiologic studies.

   c. Laryngocele usually originates from the posterior end of the ventricle.

   d. **Laryngocele has the same pathology as a saccular cyst.**

2. Which of the following statements on surgical treatment of laryngocele is TRUE?

   a. Marsupialization is one of the standard surgical approaches for laryngocele.

   b. Lateral thyrotomy should be made after a perichondrial flap is elevated.

   c. **Microsuspension laryngoscopy should be done prior to both**

endoscopic and external approach.

d. False vocal fold mucosa should be preserved during endoscopic resection of a laryngocele.

3. Which of the following statements about laryngocele is FALSE?

a. **Most laryngoceles are symptomatic.**

b. There is association with laryngeal cancer.

c. A glassblower is more likely to develop a laryngocele than others.

d. Laryngocele is lined with ciliated pseudostratified columnar epithelium.

Laryngeal Trauma

Apurva Thekdi, and Clark A. Rosen

Introduction

Trauma to the larynx accounts for less than 1% of all trauma. This is explained in part by the fact that the larynx is relatively protected by the mandible, sternum, and flexion mechanism of the neck. An alternative perspective is the percentage of patients with laryngeal injuries who are dead on arrival at the emergency department. Line and associates[1] reported a series of 171 victims of blunt neck trauma (strangulation), of whom 112 persons (65%) did not survive. It has been estimated that the emergency departments in busy trauma centers will treat one patient with laryngeal trauma for every 5000 to 30,000 emergency department visits.[2]

A basic knowledge of the laryngeal anatomy and physiology is fundamental to understanding the principles established for the management of laryngeal trauma. The larynx is classically divided into three anatomic areas with different functions and characteristics (Fig. 8.1). The primary functions of the larynx are to serve as an airway conduit and to protect the lower respiratory tract. The production of voice, although extremely important for socioeconomic development, is of teleological secondary importance. Respiratory epithelium that is part of the mucociliary clearing system of the respiratory tract lines most of the larynx. The sensory innervation of the supraglottic larynx is supplied by the paired superior laryngeal nerves, which are also branches of the vagus nerves. The superior laryngeal nerves also innervate the cricothyroid muscle, which tightens the vocal folds and, accordingly, is responsible for pitch. The function of the larynx depends on a complex arrangement of intrinsic muscles innervated by the superior and recurrent laryngeal nerves, which are branches of the right and left vagus nerves. A framework composed of cartilage and ligaments supports the

laryngeal soft tissue. The cartilaginous framework of the larynx relies on the blood supply provided by the perichondrium. This framework is then suspended on a sling between the mandible (via the hyoid bone) and sternum.

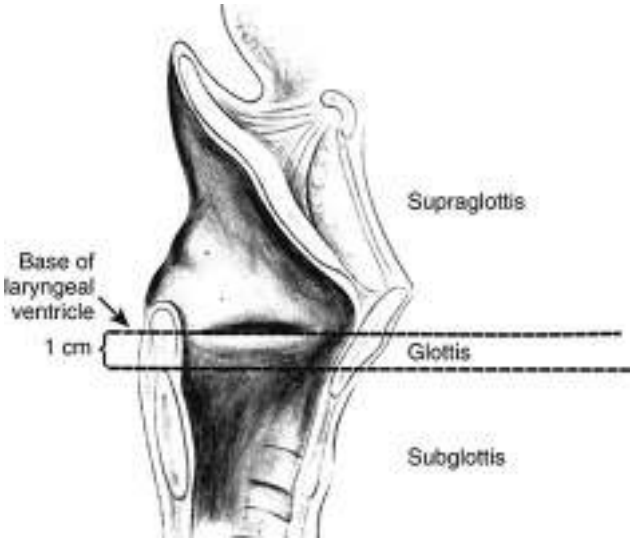

FIG. 8.1 Sagittal drawing of the larynx depicting the three anatomic areas. The glottic larynx extends from the free edge of the true vocal cord inferiorly 1 cm. This approximates the histologic observation of stratified squamous epithelium on the glottis changing to respiratory epithelium of the subglottis.

Trauma to the larynx may manifest in a wide variety of ways, reflecting a multitude of uncontrollable variables. Accordingly, evaluation and management of the patient with laryngeal trauma requires accurate assessment, a working understanding of the principles of laryngeal reconstruction, and an ability to accommodate unexpected findings at exploration in the operating room.

Children rarely suffer direct trauma to the larynx. This reflects the morphologic differences between children and adults. The larynx in children is relatively protected since it is high in the neck and generally shielded from direct trauma by the mandible. In addition, the soft, flexible cartilaginous structures of the pediatric laryngotracheal complex are more tolerant of blunt trauma.

The mechanism of trauma greatly influences the likelihood for associated injury and the need for multidisciplinary collaboration. In general, laryngeal trauma is classified as *blunt* or *penetrating*. The most common mechanism of injury is blunt trauma.[3] With a patient injured in a motor vehicle accident, a broad general assessment of the patient's overall well-being is clearly mandated.

Blunt trauma to the cervical region may produce serious and life-threatening injury, including total obstruction of the airway and significant life-threatening vascular disruption (Fig. 8.2). Cervical spine injuries occur in a significant percentage of patients and may not be appreciated initially because of the obvious soft tissue damage. Injuries to major structures are more clearly apparent when a sharp instrument or penetrating missile results in soft tissue wounds. Nevertheless, injury may be significant even with minimal signs of external wounds. Any type of blunt trauma may disrupt the laryngeal soft tissue or its cartilaginous framework, producing scarring, loss of support, and subsequent collapse of the airway and stricture. It may also dislocate the cricoarytenoid joint, leading to fixation of the vocal cord, or disrupt the laryngeal innervation, paralyzing the vocal cords. It is important to realize that significant laryngeal trauma may be possible in the absence of signs of external injury.

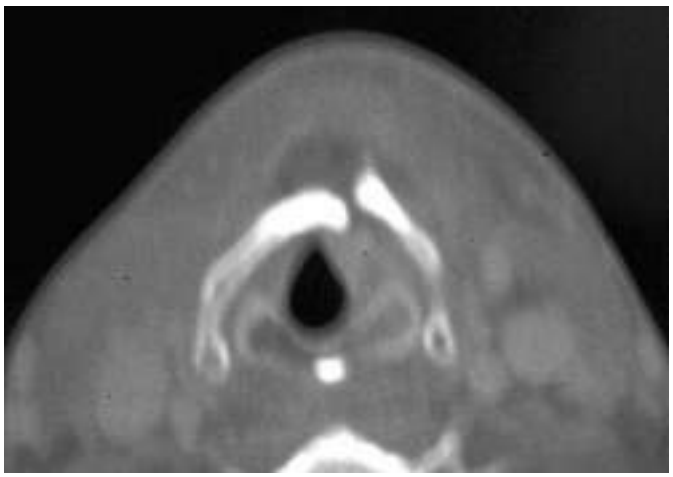

FIG. 8.2 Computed tomography demonstrates a displaced cartilage fracture of the thyroid cartilage. The integrity of the mucosa should be confirmed endoscopically. The cartilage requires reduction and

fixation.

The larynx may also be involved in penetrating trauma to the neck. It is important to recognize that approximately 60% of the patients with penetrating trauma to the larynx will have other associated injuries, such as neurologic vascular or esophageal injuries.[2] Penetrating trauma includes a wide range of injuries, ranging from stab wounds to gunshot wounds. Although stab wounds usually follow a straight line or predictable path, bullets or other projectiles tend to follow planes of least resistance (e.g., fascial planes), producing less predictable injuries. Bullets cause injury both by direct contact as well as tissue distention caused by the abrupt displacement of the tissues produced by the bullet's shock wave (Fig. 8.3). The trauma caused by this shock wave increases as the square of the velocity, hence high-velocity weapons such as assault rifles cause much greater injury.

A peculiar injury is one produced by strangulation, which is a broad term that includes hanging, garroting (ligature strangulation), throttling (manual compression), and chokeholds. Strangulation accounts for 10% of the violent deaths in the United States.[1] Victims of strangulation most often die at the site of the incident, accounting for its infrequency as an emergency department visit.[4] Strangulation is characterized by the application of a static force over the laryngeal framework, which may fracture the cartilage and not disrupt the mucosa. This latter fact frequently leads the examiner to the false assumption that the victim has not suffered a significant injury. The classic injury in strangulation victims is a fracture of the superior thyroid cornu, which may be accompanied by cordal hematomas, petechiae of the endolaryngeal mucosa, or arytenoid dislocation. A history of significant bleeding that has spontaneously resolved or a hematoma that developed rapidly suggests a major vascular injury that will require evaluation. The Isadora Duncan syndrome consists of strangulation with carotid contusion, avulsion, or occlusion and laryngeal rupture.[5]

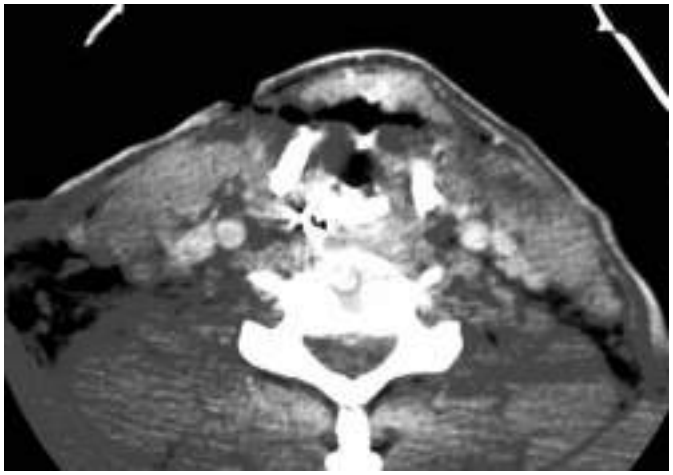

FIG. 8.3 This open laryngeal injury (gunshot wound) requires emergent establishment of a tracheostomy and then comprehensive repair of both mucosa and framework trauma.

Key Operative Learning Points

- The glottis depends on cartilaginous support, mobility of the cricoarytenoid joint, and perfect neuromuscular coordination to perform its sphincteric and voice-producing functions.
- The adult airway is narrowest at the glottic level; therefore any decrease in the cross-sectional area of the airway at the level of the vocal cords may result in significant compromise of the airway (proportional to the square of the radius).
- The subglottis is supported by the cricoid cartilage, which is the only circular cartilage of the laryngotracheal complex.
- Penetrating laryngeal trauma requires endoscopic evaluation and repair of disrupted epithelium and cartilage.
- Voice change following blunt cervical trauma mandates evaluation of the laryngeal anatomy.
- All patients with significant laryngeal trauma should be considered at risk for an injury to the cervical spine.
- Penetrating airway trauma may be associated with significant neurovascular injury.

- Tracheostomy (or cricothyrotomy) may be required when laryngeal trauma results in stridor or cyanosis.
- Displaced fractures of the thyroid and cricoid cartilage require early reduction to improve long-term results.
- Keels and stents may facilitate epithelial regrowth and prevent scarring after major disruption of the laryngeal structures.
- Keels are preferred to stenting. If stenting is required for support, minimize the length of time the stent is in place to prevent scarring.
- Tracheostomy tubes must be secured in the presence of severe laryngeal trauma.
- Airway evaluation (often with flexible laryngoscopy) in the patient who is suspect for laryngeal trauma is vital prior to "elective" radiologic evaluations.
- When possible, awake transnasal flexible laryngoscopy is a vital tool in the evaluation of the injury.
- Lacerations of the cervical esophagus or pharynx may occur, primarily with penetrating injuries, and need to be ruled out. Failure to recognize and treat them can lead to serious infectious complications. Depending on the circumstances, evaluation with either contrast radiographic studies or endoscopy is appropriate.

Preoperative Period

History

- The nature of the trauma is pivotal to assessment of laryngeal trauma.
- When evaluating patients with penetrating trauma, it is important to know the circumstances of the attack: factors such as angle of penetration, types of bullet and weapon, and distance of attack are all important to estimate the degree of trauma.
- Factors that may significantly affect subsequent patient care include patient age, mechanism of injury, velocity of injury, and cutaneous penetration.

- The integrity of the airway must be initially assessed. Cyanosis and stridor are indications for immediate intervention. Intubation of the acutely traumatized airway may be dangerous or impossible. Tracheostomy or, under some circumstances, cricothyrotomy should be initiated.[3]
- When the status of the cervical spine is either suspect or uncertain, manipulation of the neck and positioning of the patient for tracheostomy may be difficult and imprudent.
- Under extreme circumstances, insertion of a large-bore needle directly through the cricothyroid membrane or into the trachea with administration of oxygen may be lifesaving and "buy time" for definitive airway intervention.
  - Patients with laryngeal trauma almost invariably have primarily inspiratory obstruction owing to collapse of the soft tissues during inspiration.
  - Oxygen delivered directly into the trachea may be expired through the injured larynx in most patients.
  - Concurrent intrathoracic injury, including pneumothorax, fractured ribs with a flail chest, or a pulmonary contusion, may be the cause of respiratory distress and must be ruled out.

Physical Examination

- The principles (airway, breathing, circulation) of trauma care must be recalled and be kept primal.
- Even with trauma limited to the head and neck, the integrity of the cardiovascular system, potential for intracranial injury, and status of the cervical spine must always be assessed as an initial step of management.
- Airway assessment
- Cranial nerve assessment
- Flexible laryngoscopy, when possible, is a vital aspect of the physical examination to assess airway patency, mucosal integrity, and vocal fold motion.

- Dysphonia, hoarseness, dysphagia, or odynophagia in the setting of blunt trauma to the neck must be considered evidence of severe laryngeal injury until proven otherwise.
- The patient suspected of having trauma of the larynx must have an airway assessment (ideally, flexible laryngoscopy) prior to being sent out of the emergency department for radiologic testing.
- The finding of cervical subcutaneous emphysema warrants a presumptive diagnosis of a ruptured viscus.[6] It is incumbent on the emergency team to identify the injured area and make plans for subsequent management.
- The potential for injury to cranial nerves must be considered.
  - Neuropathy in the face of a sharp or penetrating injury is an indication for nerve exploration and neurorrhaphy as needed at the time of surgical exploration.
  - Neurorrhaphy may result in synkinesis, but some authors have reported useful return of motion or at least tone.[7]
- The potential for vascular injury must be considered. An expanding hematoma or continuing hemorrhage from an open wound is an indication for immediate operative exploration.
  - The presence of a bruit may be one indication of such an injury. The value of close collaboration with a vascular surgery team is critical.
- When circumstances permit, a careful physical examination followed by directed imaging studies will facilitate subsequent treatment planning and intervention.
- In one study of patients with laryngotracheal injury, the most prevalent findings on physical examination were subcutaneous emphysema (53%), hoarseness (47%), neck tenderness (27%), and stridor (20%).[8]
- Physical examination should include assessment of the airway and voice.
  - Dysphonia or hoarseness suggests laryngeal injury.
- The soft tissues of the neck should be carefully observed and palpated.
  - The loss of the prominent contours of the thyroid cartilage and cricoid ring may be significant observations.

- Point tenderness should lead to suspicion of a fracture.
- Soft tissue abrasion and ecchymosis help confirm the severity and direction of injury.
- The presence of a mass often indicates vascular injury.
- Soft tissue emphysema indicates perforation of an air-containing viscus.

- Examination of the oral cavity and oropharynx should be supplemented by direct visualization of the larynx and hypopharynx. This can be undertaken with either a rigid telescope or flexible laryngoscopy. The observer should note soft tissue disruption, lacerations, edema, or ecchymosis.
- Patency of the airway and vocal fold function should be ascertained.
  - Shortening of the anteroposterior diameter of the glottis is an indication of fracture and subluxation of the thyroid cartilage.
  - The arytenoid cartilage may be dislocated.
- Traumatic separation of the larynx from the trachea can occur even in blunt injuries and is frequently associated with bilateral vocal cord paralysis.

Imaging

- The airway must be secure. Flexible laryngoscopy must be done prior to any imaging.
- Cervical spine imaging is primal for most patients suspected of potential laryngeal trauma.
- Angiography or computed tomography (CT) angiogram should be done when vascular injury is suspected.
- Fine-cut CT scan of the larynx with contrast (coronal and axial) (Figs. 8.4 to 8.6)
- Presence or absence of laryngeal fracture
- Laryngeal fracture displaced or nondisplaced
- Esophagram should be considered for penetrating trauma near the

esophagus.

Indications

- Displaced laryngeal fracture
- Foreshortened vocal fold
- Exposed cartilage
  - Arytenoid
  - Thryoid
  - Cricoid
- Narrowed airway due to cricoid fracture

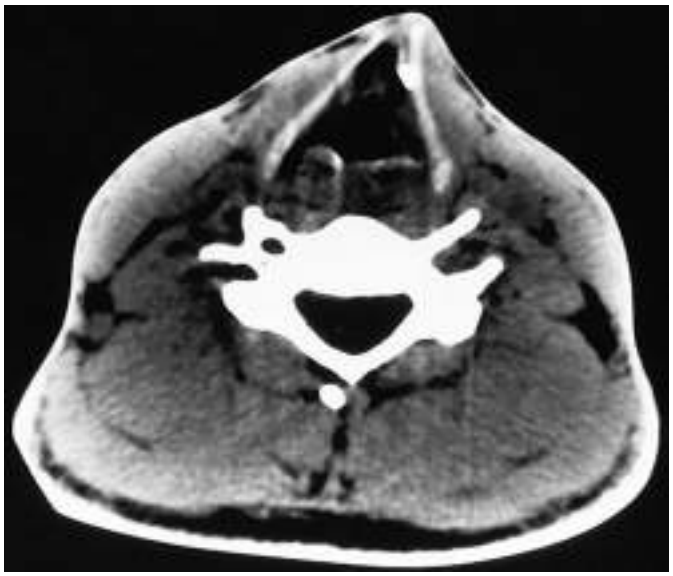

FIG. 8.4 Computed tomography scan shows diffuse subcutaneous emphysema. Asymmetry of the laryngeal framework suggests a fracture of the larynx.

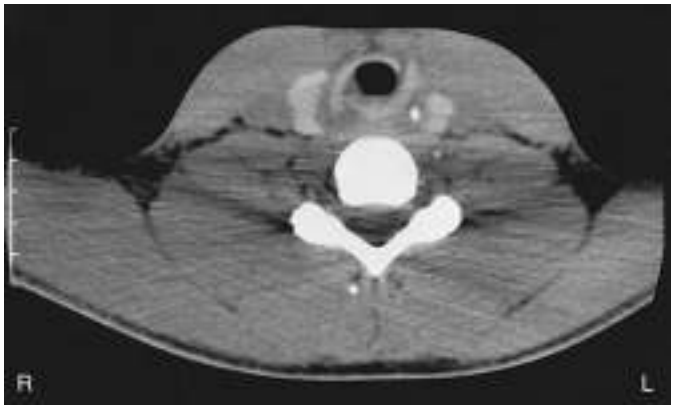

FIG. 8.5 This telescoping fracture of the cricoid cartilage was the result of strangulation.

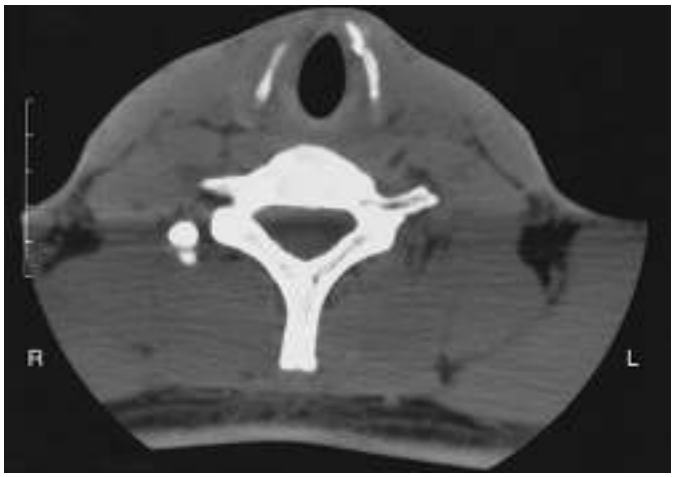

FIG. 8.6 Minimal displacement of the thyroid cartilage demonstrated on computed tomography scan.

- Displaced fractures or soft tissue disruption almost always requires surgical exploration and repair.
- Nondisplaced fractures should be treated only when obvious symptoms arise from the fracture.
- With soft tissue disruption, interval tracheotomy may need to be performed. Early exploration invariably results in easier reduction of cartilaginous injury and more accurate soft tissue repair.[9] Delay in the performance of the procedure leads to scarring, edema, local infection, and distortion of tissues that may result in a suboptimal outcome.
- When possible, laryngeal exploration within 24 to 48 hours is ideal if

the patient's general condition permits.

Contraindications

- Unstable from a cardiovascular perspective
- Severe neurologic trauma
- Presence of vascular trauma

Preoperative Preparation

- Cervical spine clearance
  - Radiologic
    - Functional
- Cardiovascular clearance
- Neurosurgical clearance
- Trauma surgeon assessment is complete
- Coordination of surgical procedures and sequence of repairs between different surgical teams/specialties

Operative Period

Anesthesia

- The first initiative in the management of patients who have trauma to the laryngotracheal complex is to establish a secure and safe airway.
- Under many circumstances, this is the most challenging and dangerous aspect of the entire procedure. The most experienced members of both the surgical and anesthetic teams must be present at this time. Delegation of this aspect of the case to the junior members of the team is a serious error in judgment.
- When preoperative assessment has indicated significant disruption of the laryngotracheal anatomy, an airway must be secured with a

tracheostomy. When time permits, we prefer a tracheostomy between the second and third or third and fourth tracheal rings rather than cricothyrotomy. If a cricothyrotomy is performed, it should be changed to a tracheostomy if it will be needed for more than 7 days.

- The presence of a fracture of the cervical spine must be ruled out before any airway or endoscopic procedure in which the head is moved. If it cannot be ruled out, the safest choice is tracheostomy without extending the neck.

Positioning

- Supine
  - If patient is not in cervical spine precautions
    - Neck flexion
    - Head extension
- Head of the bed is elevated 15 degrees, which reduces intraoperative edema

Perioperative Antibiotic Prophylaxis

- No antibiotics are indicated if there is no mucosal disruption.
- If there is mucosal disruption, guidelines for clean-contaminated surgery should be followed.

Monitoring

- Routine anesthesia monitoring
- Muscle paralysis is required for direct laryngoscopy and helpful for the exploration of laryngeal fractures.

Instruments and Equipment to Have Available

- Direct laryngoscopy
- Microlaryngoscopy
  - Endoscopic suture equipment
  - Endoluminal stent (Montgomery laryngeal stent)
- Esophagoscopy (rigid)
- Bronchoscopy (rigid)
- Tracheostomy set
- Small miniplate system (midface, 1.0 to 2.0 mm)

Key Anatomic Landmarks

- Patent airway
  - Glottic
  - Subglottic
  - Tracheal
- Esophageal integrity
- Tracheal integrity
- Arytenoid position and motion to palpation
- Anterior commissure

Prerequistive Skills

- Direct laryngoscopy
- Microlaryngoscopy
- Laryngeal framework surgery
- Laryngofissure surgery
- Tracheostomy

Operative Risks

- Loss of airway during the induction of general anesthesia
- Separation of laryngotracheal complex with intubation
- Injury to recurrent laryngeal nerve(s)
- Incomplete reduction of laryngeal fractures
- Inadequate mucosal coverage

Surgical Techniques

- Following establishment of a secure airway, diagnostic endoscopy is almost always indicated. Again, the cervical spine must be "cleared" before endoscopic manipulation.
- The cervical esophagus and the larynx should be examined.
- Cartilage displacement without significant mucosal disruption may be successfully managed without formally entering the airway.
- Significant injury to the laryngeal skeleton with soft tissue disruption requires a direct approach that allows for soft tissue repair and reduction of the laryngeal fracture.
- The choice of incision must consider the need for exploration and repair of concurrent injuries, as well as the position of coexistent lacerations.
  - When a procedure is to be limited to the laryngotracheal complex, a transverse incision may be sufficient.
  - A superiorly based apron flap is appropriate. The inferior aspect of the apron will be the site of the tracheostomy.
  - The strap muscles are separated, allowing direct observation of the site of injury.
  - Fractures may be reduced by using small elevators and hooks, taking care to avoid further damage to the cartilaginous structures and underlying mucosa.
- When exploration of the mucosal surfaces is required, efforts should be made to place the cartilage incision directly through the midline at the level of the glottis, even if another paramedian fracture is present.

- This is facilitated by incising the mucosa horizontally at the cricothyroid membrane, then cutting superiorly under direct visualization.
- Entering the anterior commissure from either side is a serious technical error that will adversely affect the outcome of the repair. Mucosal repair then is undertaken using fine absorbable sutures. Attachment of the true vocal cord to the anterior commissure must be ensured (Fig. 8.7).
- Use a fine nonabsorbable suture to fix the anterior-most portion of the vocal cord to the anterior commissure.
  - If available, the outer perichondrium thyroid cartilage can be used. Soft tissue avulsion injuries are unusual, so that repair is similar to assembling a puzzle.
- Lacerations and flaps can be repaired and the anatomy restored. Rarely, denuding injuries are close to one another, especially with penetrating injuries; these may result in scar contracture and subsequent stenosis, so replacement of lost mucosa with mucosal grafts (typically buccal mucosa) or flaps and stenting may be required.

- Stents are typically soft and require stabilization with nonresorbable sutures passed through buttons. Wire tends to break and should be avoided.

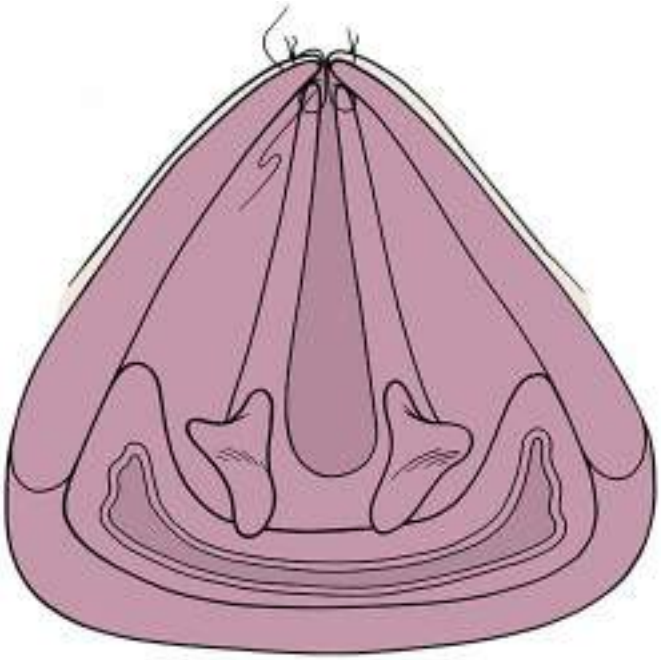

FIG. 8.7 When laryngofissure is used to expose the larynx, the surgeon must ensure that the anterior commissure is fixed at the completion of the case. This is best done by using fine nonresorbable suture.

- The use of stents in the lumen is controversial since the presence of a foreign body carries with it the potential for further trauma to the mucosal surfaces of the laryngotracheal complex.
- This potential disadvantage must be weighed against the need to support cartilaginous and soft tissue repairs. It is important to clearly distinguish the functional difference between a stent and a keel.
- A stent is designed to support 360 degrees of the airway, thereby providing support to the cartilaginous framework and mucosa. This is best thought of as "internal support" and is indicated when the injury and external framework repair will not provide adequate support, especially in an anteroposterior dimension.
- One should consider using female stents for males and child stents for females. Stents are removed within 2 to 4 weeks.
- In contrast, a keel is designed to keep the opposing surfaces of the two vocal folds from contracting, thereby allowing the surface to fully mucosalize to prevent web formation (Fig. 8.8).

- The presence of the keel inserted through a laryngofissure may lengthen the anteroposterior dimension of the larynx. The need for a keel to prevent webbing at the anterior commissure in patients with significant injury to the true vocal cord is far less controversial.
- Insertion of a keel allows migration of mucosa anteriorly and prevents the formation of an anterior commissure web.
- Repair of the cartilage must be meticulous and may be undertaken with nonresorbable suture, wire, or miniplating systems (Figs. 8.9 through 8.12).
- This is done with using small plates to repair injuries to the thyroid and cricoid cartilages.[10]
- Resorbable miniplates that are malleable in hot water are also available.
- The surgeon must be certain that the screws are properly sized such that they do not penetrate the mucosal surfaces. Younger patients may have nonossified cartilage, and great care must be taken to avoid stripping the screw threads. Self-drilling, self-tapping screws are less likely to strip.

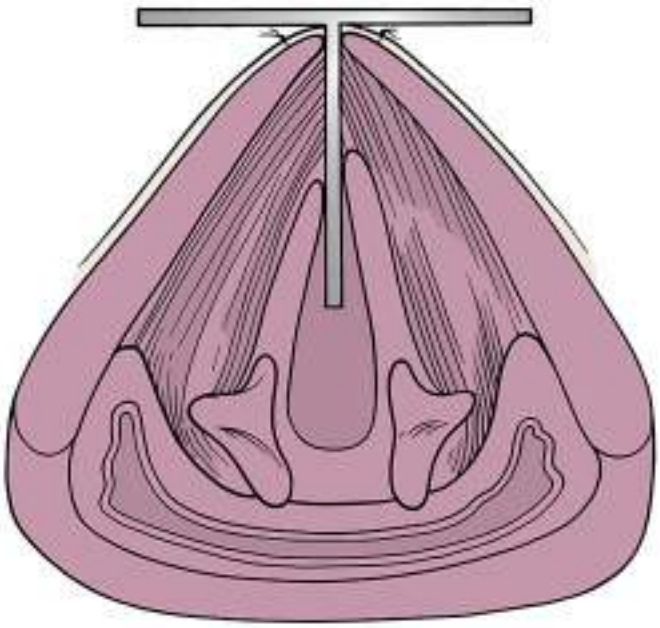

FIG. 8.8 The use of a keel is intended to allow the injured surface of the vocal cord to re-epithelialize to the anterior limit of the keel, thereby avoiding development of a side-

to-side web.

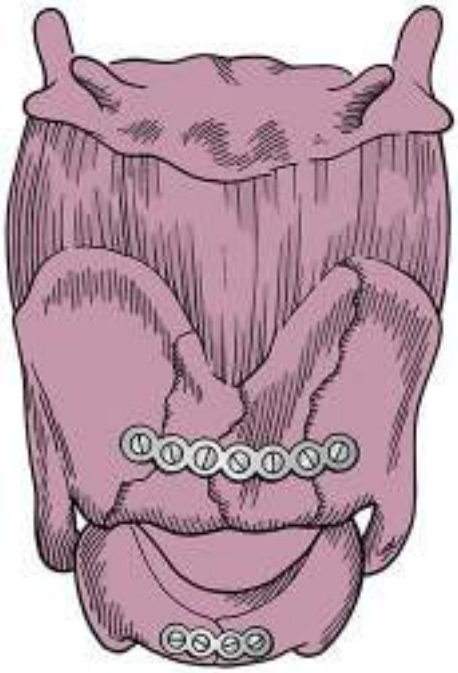

FIG. 8.9 This schematic demonstrates how miniplates can be used to repair fracture of the thyroid or cricoid cartilage.

- Supporting the framework in an anatomic position often requires overcorrection of the thyroid cartilage because the natural vector of force tends to spread the alae, thereby shortening the anteroposterior dimension of the larynx. Rigid fixation of the laryngeal framework, in some cases, may prevent the need for stenting.
- Cricoid fractures can be elevated and either wired together or to a microplate.
- Soft tissues are returned to the anatomic position, and the wound is closed in layers.

FIG. 8.10 Miniplates, with appropriate length screws, are ideally suited to repair and stabilize cartilage fractures.

FIG. 8.11 Complex fractures may require more than one plate for fixation.

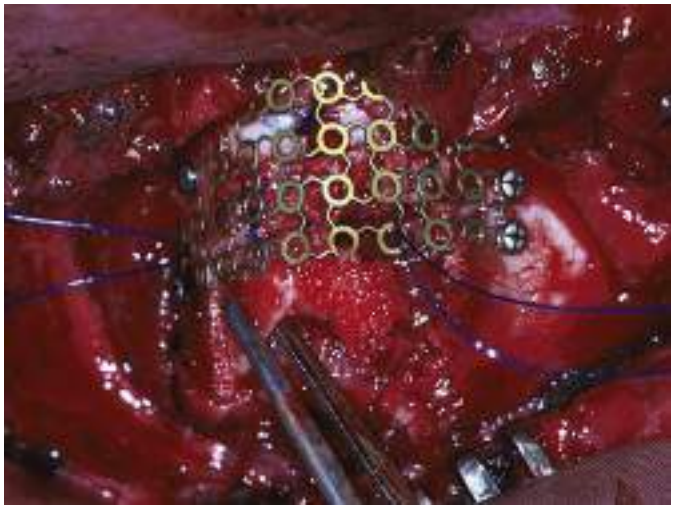

FIG. 8.12 Shattered laryngeal cartilage is supported by mesh framework. A Montgomery stent is fixed with translaryngeal-transcutaneous sutures.

- A passive drain (e.g., Penrose) should be used because a watertight mucosal closure is rarely possible. Accordingly, use of a suction drain is imprudent in that it will aspirate mucus into the wound.
- If the skin incision incorporates the tracheostomy, efforts must be made to seal the tracheotomy wound from the rest of the wound by approximating the subcutaneous tissues of the flap to the strap muscles. Use of a compressive dressing may be ill advised, especially in the face of cartilage injury. The administration of perioperative prophylactic antibiotics that are effective against oral flora is indicated.

Common Errors in Techniques

- Not providing complete mucosal coverage, which will result in granulation tissue formation and severe scarring
- Incomplete reduction of laryngeal fracture(s) resulting in foreshortened vocal fold and/or vocal fold level mismatch
- Not providing "internal" support for the severely injured laryngeal framework, which results in laryngeal stenosis that may not be able to ever be properly restored

Postoperative Period

Postoperative Management

- Patients undergoing surgery for laryngeal trauma should be observed postoperatively in an acute care setting.
- Routine use of oximetry is advisable.
- Nothing is given by mouth in the acute period.
  - In the face of injury to the hypopharynx or esophagus, the patient may be fed through a nasogastric tube until edema and pain have resolved enough to permit oral feeding.
  - Patients with injuries limited to the laryngotracheal complex can frequently be fed by the third or fourth postoperative day.
- Routine tracheostomy care includes the use of humidified air delivered to the tracheostomy with a tracheostomy mask.
  - A T-tube connector should be avoided because it may torque the tracheostomy, producing unnecessary damage.
  - The nursing service should begin regular tracheostomy care with suctioning and cleansing of the inner cannula.
- The neck plate of the tracheostomy tube should be sutured to the cervical skin. Ties around the neck are used as reinforcement.
- Recovery room and intensive care personnel must be advised of the nature of the injury. If intubation is not possible, these personnel, especially, must be briefed on the management of accidental tube displacement.
- Tube reinsertion can be facilitated by the placement of traction sutures through the tracheal ring above and below the tracheotomy site. These sutures are taped to the skin during the postoperative period.
  - The placement of a fresh tracheostomy tube is facilitated if the patient can be placed in a head-extended position.
  - Direct visualization of the tracheostomy site facilitates proper placement of the tube.

- Blind insertion of the tube into the tracheostomy site may lead to placement in the peritracheal soft tissue anterior to the trachea, with subsequent efforts at ventilation associated with a high resistance and the development of subcutaneous emphysema or pneumothorax.
- This disastrous circumstance can be prevented only by placing the tracheostomy cannula into the lumen of the trachea. Immediate access to proper lighting, suction, retraction instruments, and small-caliber replacement tubes may facilitate management under emergent situations.

- The tracheostomy tube can be removed when the airway is stable and the glottis is competent to prevent aspiration.
- Test for glottic competency by deflating the cuff of the tracheostomy tube.
  - Aspiration is an indication that the glottis is incompetent, and the continued use of a cuffed tracheostomy tube is necessary.
  - Continued cough may be a more subtle indication of aspiration.
- The adequacy of the airway can be ascertained through direct visualization with flexible endoscope.
  - The airway can be functionally assessed for integrity by changing the tracheostomy to a smaller uncuffed tracheotomy tube.
  - The tube is then plugged and the patient observed for respiratory distress.
  - Patients who tolerate the use of a plugged tracheostomy tube during a 24-hour day may be safely decannulated.
  - The tracheostomy site is allowed to heal by secondary intention.
- It may be advisable to prepare patients with significant laryngotracheal trauma for home tracheostomy care and to discharge them for subsequent follow-up and decannulation as an outpatient.

Complications

- Accidental decannulation may be life threatening in the case of acute

repair of a laryngotracheal injury. This is especially true in patients in whom a stent has been inserted. Prevention is the first principle in the management of this complication.

- Failure to reduce a significant laryngeal fracture may result in permanent dysphonia.
- Failure to establish normal contour of the thyroid cartilage will result in poor voice and often requires rigid fixation.
- Failure to observe and document posttraumatic injuries may lead to patient dissatisfaction.
- An inadequately secured tracheostomy tube may lead to obstruction of the airway.
- Laryngeal stents and keels may obstruct the airway if poorly secured.
- Mucus or saliva coming from the drain is an indication of wound dehiscence and a fistula.
  - The drain should be maintained until soft tissues have had an opportunity to seal.
  - This usually takes 7 to 10 days, following which the drain can be advanced and the fistula tract will close.
  - Antibiotics may be administered to prevent the development of systemic sepsis.
  - Premature removal of the drain may result in a subcutaneous collection of fluid with subsequent elevation of the cervical skin flap.
  - Collections require opening of the wound and reinsertion of a drain.
- The most significant long-term complication of laryngotracheal repair is stenosis.
  - All healing tissue goes through a period of wound contracture.
  - Circular wounds are the most likely to lead to stenosis.
  - The medical literature is replete with a menu of secondary reconstructive techniques. Prevention of stenosis through gentle handling of tissue, accurate re-approximation of injured tissue, and judicious use of stents, keels, and other lumen-keepers seems to be the most reliable tactic.

- Long-term stenting may succeed in maintaining a lumen, but it will not prevent stenosis due to scar contracture. Eventual open exploration with adequate grafting may be necessary to create a permanent lumen.

Alternative Management Plan

- Tracheostomy alone may be an option for the critically ill trauma patient who may not survive over other injuries.

Discussion

Evidence-Based Medicine Question

Females have a higher incidence of laryngeal trauma due to their longer and thinner necks compared with men. Yes or No?

Answer: No.

The ratio is approximately 3:1 (male to female) most likely because men participate in more "at-risk" sports and activities.

Editorial Comment

This chapter presents a concise yet comprehensive review of the evaluation and management of laryngeal fractures. As discussed in this chapter, laryngeal fractures are rare events, albeit with potentially lethal complications, due to the loss of airway, and long-term sequelae that affect all functions of the larynx. With the advent of laws mandating the use of safety belts, motor vehicle accidents have been replaced as the most common cause of a laryngeal fracture by violent altercations and sports.

Management of a patient suspected of having a laryngeal injury is geared to correct or prevent acute and future problems. First and foremost, the evaluation of such a patient pivots on establishing or minimizing the risk of losing the airway, and the initial assessment is composed of four main components: clinical assessment, fiberoptic laryngoscopy, noncontrasted CT scan of the laryngotracheal complex, and imaging to rule out concomitant cervical spine, esophageal, or

vascular injuries.

Ascertaining the mechanism of injury is important because it will provide the examiner an idea of the potential magnitude and extent of the injury. By the way of illustration, a patient with a history of a clothesline injury may suffer a partial or complete laryngotracheal separation and recurrent laryngeal nerve avulsion. However, its range of injury and presentation varies widely, with most of these patients dying before adequate assistance can be provided, some surviving after establishing an emergency airway, and less commonly the patient may appear stable but suddenly lose the airway upon extension of the neck. Another example is a patient who has been the victim of a chokehold and who may look unaffected clinically, endoscopically, and by CT scan but may develop significant edema within hours of the event.

Surgical management of patients with laryngeal fractures strives to:

- reestablish the airway via tracheotomy (much preferred over a cricothyroidotomy but the latter perfectly acceptable in an emergency),
- reconstruct the cartilaginous external support (elegantly and most efficiently accomplished with titanium adaptation plates or mesh, although wiring or suture may be used when the former are not available),
- bolster extensive internal reconstruction (using soft stents to support extensive soft tissue repair or grafts),
- repair any other associated injury involving hypopharynx, esophagus, or vessels.

One should note that, although not universally accepted, surgical indications have evolved significantly. Conservative treatment is no longer advocated for patients presenting a complete fracture of the thyroid cartilage (displaced or not) or patients with more than one fracture line through the cricoid. A significant number of these will respectively develop chronic dysphonia or airway compromise as the fracture segments displace with the movement of the laryngeal and neck muscles.

Review Questions

1. Laryngeal trauma in the pediatric population occurs less often than in adults because

   a. In children, there is greater protection of the larynx from the mandible.

   b. In children, the larynotracheal complex has less calcification and thus is less likely to fracture in response to bulk force.

   c. Different seat belt placement for children

   d. Children do not sit in the front seats of cars.

   e. **Both a & b**

2. All of these statements are key aspects of head and neck trauma evaluation, except

   a. Prioritizing the ABCs of trauma care

   b. **Asking the patient to produce a high-pitch voice to evaluate for superior laryngeal nerve injury**

   c. Careful evaluation of the cervical spine

   d. Endoscopic airway evaluation of the nonintubated laryngeal trauma patient prior to sending the patient for radiologic evaluation

3. All of these statements apply to open repair of median and paramedian laryngeal fractures, except

   a. A minimal dissection of soft tissue away from the fracture line

   b. Careful multidimensional re-approximation of major laryngeal fractures

   c. **Exploration of both recurrent laryngeal nerves**

   d. Use an internal stent when the fractures are so severe that there is major loss of the anteroposterior dimension of the larynx

Bilateral Vocal Fold Immobility

Libby J. Smith, and Clark A. Rosen

Introduction

Bilateral vocal fold immobility (BVFI) is an uncommon condition with potentially significant negative effects on breathing and quality of life. Patients usually have symptoms of airway obstruction, such as biphasic stridor and dyspnea, with a normal or nearly normal voice. This is in contrast to patients with unilateral vocal fold immobility, who usually complain of a breathy voice and aspiration. Etiologies of BVFI include immobility from both neurogenic causes (vocal fold paralysis) and mechanical fixation of the cricoarytenoid (CA) joints.

Neurogenic causes of bilateral vocal fold paralysis (BVFP) may be due to (1) iatrogenic injury to the recurrent laryngeal nerve (e.g., thyroidectomy, anterior cervical disc surgery, carotid endarterectomy, esophageal surgery, cardiac surgery, mediastinal surgery), (2) progressive neurologic disorders (e.g., amyotrophic lateral sclerosis, Shy-Drager syndrome, syringomyelia, Guillain-Barré syndrome), or (3) idiopathic causes.

Mechanical fixation of the CA joints causing BVFI may be due to (1) fixation of the CA joint secondary to radiation therapy, rheumatoid arthritis and other connective tissue disorders, benign infiltrative disorders such as amyloidosis, granulomatous diseases; (2) trauma; or (3) posterior glottic stenosis (PGS).

PGS is a common cause of BVFI. It is typically associated with intubation, although extraesophageal reflux disease may be a cofactor. The development of PGS is characterized by progressive airway obstruction, usually 4 to 8 weeks after extubation. Granulation tissue can cover the arytenoid cartilages and interarytenoid cleft. If this is observed, prompt débridement, steroid injection, and antacid treatment may be

associated with less scar tissue formation and consequently less airway stenosis. Laryngeal balloon dilation may also have a therapeutic role in the acute or subacute setting.

Bogdasarian and Olsen developed a classification system for PGS that is useful to characterize the nature and severity of the posterior laryngeal stenosis.[1] The least severe group of patients has an interarytenoid synechiae and posterior sinus tract. The next group includes those with a posterior glottic web that limits movement of the arytenoids, without fixation of the CA joints and no posterior sinus tract. The third group appears similar to the second; however, one CA joint is fixed. The most severe group and the most difficult to treat consists of patients with fixation of both CA joints (Fig. 9.1).

Correctly identifying the cause of BVFI (neurogenic or mechanical) is critical in guiding treatment and shaping the expectations of both the patient and surgeon. The aim of treatment is to improve the airway while minimizing adverse effects on the voice.

Key Operative Learning Points

- Patients with BVFI secondary to mechanical fixation of the CA joints typically have more severe airway restriction and require more aggressive surgical enlargement of the glottis than patients with BVFP.
- Laryngeal electromyography (LEMG) is crucial in determining the presence of neurologic injury and may guide the surgeon in determining the operative side.
- Palpation of the arytenoid, either in the office or in the operating room, to confirm passive motion or immobility is critical information that helps guide treatment.
- Endoscopic techniques have replaced larger, more destructive surgery and have resulted in decreased morbidity.
- Granulation tissue formation is minimized by the use of perioperative antacid medications and the application of mitomycin-C to any mucosal defects.
- Only patients with realistic expectations of the balance between voice and airway improvement should undergo surgery to enlarge the

glottic airway.

- Overly aggressive primary surgery will probably leave the patient with more severe breathy dysphonia and dysphagia than was necessary for airway improvement or decannulation.
- Posterior glottic airway surgery may worsen glottic protection during swallowing, thereby increasing the risk of aspiration.
- BVFP must be differentiated from PGS because the initial surgical options may be different.
- Exposure of arytenoid cartilage during transverse cordotomy may lead to the formation of granulation tissue and the need for further treatment.

Preoperative Period

History

1. History of present illness
   a. What are the patient's symptoms (e.g., dyspnea, dysphonia, dysphagia)?
   b. When did their symptoms begin?
      1) Suddenly: After surgery where the recurrent laryngeal nerve is at risk? Remember that the endotracheal tube (ETT) cuff can also result in vocal fold paralysis, although bilateral paralysis is very rare from ETT cuff pressure itself.
      2) Progressive: Progressively worsening dyspnea 4 to 8 weeks after extubation suggests PGS as the more likely etiology for vocal fold immobility.
2. Past medical and surgical history
   a. Previous surgery where the recurrent laryngeal nerve is at risk. Was hoarseness present after surgery?
   b. Prolonged intubation? One to two days is sufficient to develop PGS in diabetic patients.

c. Neurologic diseases such as stroke or progressive neurologic diseases?

d. Previous external beam radiation to the head and neck region?

e. Rheumatologic diseases? Rheumatoid arthritis can result in CA joint fixation.

Physical Examination

1. Flexible laryngoscopy is the most important part of the examination. It allows for evaluation of vocal fold motion during vocal fold adductory (saying /i/) and abductory (sniffing) tasks.

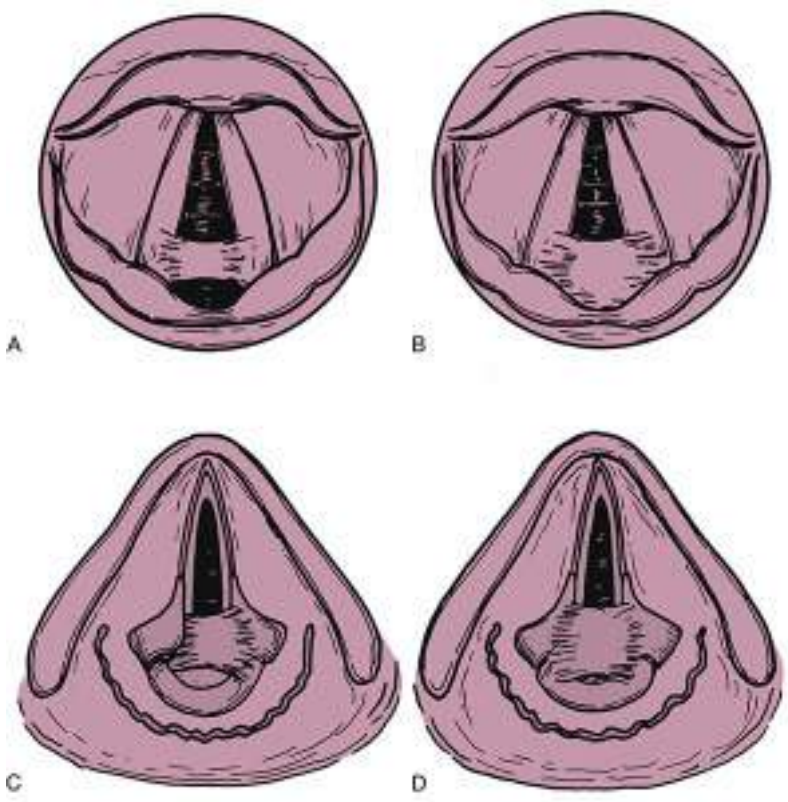

FIG. 9.1 Grading of posterior glottic stenosis.

A, Interarytenoid synechia with a posterior sinus tract. **B,** Posterior glottic web with mobile arytenoid cartilage. **C,** Posterior glottic web with fixation of one arytenoid cartilage. **D,** Posterior glottic web with fixation of both arytenoid cartilages. Modified from Cotton RT, Manoukian JJ: Glottic and

subglottic stenosis. In Cummings CW [ed]: Otolaryngology–Head & Neck Surgery. St Louis: CV Mosby; 1986, pp 2168.

2. Manual palpation of the CA joints, either in the office or in the operating room, can further help detect the cause of BVFI and assist in guiding surgical planning. When both joints are impaired, palpation can determine the CA joint with the least range of motion. This is the optimal side for static, glottic enlargement surgery.

Imaging

1. Imaging studies can be important in evaluating a patient without obvious causes of vocal fold immobility.

2. Enhanced computed tomography (CT) or magnetic resonance imaging (MRI) of the skull base, neck, and upper part of the chest can help identify the site of a lesion in the brainstem, vagus nerve, or recurrent laryngeal nerves, which results in BVFI.

3. Enhanced CT with fine cuts through the larynx may be used to evaluate the CA joint for abnormalities or, in the case of PGS, the extent of stenosis, which may change the type of surgical intervention. Arytenoid subluxation or dislocation may also be identified.

4. MRI of the brain is needed when brain or brainstem causes are suspected, such as stroke or Arnold-Chiari malformation.

Laryngeal Electromyography

1. LEMG of both the thyroarytenoid–lateral cricoarytenoid (TA–LCA) muscle complexes is useful to determine the cause of BVFI.

2. If BVFP is present, there will be evidence of significant neurologic injury, with or without partial recovery. If the neurologic pattern shows a new injury with a chance of recovery, delaying destructive surgery is prudent.

3. The authors advocate that in an attempt to preserve the voice, surgery should involve the vocal fold with the worse neurologic status. This may improve voice outcomes by not altering the vocal fold that has a better neurologic status and thus possibly better muscle tone.

4. Patients with BVFI and PGS, in contrast to those with BVFP, will have normal electromyographic activity of the TA–LCA muscle complexes.

5. LEMG may also suggest a "mixed" etiology of the BVFI—one side neurogenic and the other mechanical.

Swallowing Studies

1. Swallowing studies are crucial in patients who complain of dysphagia. Because the incidence of aspiration is high after many types of surgery to improve the airway, more conservative surgery or tracheostomy may be most appropriate for patients with dysphagia or compromised swallowing ability.

Indications

1. Patients with symptomatic airway obstruction due to BVFI

2. Patients desiring decannulation after tracheostomy to bypass airway obstruction due to BVFI

Contraindications

1. Contraindications to directly treating the laryngeal obstruction of BVFI, other than performing a tracheostomy, are the presence of aspiration or a rapidly progressive neurologic disorder.

2. Relative contraindications include compromised pulmonary status, uncontrolled diabetes, and previous radiation therapy.

3. Unrealistic expectations on the part of the patient are a relative contraindication to treating all types of BVFI.

Preoperative Preparation

1. Patients must understand and accept that to improve their glottal airway, the quality of their voice may be adversely affected. Therefore patients should expect to have worse vocal quality at the expense of an improved airway. Such counseling needs to be frank and well

documented. A patient who is unwilling to accept any decrease in vocal function should be considered for tracheostomy and not glottic enlargement surgery.

2. The patient should understand that multiple procedures may be necessary to optimize the airway with the least potential impact on the voice. This allows the surgeon to enlarge the glottic airway in a staged, conservative fashion, which hopefully will minimize the negative impact on both voice and swallowing.

Operative Period

Anesthesia

1. General anesthesia: The patient's airway is secured by one of the following, depending on the patient's airway restriction, comorbid conditions, the surgery to be performed, and surgeon preference or comfort level.

   a. Laser-safe ETT, if appropriate. A small ETT (i.e., 5.0 or 5.5 microlaryngeal tube) is needed if the ETT is to remain during surgical intervention.

   b. Jet ventilation is also a common modality used for glottal airway surgery. Subglottic jet ventilation with a Hunsaker catheter is effective. Supraglottic jet ventilation through the laryngoscope is possible but is hampered by subsequent laryngeal desiccation and motion from the air puffs. Jet ventilation should only be used by anesthesiologists who are familiar and comfortable with this technique, as there are risks of hypercapnia and pneumothorax.

   c. Intubation with intermittent extubation and subsequent apnea is less commonly used but is a good option for patients being treated with shorter duration procedures, such as dilation.

   d. Tracheostomy provides the most stable airway and leaves the glottis devoid of accessory instrumentation. However, if the patient is without a tracheostomy, the goal is often to avoid it. Possible placement of a tracheostomy at the time of glottic airway surgery needs to be openly discussed with the patient and listed on the surgical consent form.

Positioning

1. Supine: The patient is placed supine, with neck flexion and head extension. A shoulder roll does *not* help achieve this. Rather, the patient's head is placed on a "donut" pillow, and the head of the bed is flexed as needed.

2. If the patient is obese, then a "ramped" position may be needed. Blankets are placed below the patient's head and upper back such that the tragus is in-line horizontally with the manubrium. This helps achieve the proper "sniffing" position required for optimal laryngeal exposure in patients with a larger body habitus.

3. Proper surgeon ergonomic positioning is also important to reduce surgeon musculoskeletal injuries. After laryngeal exposure is achieved, the proper surgeon ergonomic position is achieved by moving the bed angle (usually Trendelenburg, "head down") so the laryngoscope is ~40 degrees off the horizontal plane. The surgeon's neck should be in a neutral position or slightly flexed but never extended. Sometimes lowering the height of the bed is needed to allow for more comfortable placement of the surgeon's arms and hands. Arm rest support while operating is also important.

Perioperative Antibiotic Prophylaxis

1. Perioperative antibiotics are not necessary unless the patient's medical history requires them—for instance, mechanical heart valves or stents.

Instruments and Equipment to Have Available

1. Various sizes of laryngoscopes: The largest laryngoscope that fits the patient's anatomy is best to provide optimal exposure.

2. Standard microlaryngeal surgical tray

3. Rigid telescopes (0-, 30-, and 70-degree; 30 cm length, 5 to 10 mm diameter): These are used to better visualize the extent of lateral extension of the surgical field.

4. Laser: CO_2 laser is the most common type of laser used for glottic airway surgery.

5. Airway dilators: Balloon and Jackson dilators

Key Anatomic Landmarks

1. True vocal folds and arytenoids: Depending upon the position of the arytenoids and true vocal folds, the glottis, which is defined as the space between the vocal folds, may be too small for the patient to breathe without restriction. Scarring between the arytenoids can range from mild to severe, with complete obliteration with scar of the respiratory glottis up to the vocal processes.

2. Cricoid cartilage: The cricoid cartilage is a complete cartilaginous ring located below the true vocal folds. There is no benefit to performing surgery outside the confines of the inner table of the cricoid cartilage.

Prerequisite Skills

1. Microsuspension laryngoscopy

2. Laser certification

3. Balloon dilation

4. Tracheotomy (see Chapter 19).

Operative Risks

1. Airway compromise: Inability to properly secure the airway prior to the start of surgery requires the placement of an emergent surgical airway.

2. Bleeding: Although bleeding is not usually a major concern, there is often increased bleeding experienced during the transverse cordotomy procedure. Defocused laser energy or suction cautery is usually sufficient for hemostasis.

3. Laser airway fire: It is critical that laser safety precautions be followed at all times when using the laser—optimally FiO_2 less than 40%, saline

readily available if case of fire (preferably in a bulb syringe within reach of the surgeon), wet towels over the patient's head (avoiding air pockets under the towels), proper eye protection for the staff, laser-resistant ETT (or wrapped in tin foil) if applicable, and placement of a saline-soaked pledget over the ETT or tracheotomy tube cuff (if applicable). A laser operator is also to be in the room at all times while the laser is in use. All operating room staff must be trained on what to do in case of airway fire —turn off oxygen while removing the endotracheal, Hunsaker, or tracheotomy tube; place saline in the airway; use bronchoscopy to evaluate for injury; and reintubate. These types of laser surgeries should only be performed by surgeons who are comfortable performing airway laser surgery.

Surgical Technique

Surgical treatment of BVFI involves static enlargement of the glottic airway, given that no method exists presently to restore dynamic, purposeful motion of the vocal fold(s). A stepwise approach to create an adequate airway is prudent. The surgeon must integrate the patient's comorbid problems into the surgical decision-making process. In general, patients with rapidly progressive neurologic disorders or other serious comorbid conditions tend to be best treated with a tracheostomy. Most other causes of BVFI can be treated with conservative endoscopic techniques. Transverse cordotomy, medial arytenoidectomy, or a combination of these procedures are ideal conservative options because the airway is enlarged with fewer detrimental effects on vocal quality and possibly swallowing ability than occur with more extensive total arytenoidectomy procedures (endoscopic or open). Total arytenoidectomy creates a larger posterior airway but is more likely to lead to aspiration and a substantive decrease in vocal quality. Endoscopic suture lateralization is useful as a temporary measure when there is no loss of mucosa in the posterior glottis. This procedure can be done with glottal enlargement procedures or a permanent treatment. Treatment of PGS, specifically, may be achieved by endoscopic or open techniques and consists of lysis of the interarytenoid synechiae, creation of a microtrapdoor flap, balloon dilation with steroid injections, or the techniques mentioned earlier. If the patient already has a tracheostomy before arytenoid surgery, it should remain in place until a proper

capping trial for decannulation can be conducted, approximately 2 months after surgery.

Surgical outcomes vary upon the extent of surgery, location of surgery (i.e., arytenoid involvement), and patient factors. Patients with reduced wound healing, such as with diabetes, may have a compromised surgical outcome. The addition of acid suppression, mitomycin-C, and steroids is to improve the outcome, though direct studies of their effects are unclear.

Prognosis of glottic airway enlargement surgery varies, depending upon the type and severity of the clinical situation. A patient with an interarytenoid adhesion usually has an excellent result from lysis of the fibrotic adhesion, usually with no further intervention needed as long as there is no concurrent CA joint fixation. Treatment of patients with BVFP can differ from those with BVFI, because the addition of arytenoid procedures and temporary suture lateralization procedures are viable options, whereas patients with severe PGS have more restricted options of glottal airway surgery (transverse cordotomy, microtrapdoor flap). Healing after these surgeries is effected by the surgery performed and the patient's general health status. If the patient is willing to have reduction in voice quality, and he or she does not have dysphagia complaints, the prognosis of tracheostomy tube decannulation is excellent after this type of surgery. However, sometimes the patient and surgeon decide that further glottal airway opening at the detriment of voice and swallowing quality is not acceptable. In those cases, the patients must be willing to accept long-term tracheostomy for airway management.

1. Palpation of the CA joint

   a. Place a sturdy instrument adjacent to the vocal process and push laterally. Both CA joints are evaluated to compare the degree of effort required to displace the vocal process and the speed of medial tissue recoil. If one CA joint displays better movement, surgery is initially performed on the contralateral (worse) side. If the interarytenoid region moves during this maneuver, then PGS is present.

      1) If the patient is awake and being evaluated with flexible laryngoscopy with the addition of topical anesthesia, an instrument such as an Abrams cannula can be used.

2) If the patient is being evaluated under general anesthesia, a blunt laryngeal elevator or large cup forceps can be used to palpate the joint. During CA joint palpation under general anesthesia, the laryngoscope must be placed above the arytenoid to avoid artificial reduction in CA joint movement.

2. Tracheostomy

a. This is a reasonable option for patients with BVFI, especially those with dysphagia or rapidly progressive neurologic disease, as well as for patients who do not want decreased vocal function (see Chapter 19).

3. Lysis of interarytenoid synechiae

a. When a bridge of scar tissue exists between the vocal processes with the presence of a posterior sinus tract, the bridge of scar tissue can be excised.

b. Suspension laryngoscopy with exposure of the posterior glottis is carried out after the airway is secured.

c. The mucosal integrity of the posterior glottis is assessed with the aid of 0, 30, and 70-degree angled telescopes.

d. The interarytenoid bridge of mucosa is excised using laser or cold knife technique.

e. Mitomycin-C can be applied to the defect in the mucosa to reduce the risk of reformation of synechiae.

f. Release of the bridge should restore at least some passive mobility of the arytenoid.

g. If patients do not achieve long-term improvement with this procedure, injury to the CA joint (fixation) is likely. A more aggressive static glottic enlargement procedure is then necessary.

h. Balloon dilation of the posterior larynx may further assist after the lysis of the synechiae.

4. Transverse cordotomy

a. Described by Dennis and Kashima[2] in 1989 as a more conservative surgery than total arytenoidectomy

b. The patient is intubated with a 5.0 or 5.5 laser-safe ETT if a pre-

existing tracheostomy is not present.

c. Usually, the ETT can be placed in the posterior glottis to allow exposure of the vocal process on the side to be operated. Alternatively, the ETT can be placed anterior to the laryngoscope, or jet ventilation can be used.

d. The laryngoscope is suspended and angled toward the operative side.

e. CO_2 laser precautions are implemented.

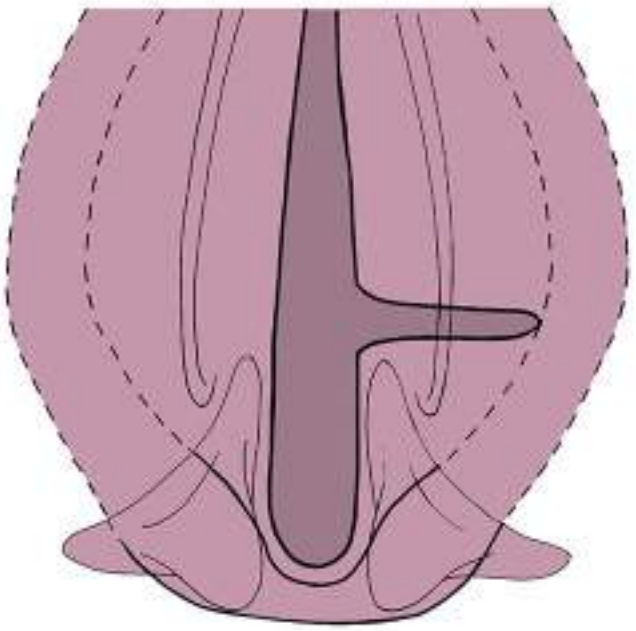

FIG. 9.2 CO_2 laser incision extending laterally to the cricoid ring for transverse cordotomy.

f. Typical CO_2 laser settings depend upon the type of CO_2 laser, but in general, the least amount of energy needed to complete the cordotomy is recommended. For example, CO_2 laser setting could be 4 W, superpulse, with a small (0.25 to 0.4 μm) spot size to minimize collateral thermal damage.

g. After confirming the location of the vocal process, an incision is made just anterior to it. Care is taken to not expose the arytenoid cartilage in order to avoid the formation of a granuloma. The cordotomy extends across the entire width of the true vocal fold,

extending to the inner table of the lateral cricoid cartilage. This completely separates the vocal fold from the vocal process/arytenoid and allows scarring to retract the muscular portion of the vocal fold anteriorly and laterally, thus leaving a triangular-shaped glottal airway.

h. Endoscopic evaluation with a 30-degree telescope should confirm that the cordotomy is flush with the lateral wall of the cricoid cartilage.

i. The incision may also include the medial 3 to 4 mm of the false vocal fold (Fig. 9.2), if needed for proper visualization.

j. Hemostasis is achieved with the laser, suction cautery, bipolar cautery, and/or epinephrine-soaked (1:10,000 concentration) pledgets. There is often increased bleeding near the lateral extent of the cordotomy, but cordotomy beyond this area is needed to optimize the postsurgical glottic opening once it has healed.

k. The application of topical mitomycin-C (0.4 mg/mL) to the wound for 5 minutes or for 2 minutes repeated once is an optional adjunctive treatment in an attempt to decrease fibroblast formation and thus scar tissue at the operative site.

l. Laryngotracheal anesthesia with 4% topical lidocaine is used to minimize postoperative laryngospasm.

5. Medial arytenoidectomy

a. Crumley (1993) described a more conservative version of total arytenoidectomy.[3]

b. The patient is intubated with a laser-safe 5 or 5.5 ETT.

c. CO_2 laser precautions are implemented.

FIG. 9.3 Defect after medial laser arytenoidectomy.

d. CO_2 laser ablation of the most medial 2 to 3 mm of the body of the arytenoid cartilage results in enlargement of the posterior glottic airway. The ablation begins posterior to the vocal process and at least 2 mm anterior from the posterior commissure (Fig. 9.3). If the posterior mucosa is disturbed, then PGS can occur. The amount of arytenoid cartilage obliterated is guided by the degree of airway compromise and tissue reaction.

e. This surgery is not possible to complete in patients with severe PGS, since the medial aspect of the arytenoids is obscured with scarring.

f. Hemostasis is achieved with the laser and/or epinephrine-soaked (1:10,000 concentration) pledgets.

g. Application of mitomycin-C is optional.

h. Laryngotracheal anesthesia with 4% topical lidocaine is used to minimize postoperative laryngospasm.

6. Transverse cordotomy with medial arytenoidectomy

a. After failure of either transverse cordotomy or medial arytenoidectomy, the surgeon may choose to proceed with revision glottal surgery incorporating both of these procedures. This produces a larger glottal defect, though not as aggressively as an endoscopic total arytenoidectomy (discussed later).

b. Since this surgery results in a greater glottal airway, increased

dysphonia and swallowing difficulties are expected, and the patient should be counseled appropriately.

7. Total arytenoidectomy

   a. The classic total arytenoidectomy procedure was described by Ossoff et al. in 1983.[4] This surgery is usually reserved for patients with BVFI who have failed with more conservative surgeries (transverse cordotomy, medial arytenoidectomy). A more adverse effect on voice quality and swallowing is expected.

   b. The same initial steps are taken as with the medial arytenoidectomy procedure. CO_2 laser ablation of the entire body of the arytenoid is achieved by removing cartilage until the defect is flush with the wall of the cricoid ring (posteriorly and laterally; Fig. 9.4). This can be verified with a 70-degree telescope. There is no reason from an airway standpoint to remove more of the arytenoid than what is within the cricoid ring, as that would not improve the glottal airway.

   c. Modified versions of this surgery have been developed, with creation of arytenoid tissue defect after elevation of a lateral mucosal flap. The flap is sutured laterally after laser tissue ablation, resulting in a mucosal lined triangular defect in the posterior glottis.

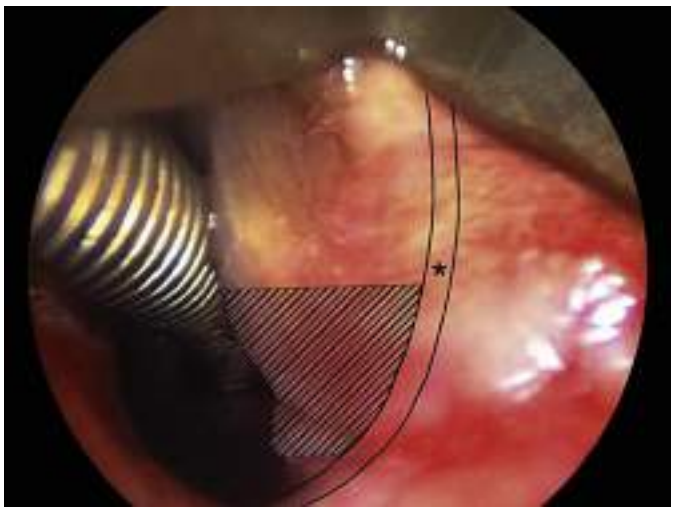

FIG. 9.4 Total arytenoidectomy results in the removal of arytenoid cartilage *(shaded region)* within the cricoid ring *(asterisk)*.

d. The laser and epinephrine-soaked pledgets (1:10,000 concentration) are used to achieve hemostasis.

e. Application of mitomycin-C is optional.

f. Laryngotracheal anesthesia with 4% lidocaine is used to minimize postoperative laryngospasm.

8. Open arytenoidectomy

a. Reserved for patients in whom endoscopic procedures have failed or when adequate laryngeal exposure is impossible due to anatomic limitations

b. A laryngofissure (see Chapter 69) or a lateral approach with resection of the posterior rim of thyroid cartilage and elevation of the piriform sinus mucosa may be used to expose and remove the arytenoid cartilage. However, with the advances in endoscopic techniques, these approaches are rarely necessary.

9. Posterior scar—microtrapdoor flap

a. Dedo and Sooy[5] first described an endoscopic flap technique to treat PGS.

b. A CO_2 laser or knife is used to make an incision over the less mobile arytenoid, from the vocal process into the interarytenoid cleft and extending up to the contralateral CA joint and for 4 to 5 mm below the vocal folds in the interarytenoid cleft.

c. A mucosal and submucosal flap are elevated from the underlying scar. The scar tissue is excised or vaporized until mobility is restored or the limits of dissection are met.

d. The flap is repositioned, and sutures or fibrin glue may be required to secure the flap in proper position.

e. If joint mobility is not regained, additional glottic enlargement procedures may be necessary, as described earlier.

f. Placement of an endolaryngeal stent may be necessary in patients who require revision surgery.

g. Epinephrine-soaked pledgets (1:10,000 concentration) provide hemostasis.

h. Mitomycin-C may be applied to the exposed CA joint.

i. This procedure is not often used.

10. Temporary/reversible procedures

a. Endoscopic suture lateralization

1) This procedure is based on the technique of Lichtenberger and Toohill.[6]

2) Temporizing measure in patients with early symptomatic BVFP who have an uncertain prognosis for vocal fold motion recovery

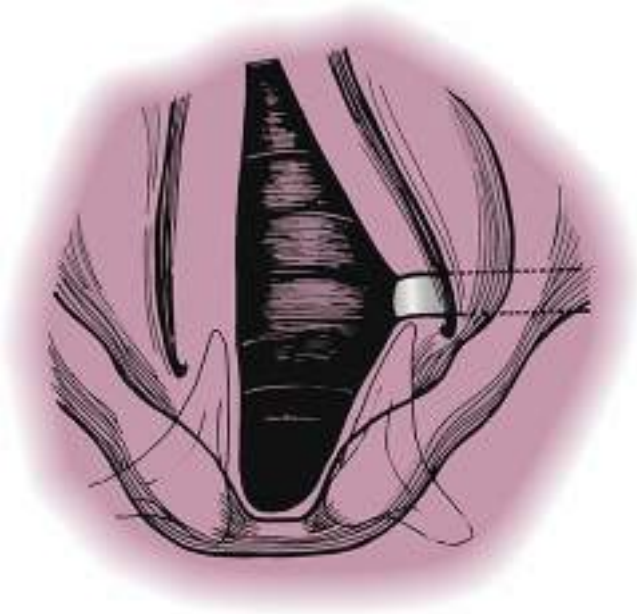

FIG. 9.5 Sutures are placed around the vocal fold and sutured over a button on the skin, thereby lateralizing the vocal fold.

3) Contraindications to endoscopic suture lateralization are recent trauma to the posterior glottis from an ETT or if the patient is currently intubated.

4) Under microscopic or telescopic visualization, an endo-extralaryngeal needle carrier device is loaded with 2-0 Prolene suture. The needle is driven through the skin and larynx, just anterior and below the vocal process of the most medialized vocal fold. The suture is secured outside the neck. The proximal end of the same suture is fed through the free needle designed to be used with the needle carrier. This needle is then driven

through the larynx slightly superior to the vocal fold. Traction is placed on these two sutures to lateralize the vocal fold.

5) The sutures are tied over a silicone button on the skin or over the strap muscles.

6) This step is repeated, with placement of another lateralization suture 1 to 2 mm anterior to the first suture (Fig. 9.5).

b. Laryngeal botulinum toxin injections

1) Botulinum toxin injection into the TA/LCA muscle complex(s) results in the vocal fold becoming more flaccid. This may result in a small increase in the glottal airway during respiration. This technique has been shown to help reduce symptoms of dyspnea in patients with new onset BVFI. However, it is only meant to be a temporary treatment and is thus not often necessary.

c. Glottal dilation

1) The role for laryngeal balloon dilatation for the posterior glottis is not well established. However, Belafsky et al. explored a unique balloon dilatation technique in the treatment of upper esophageal stenosis.

2) Anatomic studies of the exact geometric shape of the upper esophageal sphincter led to an altered balloon dilatation configuration resulting in improved dilatation results. To apply the same concept to laryngeal dilatation, one must recognize that the glottis has the shape of an upside-down ice cream cone.

3) To apply affective balloon dilation to the posterior commissure, an anterior glottis spacer is required. This anterior laryngeal spacer (e.g., Jackson dilator) will (1) prevent trauma to the membranous vocal folds and (2) direct the dilatory effect of balloon dilatation to the posterior commissure.

4) This procedure maybe useful in acute and subacute settings of PGS.

5) This procedure is often done in combination with steroid injections placed around the CA joints and posterior commissure. It can be repeated approximately every 3 to 4 weeks, for two to three different treatment sessions.

Common Errors in Technique

1. Improper airway management: Performing surgery on the glottal airway requires constant communication with the anesthesia team. These cases should be discussed prior to the patient arriving in the surgical suite. All possibilities of airway management must be candidly discussed and prepared for, including emergency tracheotomy. This is one of the most important components of the surgery, since "loss of the airway" is potentially catastrophic.

2. Improper use of the laser: It is critical that there is a laser operator present when the laser is in use. The surgeon needs to feel comfortable with using the laser, knowing appropriate settings, laser safety precautions, and what to do in the case of a laser airway fire. If an airway fire occurs, the outcome is poor.

3. Not using a large laryngoscope and not angling it toward the operative side: If the visualization is not optimal, then the surgeon may think he or she has adequately opened the glottis, although he or she has not. This problem is also mitigated by using angled telescopes periodically throughout the surgery to judge the progress of the procedure.

Postoperative Period

1. Postoperative management

   a. Patients are usually observed for 24 hours postoperatively for airway difficulties. However, patients with an established tracheostomy may be suitable for outpatient surgery.

   b. Voice rest is not necessary.

   c. Perioperative antacid medications are recommended in order to decrease exposure of the healing surgical site to potential acid reflux contents. Treatment of reflux continues until healing is complete.

   d. Pain medications are sometimes required.

   e. Antibiotics are used when deemed necessary by the surgeon.

   f. Patients will experience significant worsening of their voice in the immediate postoperative period because of the large posterior glottic

defect and robust edema of the vocal folds seen after many of these surgeries. The quality of the voice should improve over the next 2 to 3 months, at which point it stabilizes.

g. Frequent follow-up examinations will not only warn the surgeon of granulation tissue formation, which requires medical and/or surgical treatment, but also serve to reassure the patient.

h. A small posterior glottic defect is expected when healing is complete.

i. Decannulation, after a successful capping trial, is deferred until healing is complete and the airway is adequate, at least 6 to 8 weeks after surgery.

2. Complications

a. Granulation tissue (usually after arytenoid surgery)

b. Restenosis of the surgical site

c. Dysphonia: Incomplete glottal closure during phonation is an expected "trade-off" for the improved glottal airway.

d. Dysphagia: The risk of dysphagia after these surgeries exists due to the inability to protect the glottis during the pharyngeal phase of swallowing. Likewise, due to the reduced glottal closure (which is needed for improved breathing), cough efficiency is reduced. This places already at-risk patients at a higher risk of aspiration pneumonia.

e. Premature decannulation: Premature tracheostomy tube decannulation can occur when the patient increases his or her physical requirements after decannulation, only to determine his or her current glottal airway is not adequate to support such activity. In those circumstances, revision glottic airway opening surgery is required. This risk is mitigated by stressing the importance of testing "desired level of physical activity" prior to the decannulation.

3. Alternative management plan

a. Tracheostomy is the alternative to glottic opening surgeries. Depending upon the patient, this may be the best option. However, most patients strongly prefer to not have a tracheotomy.

Discussion

Editorial Comment

The authors have undertaken a comprehensive review of the diagnosis and management of patients with BVFI. In addition to the most commonly observed sources such as bilateral injury to the recurrent laryngeal nerve, CA joint fixation, and PGS, I call attention to another, albeit rare, etiology of BVFI. This may be observed when an infiltrating carcinoma involves the postcricoid mucosa. This diagnosis should be considered when other etiologic entities have been reasonably ruled out. Certainly, endoscopy of the upper esophagus is required before posterior glottis stenosis can be attributed to some etiology such as esophageal reflux.

Management of patients with BVFI and resultant airway obstruction requires careful balance between airway, voice, and the patients' exercise requirements. Success is usually measured by degrees of improvement and is almost never absolute. Accordingly, careful shared decision making with the patient regarding his understanding of the problem and his goals for treatment is essential to avoid ultimate therapeutic disappointment with what the surgeon might otherwise have considered a reasonable success.

Jonas T. Johnson

Evidence-Based Medicine Question

Which glottic airway opening surgery is best for the patient in regard to decannulation rates, postoperative dysphonia, and postoperative dysphagia?

There is not one surgery that is best for all patients. The type of surgery is based upon multiple factors: patient history, medical history, laryngeal anatomy, and comfort of surgeon with various surgical techniques. Depending upon the severity of stenosis, decannulation rates are high, but at the expense of voice quality and possibly dysphagia. Patients have different goals in regard to giving up clearer voice quality for decannulation. It is important to candidly discuss with the patient about

this trade-off and proceed with the surgical intervention both the patient and surgeon agree upon.

Acquired Laryngeal Stenosis

Libby J. Smith, and Ricardo Carrau

Introduction

Basic functions of the larynx include being the conduit for air, protecting the airway from aspiration, phonating, coughing, fixing the chest for straining activities, maintaining positive end-expiratory pressure, and swallowing. All these functions can be impaired in patients with laryngeal stenosis.[1,2]

Acquired laryngeal stenosis is a rare condition. It may be a result of external or iatrogenic trauma, systemic diseases, infections, and neoplasms. The degree of laryngeal dysfunction varies widely, with a diversity of treatment methods to address the physical abnormalities and associated symptoms.

Injury to the laryngeal soft tissue or its cartilaginous framework can lead to scarring and loss of support, with subsequent collapse of the airway and stenosis. The laryngeal cartilaginous framework depends on the perichondrium for its blood supply. Cartilage deprived of its blood supply necroses rapidly and acts as a foreign body that induces an inflammatory reaction and causes further tissue destruction and scarring. After injury, the soft tissue planes of the larynx are disrupted and filled with blood, which may develop into an organized hematoma and further fibrosis. The site of injury also influences the development of stenosis. Different areas of the larynx have intrinsic characteristics that protect or predispose to various injuries, as mentioned previously.

1. Surgical anatomy

   a. The larynx is composed of three distinct regions:

      1) Supraglottic

      2) Glottic

3) Subglottic

b. All of these regions are covered with mucosa, which is susceptible to injury from direct trauma, radiation, systemic diseases, or infections. Therefore any of these regions can become stenotic from different etiologies.

c. In general, the supraglottis has more soft tissue and redundant mucosa, making it less dependent on external support than the glottis or subglottis. The supraglottic region includes:

1) Epiglottis

a) The epiglottis is a cartilaginous structure that acts like a rudder to deflect food and liquid away from the glottis and into the piriform sinuses during swallowing. The epiglottis has no muscle; therefore it inverts by the interaction of tongue base retraction and hyolaryngeal elevation during swallowing.

2) Aryepiglottic folds

a) Aryepiglottic folds are ligaments covered by mucosa that connect the epiglottis to the arytenoid cartilages.

3) Arytenoids

a) The cricoarytenoid joints allow for rotation of the arytenoids on the cricoid in three different axes, resulting in lengthening, foreshortening, abduction, and adduction of the vocal folds.

b) The arytenoid mucoperichondrium is exquisitely sensitive to injury, induced when the capillary perfusion pressure of the overlying mucosa is overcome by the external compression of an endotracheal tube cuff.

4) False vocal folds

a) The false vocal folds are soft tissue structures, containing a superior fan of thyroarytenoid muscle.

d. The glottis is defined as the area between the true vocal folds and is the narrowest portion of the adult airway. Thus the surrounding anatomic structures are responsible for maintaining a patent and functional air passage.

1) The glottis depends on cartilaginous support, cricoarytenoid joint mobility, and neuromuscular coordination for normal function.

2) The true vocal folds are multilayered, with the thyroarytenoid muscle and vocalis muscle (most medial aspect of the thyroarytenoid muscle) covered by the lamina propria and an external layer of mucosa.

3) Intrinsic muscles of the larynx move the vocal folds to:

a) adduct (lateral cricoarytenoid muscle, interarytenoid muscle, and thyroarytenoid muscle)

b) abduct (posterior cricoarytenoid muscle)

4) Primary innervation is by the recurrent laryngeal nerve with variable collateral innervation by Galen nerve, the human communicating nerve, and the interarytenoid plexus.

e. The subglottis is defined as the area within 1 cm below the glottis.

1) This is the narrowest segment of the pediatric airway.

2) The subglottic region:

a) includes the cricoid, the only complete ring within the human airway

b) is lined with respiratory epithelium over a submucosa composed of loose areolar tissue

i) Respiratory epithelium is easily disrupted and is thus not well suited to tolerate trauma.

3) Subglottic injuries often heal by secondary intention and scarring.

a) Therefore the subglottis is more susceptible to stenosis than any other region of the larynx.

f. Outcomes

1) Outcomes after surgery for acquired laryngeal stenosis vary greatly, depending upon the location, etiology, and severity of disease.

2) The expected outcome of any of these surgeries is to achieve

improvement of the stenosis and decannulation, if applicable.

3) Complete resolution of stenosis is not expected. Fortunately, patients can tolerate a small amount of stenosis without adversely affecting breathing during normal activities.

4) Each patient perceives airway restriction differently, so the surgeon must individualize the treatment plan and timing of surgery based upon each patient's unique needs, concerns, and medical comorbidities.

g. Prognosis

1) The prognosis for patients with acquired laryngeal stenosis depends upon location, etiology, and extent of disease.

a) Supraglottic stenosis from caustic ingestion or radiation therapy often recurs, requiring repeated surgeries.

b) In the case of an autoimmune etiology, treatment of the underlying autoimmune disease improves and sometimes reverses the stenosis (e.g., Wegener granulomatosis).

2) Anterior glottic webs often restenose to some extent after treatment, regardless of technique.

a) Placement of a keel improves the airway result.

b) Restoration of the mucosal wave is not expected after lysis of the web.

3) Treatment of posterior glottic stenosis (PGS) is fraught with challenges due to the compromise of voice quality and the possibility of aspiration when the posterior glottis is surgically opened.

a) Due to the nonreversible nature of the posterior glottic augmentation surgeries, conservative surgery is initially advocated, especially if the patient already has a tracheostomy tube for airway management.

b) The patient often needs to come to terms with the voice and swallowing repercussions from these surgeries because these functions may be less than normal.

c) Repeat surgery is often required, depending upon healing

and airway requirements according to the patient's activity level.

4) Subglottic stenosis can also recur, thus requiring several surgical interventions. Gastric acid reflux should be considered as a contributing factor.

5) In general, open procedures to address laryngeal stenosis are more effective than endoscopic procedures.

6) However, open procedures have increased morbidity, including tracheostomy, and longer recuperation times.

7) Endoscopic "touch up" surgeries are sometimes needed even after open resection.

Key Operative Learning Points

- Intraoperative control of the airway by either endotracheal intubation or tracheostomy is paramount in any surgery for laryngotracheal stenosis.
- Dilatation can be successfully used as primary treatment in select cases of thin congenital webs, as adjuvant therapy for endoscopic microsurgical techniques, or as palliation in patients who are medically unsuited for major reconstructive surgery.
- Endoscopic microsurgical techniques, with or without adjunctive procedures such as intralesional steroid injection or application of mitomycin C, are ideally suited for the management of thin webs or other less severe stenoses with good cartilage support.
- Anterior glottic webs less than 1 cm in height are usually amenable to endoscopic excision with subsequent placement of a stent or keel.
- Treatment success of the PGS depends on the degree and depth of scarring, mobility of the cricoarytenoid joints, and the patient's acceptance of dysphonia and dysphagia in turn for improved airway restriction.
- Endoscopic microsurgery for acquired laryngeal stenosis is likely to fail when used in patients with multiple stenotic sites, when the stenosis is associated with loss of cartilaginous support, when it is wider than 1

cm, when the lesion is circumferential, and when accompanied by the presence of bacterial infection.

- Failure to control gastroesophageal reflux in the perioperative period may contribute to persistent or recurrent laryngeal stenosis.
- Inadequate preoperative, intraoperative, and postoperative communication with the anesthesia and surgical and recovery room staff can result in catastrophic airway events.
- Changing to a cuffless tracheotomy tube too soon after laryngotracheal reconstruction may result in subcutaneous emphysema, contamination of the cervical wounds, and even a laryngocutaneous fistula.
- A persistent postoperative laryngocutaneous fistula usually signifies inadequate wound drainage and underlying infection.

Preoperative Period

1. History
    a. Symptoms
        1) Shortness of breath
        2) Dyspnea on exertion
        3) Stridor
        4) Hoarseness
        5) Difficulty swallowing
        6) Aspiration
        7) Difficulty clearing secretions
        8) Any combination of these symptoms and signs
    b. Etiology
        1) External trauma
            a) Civilian violence and motor vehicle accidents have led to an increase in the incidence of posttraumatic laryngeal stenosis.
                i) The incidence of laryngeal stenosis after external

trauma varies from 0% to 59%.

b) Even when an adequate and immediate repair is accomplished, a severe disruption of supporting structures or laryngotracheal separation is accompanied by some degree of airway narrowing.[3]

2) Intubation

a) The incidence of laryngeal stenosis after prolonged or repeated intubation has been estimated to range from 3% to 8% in both adults and children. Figures as high as 44% have been cited for low-birth-weight neonates and those with respiratory distress syndrome. Higher rates of stenosis are expected after inhalation injury.

b) Causes of laryngeal stenosis after intubation are multifactorial, including:

i) Duration of intubation

ii) Endotracheal tube size

iii) Pressure and rubbing of the endotracheal tube against the larynx

iv) Repeated intubation

v) Foreign body reaction to the tube

vi) Anatomic differences between the sexes

c) An appropriately sized endotracheal tube for each patient's anatomy, correlating with patient height, is strongly recommended. An appropriately sized endotracheal tube should decrease the risk of laryngeal stenosis, which more frequently affects the posterior glottis.

d) PGS results from disruption of the mucosa between the arytenoids.

i) Patients often complain of slowly progressive dyspnea beginning 4 to 8 weeks after extubation.

ii) Incidence of PGS increases with:

(1) Uncontrolled diabetes

(2) Excessively large diameter endotracheal tube in relation to the tracheal lumen

(3) Tube movement (especially if the patient is not sedated)

(4) Prolonged intubation

(5) Multiple medical comorbidities

iii) Therefore elective tracheostomy is recommended when intubation is expected to be needed for longer than 10 days.

e) Cuff pressure has been found to be more important than the duration of intubation.[4]

i) The use of high-volume, low-pressure cuffs has helped to prevent ischemic injury; however, maintenance of an appropriate cuff pressure is important.

ii) The microcirculation of the laryngeal mucosa is disrupted at cuff pressures greater than 22 mm Hg (30 cm H_2O), resulting in cartilage necrosis and eventual cricoid or tracheal stenosis or malacia.

3) Tracheotomy

a) A high tracheotomy may injure both the glottis and subglottis.

i) A high tracheotomy through the first tracheal ring or the cricoid cartilage leads to cricoid chondronecrosis with resultant fibrosis and stenosis.

ii) Ideally, a tracheotomy should be performed between the second and third tracheal ring; however, tracheal windows or Björk flaps are ideally performed through the third tracheal ring.

b) Similarly, a cricothyroidotomy has been associated with a higher incidence of laryngeal stenosis than tracheotomy.

i) The height of the cricothyroid membrane in adults ranges from 8 to 13 mm (average of 9 mm).

ii) Therefore tracheotomy tubes are poorly suited to

intubate the subglottic larynx because the outer diameter of most tracheotomy tubes is larger than the normal height of the cricothyroid membrane.

4) Endoscopy

a) The effects of endoscopic instruments on the laryngeal airway reflect the care and skill of the operator.

b) Rough handling of tissue, overenthusiastic biopsies, inadvertent or inaccurate laser ablation, and oversized instruments all promote tissue fibrosis and stenosis.

5) Caustic burns

a) Caustic burns are characterized by extensive destruction of mucosa, submucosa, and muscles. The subsequent wound contracture and fibrosis may result in dysfunction.

b) The sphincteric action of the supraglottis often impedes contact of an ingested caustic agent with the glottis.

c) Consequently, severe caustic burns of the supraglottis usually occur without any involvement of the glottis.

d) However, the pharyngeal walls are commonly injured as the chemical passes into the cervical esophagus.

6) Radiation therapy

a) Radiation therapy and especially concurrent chemoradiation produce damage to the microcirculation with progressive death of the soft tissues and subsequent replacement by scar tissue.

i) Ensuing fibrosis of the mucosa, submucosa, and muscles can lead to both a mechanical and functional stenosis of the supraglottic and glottic areas.

ii) Severe mucositis leads to loss of the epithelium and fibrosis, sometimes resulting in severe pharyngolaryngeal stenosis.

(1) In severe situations, a patient may require a tracheostomy and gastrostomy.

7) Nasogastric intubation

a) Nasogastric tubes are an often overlooked source of trauma.

b) Nasogastric intubation produces inflammation secondary to:

i) A foreign body reaction to the tube

ii) Swallowing impairment with pooling of secretions

iii) Pressure necrosis

iv) Gastropharyngeal reflux

c) All these factors play a role in the development of postcricoid ulceration with resultant perichondritis and subsequent fibrosis and contracture.

d) The trauma associated with the nasogastric tube may be synergistic with the trauma induced by an endotracheal tube.

e) This is termed nasogastric tube syndrome, or Sofferman syndrome.

8) Infectious and granulomatous diseases

a) Tuberculosis, histoplasmosis, blastomycosis, leprosy, and syphilis are endemic in many areas of the world.

i) They share a common phase of erythema and edema that progresses to chondritis, necrosis, and scarring.[5]

ii) Laryngeal syphilis and tuberculosis (Fig. 10.1A), as well as diphtheria, although seldom encountered nowadays in the United States, were common causes of stenosis in the past.

b) Granulomatous polyangiitis (GPA; previously termed Wegener granulomatosis) (see Fig. 10.1B and C) and sarcoidosis (see Fig. 10.1D) may involve the larynx.

i) Subglottic stenosis occurs in 10% to 20% of patients with Wegener granulomatosis.

ii) The mainstay of treatment remains nonsurgical (e.g., cyclophosphamide, steroids). Surgical therapy, which usually consists of dilatation and adjuvant modalities,

such as injectable steroids and topical mitomycin C, is typically reserved for patients who have failed medical treatment and is performed only during remission of the disease.

9) Autoimmune diseases

a) Autoimmune diseases, such as relapsing polychondritis, may destroy the cartilaginous framework, such as the cricoid, leading to collapse or stenosis of the airway, or affect the laryngeal joints resulting in cricoarytenoid joint fixation (Fig. 10.2).

i) Cricoarytenoid joint fixation may be the initial manifestation of rheumatoid arthritis.

10) Lymphoproliferative disorders

a) Amyloid of the larynx can also result in supraglottic stenosis, usually with deposition in the false vocal folds or aryepiglottic folds.

b) These patients require a complete evaluation for systemic causes of amyloid, such as multiple myeloma.

11) Gastropharyngeal reflux

a) Repeated exposure to pepsin and acid from gastric reflux produces mucosal and submucosal injury and thereby leads to more scarring (Fig. 10.3).

b) Prophylaxis with acid suppression medications is recommended after any injury to the larynx.

i) Patients should be carefully monitored for gastroesophageal reflux, and those with recalcitrant stenosis must be assumed to be suffering from gastroesophageal reflux and be treated accordingly.

c) With the recent concerns of adverse side effects from proton pump inhibitors (such as osteoporosis, heart disease, kidney disease, infections, and dementia), the risks and benefits of using these medications must be considered.

d) Antireflux surgery is considered in high-risk patients.

c. Medical comorbidities

1) The patient's medical comorbidities must be considered when planning for appropriate surgical treatment. This includes, but is not limited to, the following:

a) Uncontrolled diabetes will result in poor wound healing. Hemoglobin A1C provides the surgeon information on the patient's serum glucose levels in the recent past. Optimizing this is required before surgery.

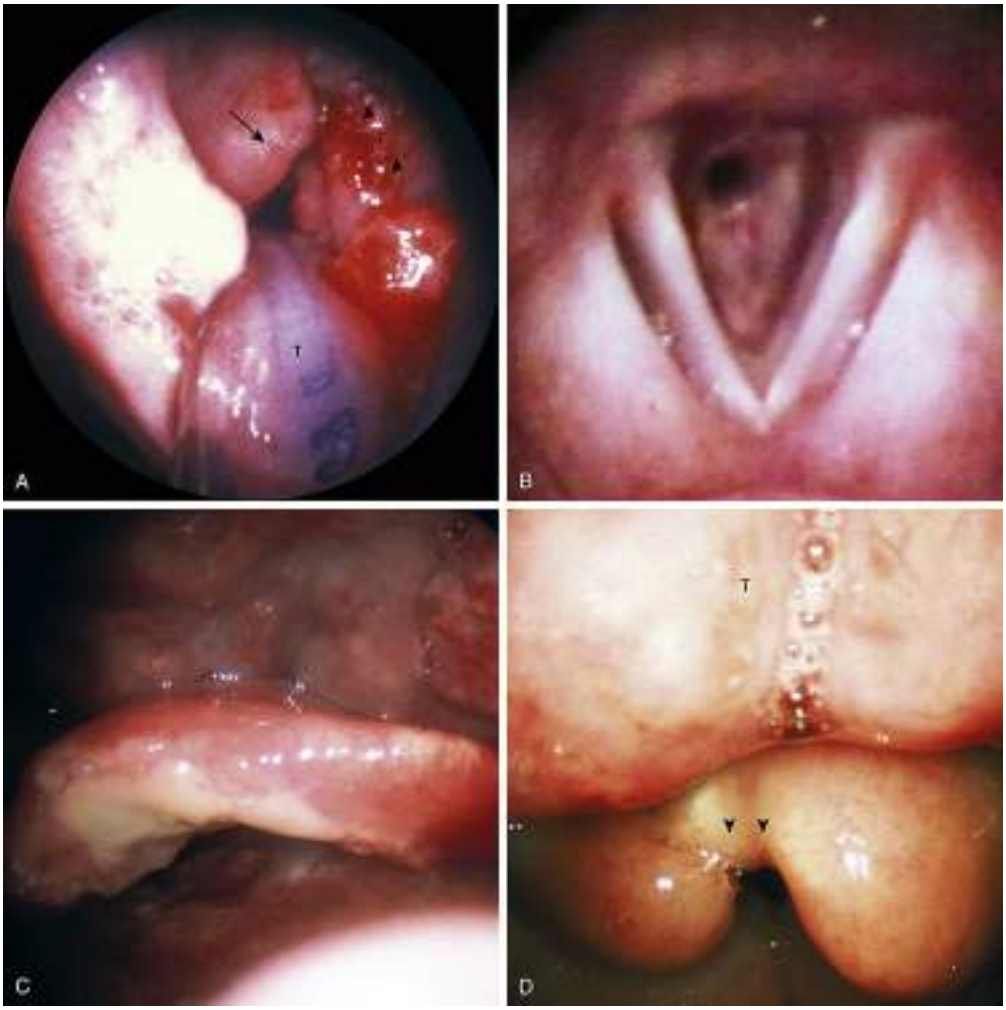

FIG. 10.1 Laryngeal involvement.

A, Tuberculosis: ulceration and granulation tissue *(arrowheads)* in the right false vocal cord; edema *(arrow)* of the left false vocal cord. *T,* Endotracheal tube placed over the posterior glottis. **B,** Wegener granulomatosis: subglottic stenosis. **C,** Wegener

granulomatosis: epiglottic ulceration. **D,** Sarcoidosis: epiglottic scarring *(arrowheads)*. *T,* Tongue.

b) Immunocompromised patients have a higher risk of infection and often slower wound healing. This must be considered for patients with immunosuppression for rheumatologic conditions.

c) Anticoagulation medication must be reversed before undergoing airway surgery. Hematoma within the surgical site can result in airway obstruction and the need for emergent airway management.

d) Pulmonary status can help guide appropriate surgical treatment. If patients have poor pulmonary clearance and require supplemental oxygen, this must be considered as a risk for the formation of mucus plugs. Providing a safe, patent airway is the goal of treatment.

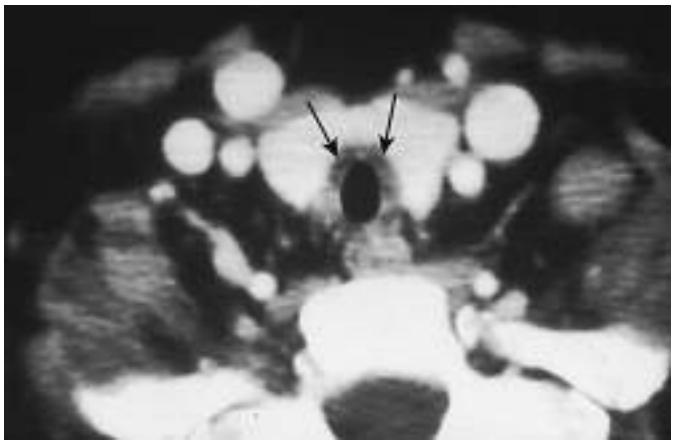

FIG. 10.2 Computed tomography scan of a patient with active relapsing polychondritis demonstrating edema of the perichondrium of the cricoid cartilage and resorption of the cartilage *(arrows)*.

2. Physical examination

a. Office

1) Flexible nasopharyngeal laryngoscopy is essential for evaluating the site and degree of stenosis, as well as vocal fold

mobility.

2) Videolaryngoscopy and still photographs provide objective documentation that can be discussed with the patient.

3) Electromyography helps differentiate neuromuscular deficits from cricoarytenoid joint fixation or subluxation.

4) An awake, flexible bronchoscopy can be performed in the office or surgical suite, with topical anesthesia.

a) When performed in the office, this helps to characterize the stenosis before evaluation in the operating room.

b) Visualization through the main stem bronchi is recommended to evaluate for synchronous areas of stenosis.

c) This information helps the surgeon prepare for airway management when the patient is under general anesthesia.

d) If there is a concern for tracheal or laryngeal malacia, which is a dynamic collapse of the airway, then fiberoptic laryngotracheal endoscopy must be performed with the patient breathing spontaneously.

i) Distinction of malacia from stenosis is critical because it directly impacts treatment and prognosis.

b. Operating suite

1) Rigid direct laryngoscopic and bronchoscopic examination with rigid endoscopes, with the patient under general anesthesia, complements the office examination.

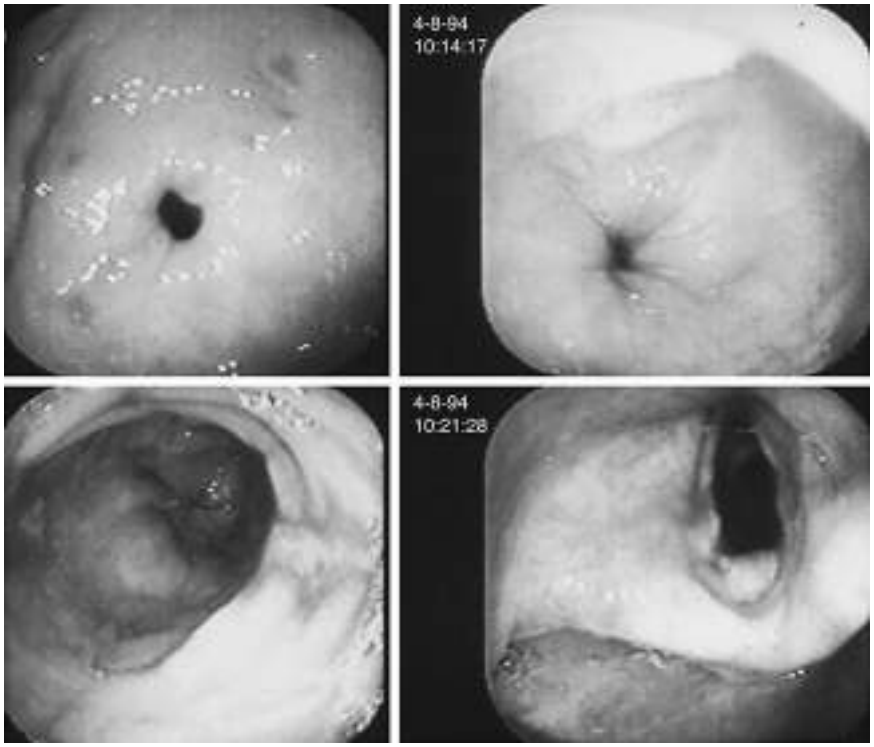

FIG. 10.3 **Lower right,** vocal cord edema, pachyderma laryngis, and granuloma at the vocal processes. The other photographs show punctate and erosive esophagitis at different levels of the esophagus.

2) Rigid direct laryngoscopy allows evaluation of the passive motion of the arytenoids and circumferential examination of the subglottis and provides an idea of the firmness of the scar tissue.

3. Imaging

a. Although imaging is important to delineate the cartilaginous framework, it does not obviate the importance of both flexible and rigid endoscopy in determining appropriate treatment.

b. Computed tomography (CT) is considered the standard imaging technique to corroborate the integrity of the cartilaginous framework (Fig. 10.4) and evaluate the cricoarytenoid joint.

c. Other pertinent imaging modalities include magnetic resonance imaging (MRI), ultrasound, and fluoroscopy.

1) MRI is useful in the evaluation of extensive laryngotracheal stenosis and does not involve any radiation exposure.

a) However, a major limitation of MRI is that the patient must remain supine for a long time, which is not tolerated by patients with significant orthopnea due to airway obstruction.

2) Ultrasound may provide a convenient, well-tolerated, noninvasive method of assessing subglottic airway diameter.

3) Fluoroscopy is most helpful in evaluating areas of tracheomalacia that collapse on inspiration but look normal during rigid direct endoscopy performed under general anesthesia.

d. Soft tissue radiographs are rarely used in the evaluation of adult acquired laryngeal stenosis.

4. Indications

a. The most common indications for a surgical intervention to correct an acquired laryngeal stenosis are dyspnea and dysphagia.

b. Patients with supraglottic stenosis often complain of difficulty swallowing and experience dyspnea only when it is severe.

c. Conversely, patients with glottic and subglottic stenosis have complaints of dysphagia less frequently. In contrast, difficulty breathing drives the timing of surgical intervention.

5. Contraindications

a. Uncontrolled anticoagulation

b. Uncontrolled diabetes

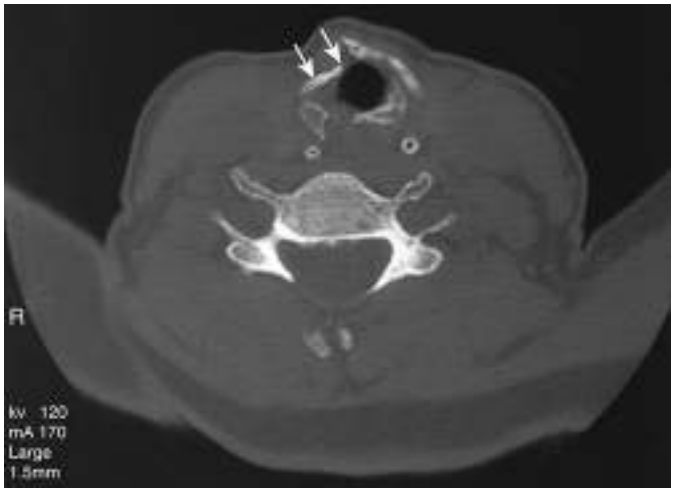

FIG. 10.4 Computed tomography scan, axial view, demonstrating fractures involving the thyroid and cricoid cartilage *(arrows)*.

c. Current smoker

d. Relative contraindications: immunosuppression, poor overall health

e. There is no strict contraindication for performing an emergency tracheotomy.

6. Preoperative preparation

a. The site and extent of the stenosis dictate appropriate surgical treatment.

b. Occasionally, the patient's condition is so dire that a tracheostomy is required to bypass the stenosis.

c. Administration of corticosteroids in the perioperative period, although their benefit has not been scientifically proven, may help minimize the postoperative edema, which is critical in patients without a tracheostomy.

Operative Period

1. Anesthesia

a. Establishing a secured airway is the keystone to all procedures in the correction of laryngeal stenosis.

1) The airway may be secured with an endotracheal tube or a tracheostomy.

2) A tracheostomy performed with the patient under local anesthesia is recommended for patients with significant airway compromise (e.g., stridor) and for those who require a transcervical approach.

3) Select patients with supraglottic, glottic, and subglottic stenosis may be intubated.

a) Intermittent removal of the endotracheal tube, with the patient apneic, is sometimes required to perform surgery.

b. Jet pressure ventilation (e.g., Venturi system) can be used if there is enough air outflow; otherwise the patient is at risk for increased lung pressures and tension pneumothorax.

1) Subglottic jet ventilation can often be used in the treatment of subglottic stenosis, delivered through the rigid laryngoscope.

2) However, both the anesthesiologist and surgeon must be very familiar with the functionality and risks of jet ventilation.

3) If there is limited exposure and familiarity with jet ventilation, then it should not be performed, and rather use endotracheal intubation or a tracheotomy.

2. Positioning

a. For endoscopic procedures: The patient is placed in a supine "sniffing" position.

1) Neck flexion, head extension

2) Shoulder rolls are not used. Rather, a head "donut" is used to stabilize the head.

3) "Ramp" position is sometimes used for obese patients. Blankets and/or towels are placed below the patients' shoulders and head such that the tragus is horizontal to the manubrium. This can facilitate proper laryngeal exposure.

b. Surgeon positioning

1) Important to reduce musculoskeletal injuries to the surgeon

2) After the larynx is exposed, proper surgeon ergonomic position is achieved by moving the bed angle (usually Trendelenburg; "head down") so the laryngoscope is approximately 40 degrees

off the horizontal plane.

3) The surgeon's neck should be in a neutral position or slightly flexed but never extended.

4) Arm rest support while operating is important.

5) Sometimes lowering the height of the bed is necessary to allow for more comfortable placement of the surgeon's arms and hands.

c. For open procedures: The patient is supine with the neck extended. This brings the laryngotracheal complex into the cervical area.

3. Perioperative antibiotic prophylaxis

a. Laryngeal surgery is classified as a clean-contaminated procedure, for which perioperative prophylactic antibiotics are recommended.

b. A prolonged therapeutic course of antibiotics may be indicated in special circumstances (e.g., active chondritis).

1) The theoretical value of a prolonged course of antibiotics is to control the infection, thus stopping a vicious cycle of chondritis, necrosis, granulation tissue formation, and scar deposition.

2) There is a highly significant association between stent colonization with specific bacteria (*Staphylococcus aureus* and *Pseudomonas aeruginosa*) and the development of airway granulation.

3) Azithromycin has been used not for its antimicrobial effects but rather its anti-inflammatory effects.[6]

c. Nebulized ciprofloxacin/dexamethasone otologic preparation (5 drops/1 mL saline, twice daily) can also be used as an adjunctive treatment.

4. Instruments and equipment to have available

a. Endoscopic surgery

1) Laryngeal suspension device

2) Various sizes of laryngoscopes

3) Surgical microscope

4) Microlaryngeal surgical set

5) Rigid telescopes (0, 30, and 70 degrees; 30 cm length, 5 to 10 mm diameter): These are used to better visualize the extent of lateral extension of the surgical field.

6) Orotracheal injector

7) Fiber-based CO_2 laser with micromanipulator airway dilators

b. Open surgery

1) Head and neck or plastic surgery set

2) Self-retaining retractors (e.g., Weitlander)

3) Double prong retractors

4) Insulated bipolar cautery

5) Rib harvesting set

c. Tracheostomy surgical set

5. Key anatomic landmarks

a. Intimate knowledge of supraglottic, glottic, and subglottic anatomy, depending upon the type and location of the laryngeal stenosis

6. Prerequisite skills

a. Endoscopic surgery skills

b. Open surgery skills

c. Laser certification

d. Airway dilation

e. Tracheostomy

f. Comfort with complex airway manipulation before, during, and after surgery

7. Operative risks

a. During CO_2 laser surgery, the safety of the patient and operating room personnel is a primary consideration. Laser safety precautions include the following:

1) All operating room personnel should use protective eyewear.

2) The patient's eyes are kept closed with adhesive dressing (e.g.,

Tegaderm) and then covered with eye pads soaked in saline solution or protective eye shields.

3) The face, the upper part of the chest, and the laryngoscope are covered with surgical towels soaked in saline solution (Fig. 10.5). A saline-filled bulb syringe should be within reach of the surgeon in the event of an airway fire.

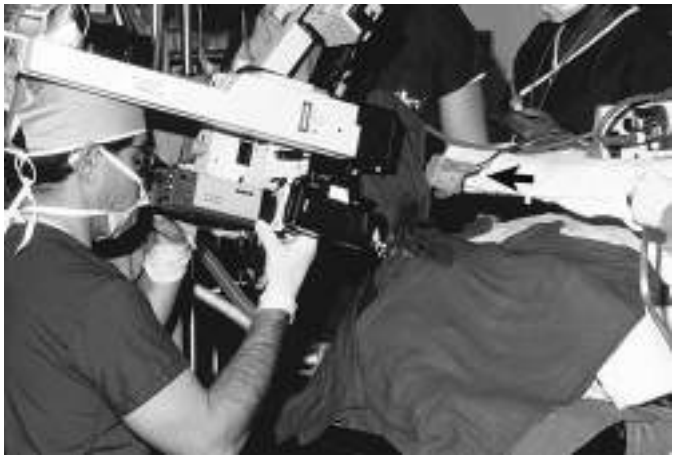

FIG. 10.5 Setup for laser microsurgery.

The patient and the laryngoscope are covered with towels soaked in normal saline solution. The *arrow* indicates the suspension system.

4) The laser-resistant endotracheal tube, exposed outside the mouth, should be covered with metal tape, foil, or wet towels. In the airway, the tube and cuff are protected with a wet cottonoid.

5) The subglottis may be protected with a cottonoid soaked in normal saline solution or by using a nonreflecting platform below the free edge of the vocal fold receiving the laser beam.

6) Communication with the anesthesia team is critical because the patient's fraction of inspired air (FiO_2) should be less than 40% and preferably less than 30%.

7) Before beginning the surgery, the laser should be tested to ensure that the aiming beam is aligned (i.e., coaxial) to the laser beam.

8) "Bouncing" of the laser beam against the laryngoscope during surgery should be avoided.

9) The laser beam should not be allowed to hit the subglottis when the surgeon is working at the free edge of the vocal fold, to avoid unnecessary damage to the subglottis and increase the possibility of inadvertent endotracheal tube puncture and fire.

10) Laser char should be removed frequently with pledgets soaked in normal saline.

11) All these maneuvers complement but are not a substitute for good judgment and careful surgical technique.

b. Certain risks are inherent to performing endolaryngeal surgery, including the following:

1) Dental injury: Dental splints should be used for all patients with dentition. For edentulous patients, foam or gauze protection of the gingiva is used.

2) Temporary change of sensation of the tongue and rarely reduced tongue motion may be the result of traction and/or compression of sensory and motor nerves.

3) Mucosal injury: from mucosal manipulation with placement of laryngoscope

4) Temporomandibular joint pain: due to prolonged mouth opening during a long procedure

c. Loss of airway

1) This risk should be mitigated by the surgeon's understanding of the patient's airway.

2) The surgeon must be in constant communication with the anesthesia team.

3) The surgeon must be ready to perform a tracheotomy when necessary.

8. Surgical Technique

a. Three basic principles are fundamental to the successful outcome of any surgery for laryngeal stenosis:

1) Adequate exposure

2) Preservation of normal tissue

3) Prevention of recurrence by promoting primary healing

b. Treatment of laryngeal stenosis has evolved from the "wait-and-see" philosophy to dilatation and eventually to endoscopic procedures with microsurgery. Surgical approaches have been combined with the use of antibiotics, stents, corticosteroids, and lumen augmentation procedures with or without grafts. Unfortunately, none of these techniques offers a 100% resolution of airway obstruction in all patients.

c. Wait-and-see approach

1) This approach has been applied to children with congenital stenosis in the hope that the patient will outgrow the defect.

2) When dealing with acquired laryngeal stenosis, the continuous process of scar maturation and contraction makes this outcome very unlikely.

a) Therefore the wait-and-see philosophy is rarely justified for patients with acquired laryngeal stenosis.

b) Symptomatic patients require treatment and cannot wait around to see what happens.

d. Dilatation

1) Dilatation is most successful when used for select cases of thin regions of stenosis.

2) The probability for a successful dilatation increases when the technique is used for soft or immature scars of minimal thickness and when it is used as an adjunct to other techniques (e.g., radial incisions).

3) Unfortunately, acquired stenosis is often characterized by hyalinization of the connective tissue and collagen cross-linking that translates into an incompressible, rigid scar resisting the effects of dilatation.

4) It may offer palliation to patients in poor general medical condition.[7]

5) A significant disadvantage of the technique is the need to repeat

the procedure a number of times on each patient.

a) Overall, approximately three-quarters of patients treated by dilatation as primary therapy will have recurrence of the stenosis and require a subsequent intervention.[8]

e. Endoscopic microsurgery: cold instrumentation versus laser

1) The outcome after endoscopic microsurgery depends upon:

a) Etiology

b) Site

c) Extent of the stenosis

d) Therefore appropriate patient selection is essential.

2) Endoscopic microsurgery for acquired laryngeal stenosis is likely to fail in the presence of[7]:

a) Multiple stenotic sites

b) Associated loss of cartilaginous support

c) Thickness of stenosis greater than 1 cm

d) Circumferential stenosis

e) Concurrent bacterial infection

3) Laser surgery offers the unique advantages of a visual field not obscured by instruments and ease of hemostasis.

a) Whether the laser is less traumatic than microsurgical instruments is controversial.

i) Experimental data suggest that wounds produced by a laser beam show early re-epithelialization with slow fibroblast proliferation and collagen formation.

ii) However, as a general rule, microsurgical instruments better preserve normal tissue.

iii) Large defects heal by secondary intention (i.e., increased scarring) irrespective of the method of incision.[1,2]

4) Currently, endoscopic management is the most frequently used method of treating supraglottic, glottic, and select subglottic

stenoses.

f. Corticosteroids

1) Corticosteroids prevent intracellular sequestration and stabilize cell membranes, thereby preventing the release of lysosomes that produce swelling and tissue destruction.

2) They also inhibit collagen synthesis, enhance collagen breakdown, and reduce mitosis and the active transport of fibroblasts.

3) Although their clinical benefits for laryngeal stenosis are yet unproven, intralesional injections may be of benefit to soften scar bands and synechiae.

g. Mitomycin C

1) Mitomycin C is an alkylating agent that inhibits protein and DNA synthesis, impeding fibroblast proliferation, thus decreasing the probability of restenosis.

2) It is generally accepted as a safe and cost-effective adjunct to laryngotracheal surgery.[9]

3) Typical dosing is topical application of 0.4 mg/mL for 4 minutes in patients who have a tracheostomy or for 2 minutes repeated once (for a total of 4 minutes) for patients without a tracheostomy, due to the apnea period needed for application.

4) Studies suggest that the use of topical mitomycin C during laryngeal airway procedures results in a significantly longer symptom-free interval than did those who underwent endoscopic treatment alone.[10]

h. External procedures

1) Basic transcervical approaches include the lateral pharyngotomy, direct resection of the stenotic segment with end-to-end anastomosis, and median thyrotomy.

2) Advocates of transcervical procedures believe that these approaches allow precise excision of scar tissue, facilitate primary closure by allowing the advancement of mucosal flaps, and therefore decrease the need for revision surgery.

i. Stenting

1) Stenting aims to maintain the lumen while allowing the dynamics of wound healing to occur about a relatively inert object that resists scarring.

2) A significant caveat to using a stent is its induction of a foreign body reaction with exacerbation of the inflammatory response, further destruction of tissue, and slow re-epithelialization.

3) Stents have been molded with rigid and soft materials.

   a) Rigid stents are not recommended because they produce trauma that is similar to that of endotracheal tubes.

   b) The most popular stents are tubular or solid prefabricated Teflon or Silastic stents (Figs. 10.6 and 10.7).

4) Stents are most useful in the postoperative setting as an adjunct to airway augmentation procedures, by supporting a free graft or a vascularized flap and to preserve the lumen.

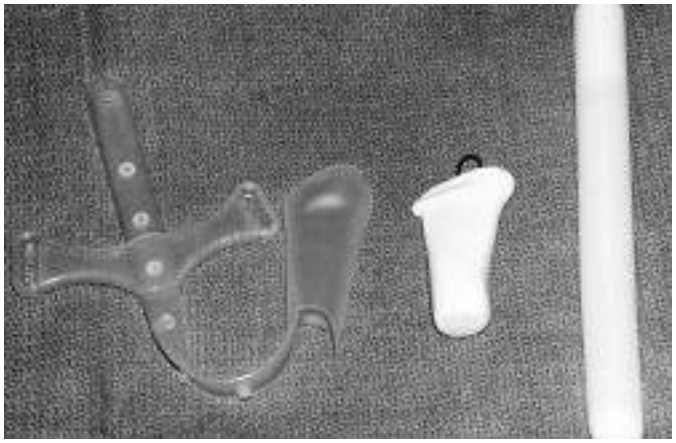

FIG. 10.6 Prefabricated stents.

Left to right are shown the Eliachar, Montgomery, and Aboulker stents.

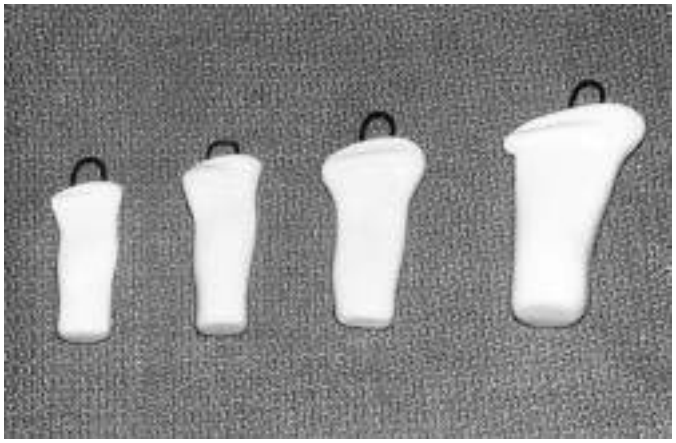

FIG. 10.7 Different sizes of Montgomery laryngeal stents.

Left to right: child, small adult, medium adult, and large adult stents.

5) The reported ideal period of stenting ranges from 2 weeks to 10 months.

   a) As a general rule, 2 to 4 weeks of stenting is sufficient. Stents need to be left in place longer if the patient has diabetes or is immunocompromised.

6) Stents can be problematic and require heightened attention to their potentially life-threatening complications.

7) Stented patients often require a tracheostomy.

8) T-tube stents can also be used as primary treatment of complex cases with stenoses at multiple sites or as a salvage effort in patients who have failed multiple attempts at airway reconstruction.

   a) Stent deterioration and foul odor, possibly from biofilm degradation, require that the T-tube stents be replaced periodically, usually approximately every 3 to 6 months.

   b) All patients with T-tubes must know how to emergently remove their T-tubes if it becomes blocked and they are unable to flush it.

j. Supraglottic stenosis

1) Supraglottic stenosis is amenable to endoscopic or open techniques.

2) Endoscopic laser resection and balloon dilation are commonly used.

a) CO_2 laser incisions are created in "quadrants" after placement and suspension of a rigid laryngoscope.

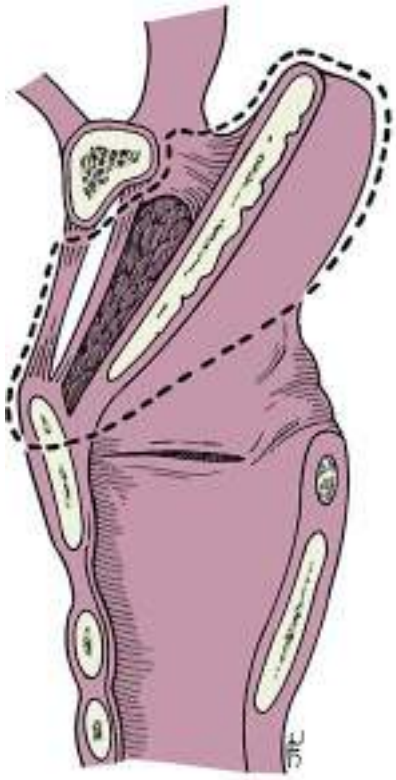

FIG. 10.8 Sagittal plane.

The *dashed line* outlines the area to be resected during partial supraglottic laryngectomy.

b) Care is made to avoid broad mucosal injury, as re-stenosis will occur.

c) The goal is to make radial cuts, allowing the expected scar process after surgery to retract the tissue.

d) This is often followed by serial balloon dilation. Rarely, retrograde balloon dilation through the tracheostoma is necessary.

3) In select cases, such as patients with poor general status, some temporary palliation may be achieved with a submucosal injection of corticosteroids and dilatation.

4) In severe cases not amendable or resistant to endoscopic techniques, open supraglottic laryngectomy is performed.

a) As opposed to an oncologic supraglottic laryngectomy, this open procedure preserves the innervation of the superior laryngeal nerves, the hyoid bone, and the soft tissues adjacent to the scarred area.

b) An incision is incorporated into a horizontal skin crease over the thyroid cartilage.

c) Subplatysmal flaps are elevated superiorly to expose the insertion of the suprahyoid musculature and inferiorly to the level of the cricoid.

d) The infrahyoid strap muscles are transected at their insertion to expose the portion of the hyoid bone medial to the lesser cornua (Fig. 10.8). The strap muscles are dissected from the thyroid cartilage and retracted laterally.

e) The pharynx is entered as described for transhyoid pharyngotomy (see Chapter 35) (Fig. 10.9).

i) This allows direct visualization of the stenosis.

f) Incisions through the thyroid cartilage are performed with a no. 10 blade or an oscillating saw if the cartilage is calcified.

i) The superior cornua of the thyroid cartilage, as well as the superior laryngeal neurovascular bundles, are spared.

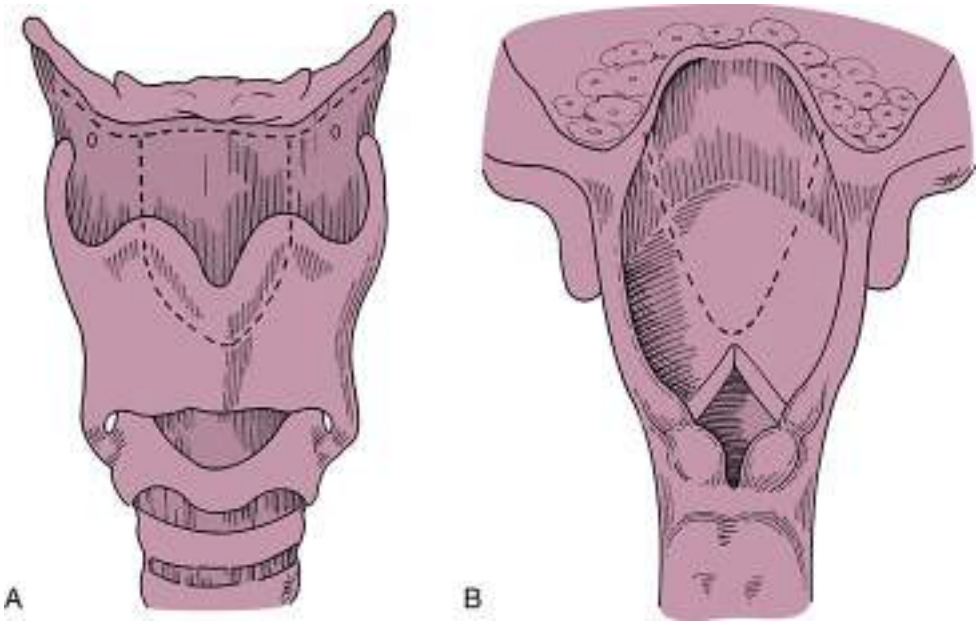

FIG. 10.9 Coronal plane.

The *dashed lines* indicate the level of incisions through the thyrohyoid membrane and the thyroid chondrotomies, **A,** and the endolaryngeal incisions, **B.**

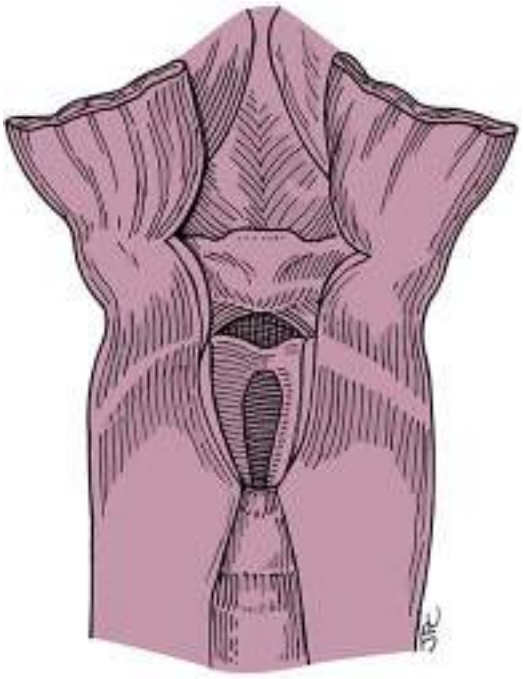

FIG. 10.10 Coronal plane.

In a transcervical view after removal of the median supraglottis, the vocal cords can be seen through the

defect. The hyoid bone has been preserved.

g) The soft tissue incisions include the stenotic area after the thyrotomy incisions are made (Fig. 10.10).

h) The defect is repaired by suturing the base of tongue to the perichondrium of the thyroid ala.

i) If the epiglottis is not sacrificed, it is incorporated into the closure.

ii) It is important to tack the epiglottis anteriorly to the remaining thyroid cartilage or the epiglottis will fold down and obstruct the view of the glottis posteriorly in the postoperative period.

i) The strap muscles are re-approximated to the hyoid bone and to each other at the midline. The wound is repaired with a multilayer technique. Suction drains are left in place.

k. Glottic stenosis

1) Stenosis of the glottic area should be further classified as anterior, posterior, or combined lesions. This simple classification is important because the cause, treatment, and prognosis are very different for each location of stenosis.

2) Anterior glottic stenosis

a) Anterior glottic stenosis usually develops after disruption of the anterior commissure by external trauma (e.g., laryngeal fracture), endoscopic surgery (e.g., vocal cord stripping), or oncologic surgery (e.g., partial vertical laryngectomy).

b) Anterior glottic stenosis causes foreshortening of the glottis and tethers the abduction of the true vocal cords (Fig. 10.11A and B).

c) The method of resection, whether to use a laser or "cold" microsurgical instruments or to approach the lesion endoscopically or transcervically, is less important than good surgical technique to improve the airway and promote primary healing.

i) Magnification of the surgical field with a microscope or loupes optimizes preservation of normal tissue.

ii) Fine instrumentation is important to minimize tissue trauma.

d) Invariably, correction of anterior glottic stenosis will result in two opposing surfaces with denuded epithelium. These two surfaces will tend to heal together and form a web (i.e., restenosis), although sometimes not as severely as before surgery.

i) A stent or keel that separates these two denuded areas prevents this problem.

ii) Alternatively, the web can be divided into superficial and deep layers based laterally at the anterior one-third of the free edge of the true vocal folds. These flaps are then rotated to cover the denuded areas of the vocal fold, thereby precluding the need for a keel.

e) Anterior glottic webs less than 1 cm in height are amenable to endoscopic incision under general anesthesia.

f) The patient is placed in a supine, "sniffing position" (neck flexion, head extension).

g) A large rigid laryngoscope is suspended, allowing binocular microscopic magnification of the anterior glottic stenosis.

h) The web may be lysed with a laser or "cold" microsurgical instruments (see Fig. 10.11A to C).

i) Anterior webs usually require low power (e.g., 4 to 6 W) for vaporization and hemostasis.

ii) Lysis of the web should extend to the thyroid cartilage but should not dissect through it.

i) When "cold" microsurgical instruments are used:

i) Hemostasis is achieved with a topical 1:10,000 adrenaline solution applied with a 0.5 × 0.5-inch neurosurgical pledget.

(1) It is important to remember that adrenaline will be absorbed into the circulation immediately.

(2) The recommended maximal dosage should be observed, and anesthesia personnel should be notified before applying the solution.

ii) The web is transected with upbiting microscissors, and granulation tissue is removed with microcup forceps.

j) Regardless of the mode of lysis of the web, topical application of mitomycin C (0.4 mg/mL solution for 4 minutes) should reduce scarring and may decrease the probability of recurrence.

k) If the surgeon decides to place a stent after lysis of an anterior glottic web:

i) Stent is endoscopically secured in place with transcutaneous monofilament sutures (Fig. 10.12).

ii) Stent is left in place for 10 to 14 days, after which the patient is taken back to the operating room for removal of the stent and inspection of the surgical site.

l) Webs thicker than 1 cm, those involving the subglottis, and those associated with PGS may require a laryngofissure approach (see Chapter 69).

i) A silicone Montgomery umbrella is left in place after the web is divided (Fig. 10.13).

(1) This prosthetic device remains in place for 2 to 4 weeks.

(2) The optimal time for removal is when the anterior one-third of the true vocal cords shows complete epithelialization, which may be ascertained by flexible laryngoscopy.

(3) Removal of the stent requires opening the incision with the patient under general anesthesia in the operating suite.

m) Loss of the anterior segment of the thyroid cartilage as a result of trauma or oncologic surgery requires

reconstruction of the cartilaginous support.

i) The preferred method for such reconstruction is the epiglottopexy described by Kambic et al.

ii) This procedure involves a transcervical approach, similar to the one described for a laryngofissure (see Chapter 69).

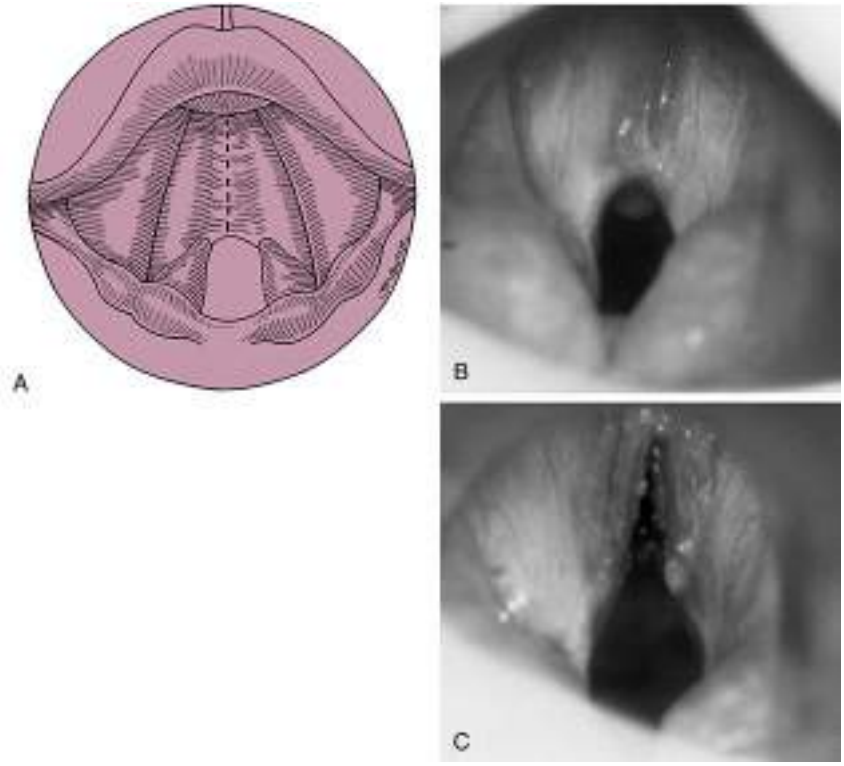

FIG. 10.11 **A,** Anterior glottic web involving the vocal folds. The *dashed line* indicates the ideal level for lysis of the web to re-create the free edge of both true vocal cords. **B,** Intraoperative view of an anterior glottic web. **C,** Intraoperative view after division of the web with a CO_2 laser.

(1) When feasible, the thyroid cartilage is transected at the midline, although the midline may be difficult to establish in the presence of scarring.

(a) In these cases the midline of the anterior commissure may be estimated through the

direct laryngoscope, before the transcervical procedure is started.

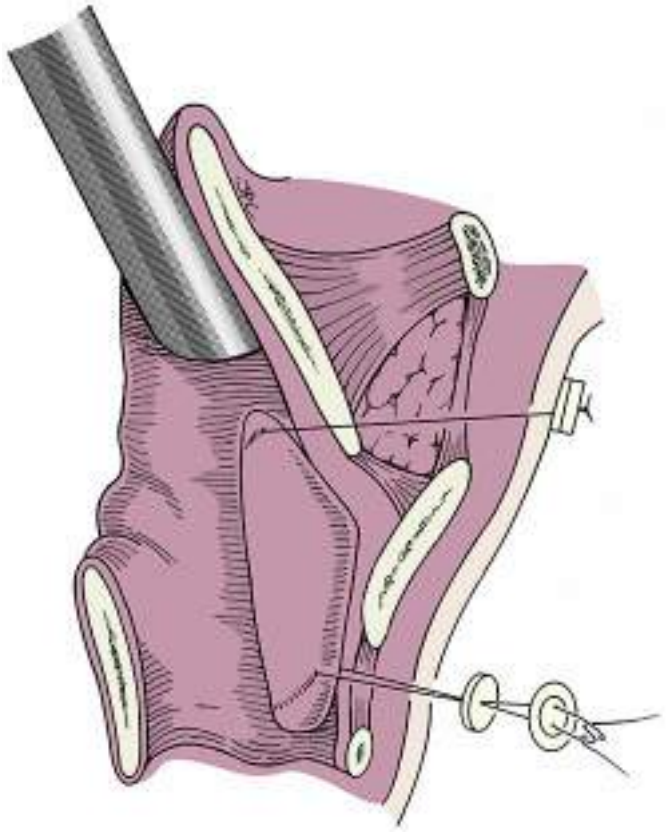

FIG. 10.12 **Sagittal plane.**

An anterior glottis keel is inserted and secured with external monofilament (transcutaneous) sutures.

(b) However, in most cases, this point is moot, because severe scarring and loss of tissue mandate reconstruction of the entire anterior laryngeal anatomy.

(2) The thyrohyoid membrane is incised between the lesser cornua to expose the superior pre-epiglottic space.

(3) The soft tissue of the pre-epiglottic space is dissected from the anterior surface of the epiglottis.

(4) The petiole of the epiglottis is then grasped and

drawn inferiorly like a window shade to facilitate lysis of the median and lateral epiglottic ligaments (Fig. 10.14A).

(5) Continuity of the lateral and superior mucosa with the base of tongue and vallecula should be preserved (see Fig. 10.14B).

(6) A Montgomery laryngeal stent is placed and secured with transcutaneous, transcervical monofilament suture.

(7) Alternatively, an Eliachar laryngeal stent may be used.

(8) The epiglottic cartilage is split by midline while preserving the mucosa of the laryngeal surface of the epiglottis to produce a sharp-angled anterior commissure (Fig. 10.15).

(9) The lateral edges of the epiglottis are sutured to the anterior edges of the thyroid ala with interrupted absorbable suture.

(10) The petiole is also sutured, usually to the superior margin of the cricothyroid membrane.

(a) Occasionally, the petiole may be mobilized low enough to augment the anterior cricoid arch, which may be necessary if the anterior subglottic stenosis involves the cricoid cartilage.

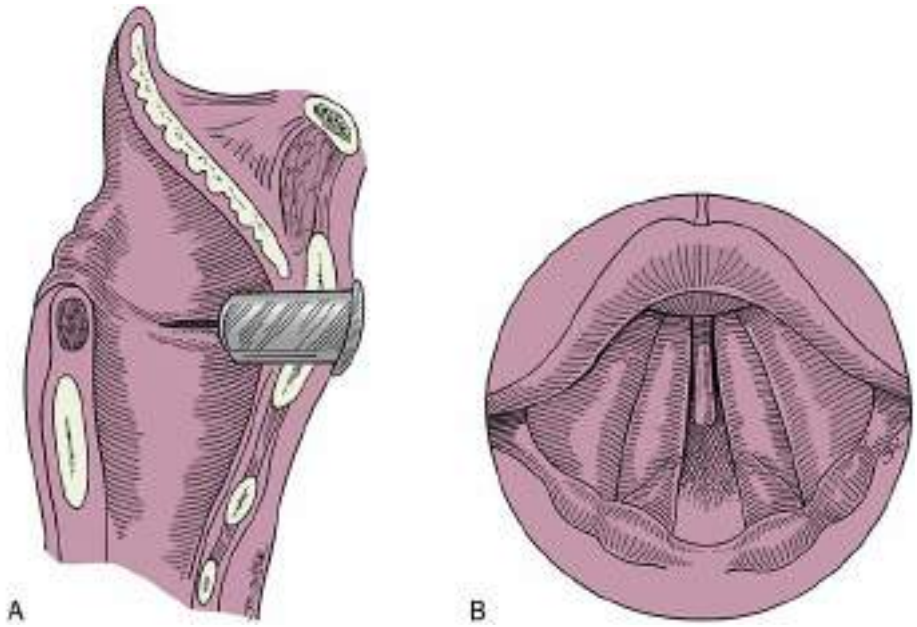

FIG. 10.13 **A,** Sagittal plane. Montgomery umbrella is in place after lysis of an anterior glottic web via laryngofissure. **B,** Axial plane. The anterior keel is in place.

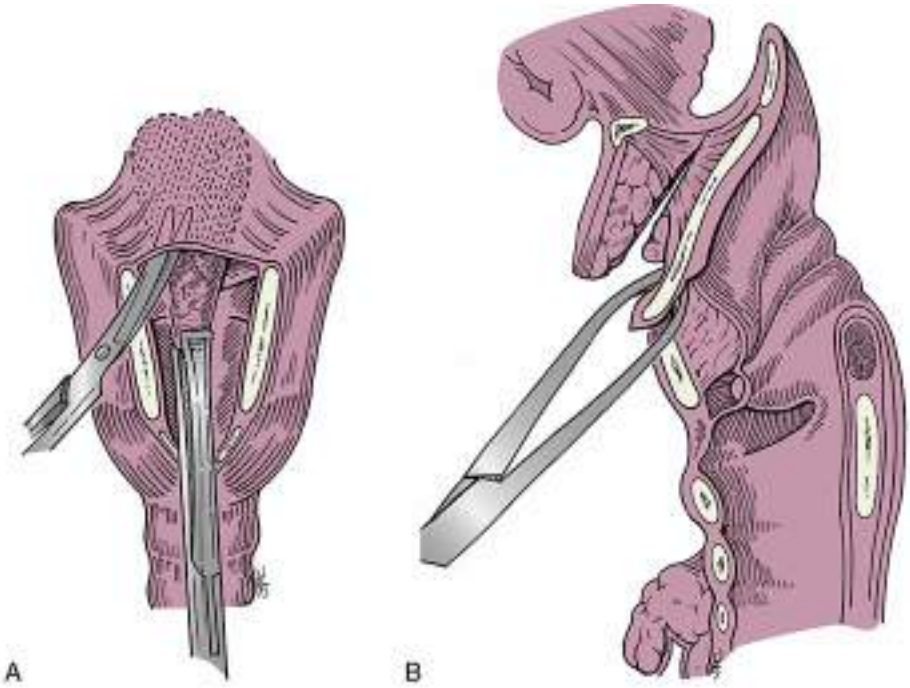

FIG. 10.14 **(A)** Coronal and **(B)** sagittal views. The petiole of the epiglottis is retracted inferiorly to facilitate dissection of the lingual surface of the cartilage from the surrounding

soft tissue.

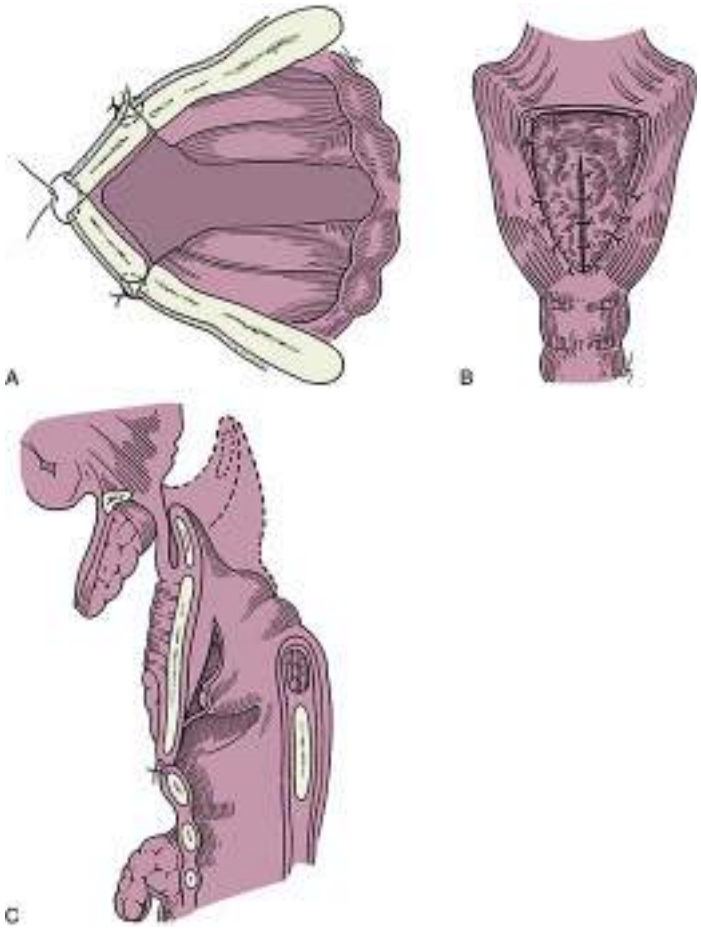

FIG. 10.15 **A,** Axial, **B,** coronal, and **C,** sagittal views. Reconstruction of the anterior thyroid cartilage has been completed. The epiglottic cartilage has been divided, with sparing of the mucoperichondrium on the laryngeal side of the epiglottis to re-create the V-shaped apex of the anterior commissure.

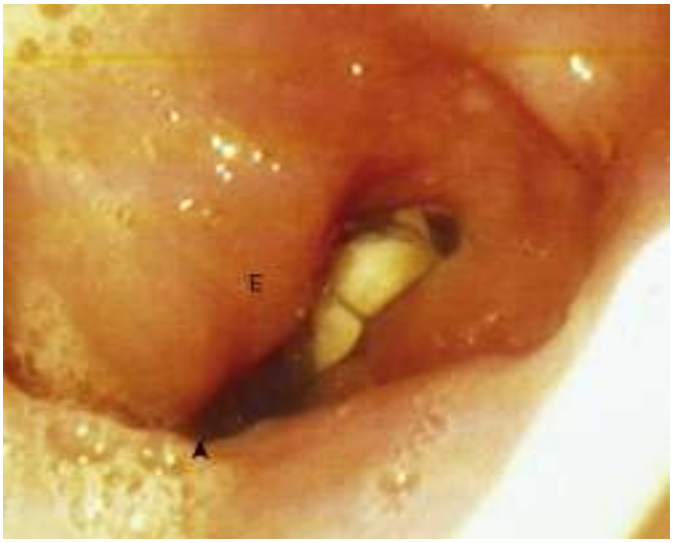

FIG. 10.16 The endolarynx after Kambic epiglottopexy for reconstruction of a glottic stenosis after right hemilaryngectomy. Notice the convex shape of the epiglottis *(E)*. The *arrowhead* indicates the anterior commissure.

(11) The strap muscles are approximated, and the wound is closed in multiple layers.

(12) A Penrose drain is left in place, and a compressive dressing is applied.

iii) This technique has the advantage of providing immediate reconstruction of the infrastructure, as well as the endolaryngeal lining, with local vascularized tissue, thereby expediting healing.

(1) Although the reconstruction is completed in one stage, the patient must be returned to the operating room for transendoscopic removal of the stent.

iv) This technique has the disadvantage of a tendency to produce a round anterior commissure, even with the described method (Fig. 10.16).

3) PGS

a) PGS is most commonly the result of interarytenoid scarring secondary to prolonged endotracheal intubation or trauma.

b) Regardless of the method or refined surgical technique, the success of the surgery depends on the degree and depth of the scarring.

c) Treatment of an interarytenoid adhesion requires transection of the scar band.

i) This is possible only if there is a posterior "port" of no scar between the scar band and posterior laryngeal mucosa.

ii) These patients have improved vocal fold motion after lysis, unless there is concurrent cricoarytenoid joint scarring.

iii) This highlights the importance of evaluating the cricoarytenoid joints before performing surgical intervention of PGS.

d) Unfortunately, severe posterior glottic scarring is common.

i) This involves scarring of the posterior commissure, often involving one or both cricoarytenoid joints.

ii) Surgery to improve their glottic airway comes at the expense of voice and swallowing ability.

iii) Treatment ranges from transverse cordotomy, medial arytenoidectomy, endoscopic total arytenoidectomy, microtrapdoor flap, or tracheotomy (see Chapter 9 for more details).

(1) Tracheostomy is the only procedure that can "bypass" the airway obstruction, leaving the patient with improved breathing and no change in voice quality.

(a) However, tracheostomy is often not a desirable option for patients.

(b) Therefore destructive endoscopic glottic airway procedures are the most common treatments for PGS.

(2) Transverse cordotomy consists of CO_2 laser transection of the posterior true vocal fold, just

anterior to the vocal process.

(a) The cordotomy extends laterally to the inner table of the cricoid cartilage.

(b) A small triangle defect results from scarring of the vocal fold anteriorly and laterally.

(3) Medial arytenoidectomy is a surgical option when there is no significant posterior glottic scar, although this is uncommon in these circumstances.

(a) This creates a "half-moon" defect in the medial aspect of the arytenoid.

(b) There must be sufficient space between the posterior glottis scar and vocal process to perform this surgery.

(4) Total endoscopic arytenoidectomy is a combination of the transverse cordotomy and medial arytenoidectomy, with CO_2 laser ablation of arytenoid and muscle within those confines, extending to the inner table of the cricoid cartilage.

(5) Lastly, a microtrapdoor flap can be performed to reconstruct posterior stenosis caused by mucosal scarring.

(a) An inferiorly based flap is elevated from the interarytenoid area with the laser or, preferably, with microsurgical instruments.

(b) The submucosal scar is removed, and passive mobility of the arytenoids is tested.

(c) The flap is repositioned over the operated area to promote primary healing (Fig. 10.17).

(6) Open surgery through a laryngofissure is rarely necessary.

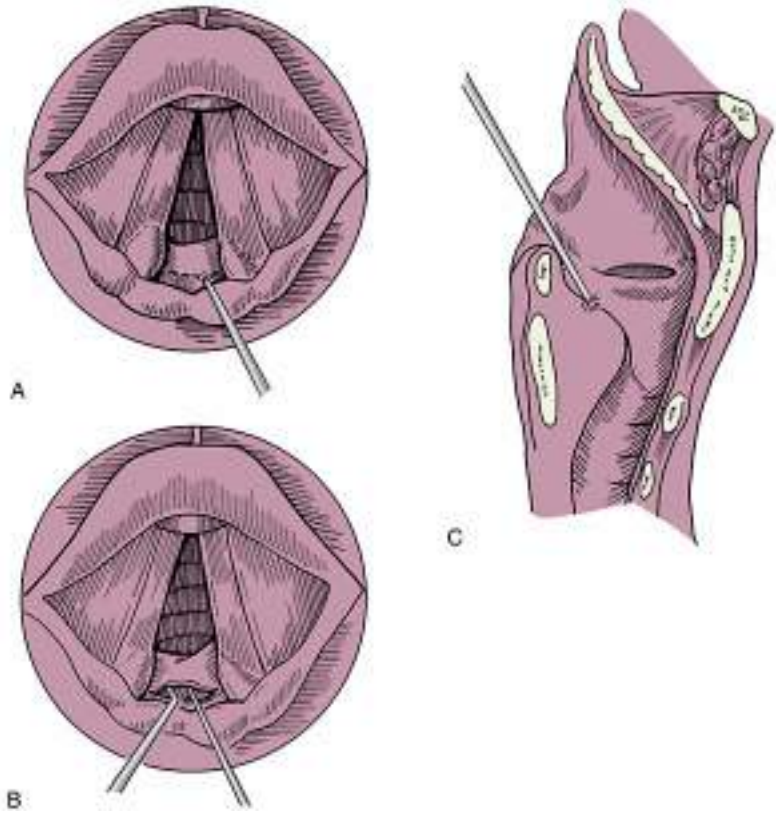
4) Subglottic stenosis

a) Acquired subglottic stenosis may be due to deposition of scar or malacia, or a combination of both.

b) Stenosis is characterized as thin or thick, partial or circumferential, and by the degree of stenosis.

c) The corrective procedure should strive to address the involved area while preserving the adjacent normal tissue.

d) Thin subglottic webs are amenable to endoscopic microsurgery.



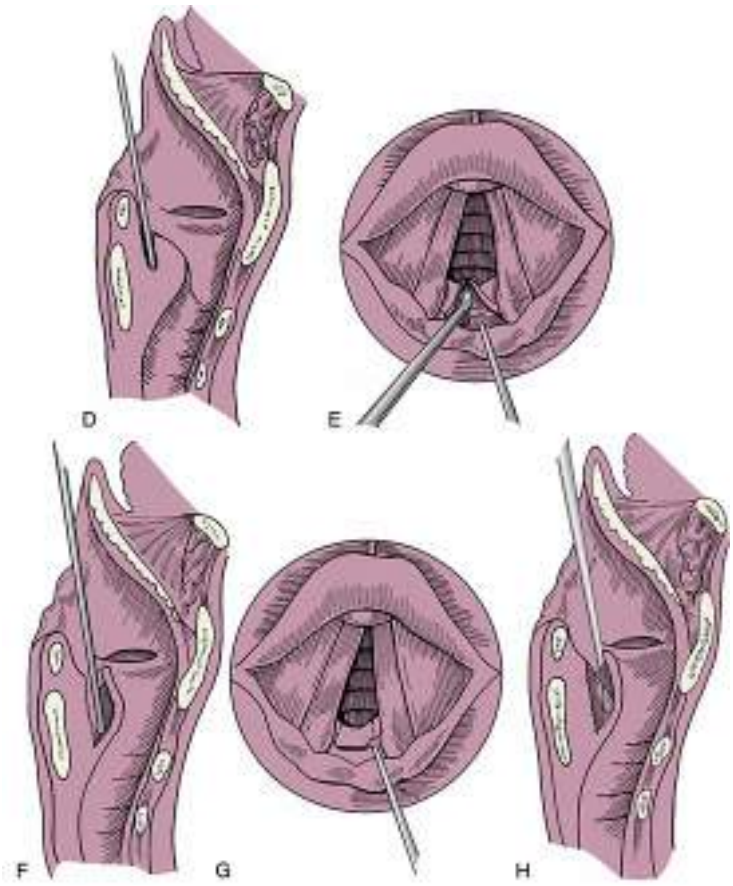


FIG. 10.17 **A** to **H,** Microtrapdoor flap to remove a posterior glottic web. Submucosal scar resection is completed with microsurgical instruments or laser vaporization while taking care to spare the overlying mucosa. From Bluestone CD, Stool SE [eds]: *Atlas of Pediatric Otolaryngology*. Philadelphia: WB *Saunders; 1995*, pp 498–499.

i) Jet ventilation or alternating intubation with apnea through a subglottiscope is useful to visualize the full extent of the lesion.

ii) Wedge excision with a laser or knife of the mucosal web at every quadrant or radial incisions augment the airway and preserve enough epithelium to prevent restenosis (Fig. 10.18).

iii) Balloon dilation is another treatment modality.

iv) Steroid injection is also often used because it may help to prevent restenosis and soften the stenosis that remains.

v) Application of mitomycin C is also performed (0.4

mg/mL × 4 minutes).

vi) Biopsy of the affected area is suggested at the time of the first surgery, especially if the etiology is unknown or suspicion for autoimmune or infectious causes exists.

e) When the stenosis is recurrent or resistant to endoscopic management, an external approach and cartilaginous augmentation procedure are necessary.

i) Cartilage from the nasal septum, thyroid ala, or rib may be harvested for use as a free graft.

ii) We prefer the latter because it is abundant, thicker, and easier to carve.

iii) A horizontal incision is performed in a skin crease over the cricoid cartilage.

iv) Subplatysmal flaps are elevated to expose the thyroid notch and upper trachea.

v) The strap muscles are separated in the midline and retracted to expose the laryngotracheal complex.

vi) A midline cricoidotomy is performed and extended into the upper two tracheal rings.

vii) The cricothyroid membrane is opened horizontally to facilitate lateral retraction of the cricoid chondrotomy segments.

viii) The mucosa is incised to expose the posterior mucosal surface of the larynx and trachea.

ix) A posterior cricoid chondrotomy is performed while preserving the integrity of the cricoarytenoid joints and postcricoid mucosa.

x) When the posterior glottis is scarred and stenotic, submucosal excision of the scar is performed.

xi) A free cartilage graft is carved to fit the posterior cricoid area (Fig. 10.19). Kirschner wires are passed into the graft to fix it in place.

xii) The same maneuver is used anteriorly.

xiii) A rigid fixation plate may be used to fix the anterior graft in place, which has been carved in a lock-and-key fashion (Fig. 10.20).

(1) Alternatively, Kirschner wires (24 gauge) can be passed through the cartilage graft and inserted through the cartilage of the receiving site (Fig. 10.21).

(2) The ends of the wires are then bent and secured in place with 28-gauge wire (Fig. 10.22).

xiv) The strap muscles and platysma are re-approximated with absorbable suture.

xv) A Penrose drain is left in place.

xvi) The skin is closed with staples, and a compressive dressing is applied.

f) A sternocleidomastoid myoperiosteal flap, as described by Friedman and Colombo, is an alternative technique for augmentation of the anterior cricoid ring and cervical trachea. This surgical approach and exposure are similar to those already described.

i) The sternoclavicular origin of the left sternocleidomastoid muscle is exposed through the cervical incision and mobilization of subplatysmal flaps (Fig. 10.23).

ii) If necessary (e.g., in a patient with a long neck), a second horizontal incision is performed closer to the clavicle.

iii) The sternal head is transected.

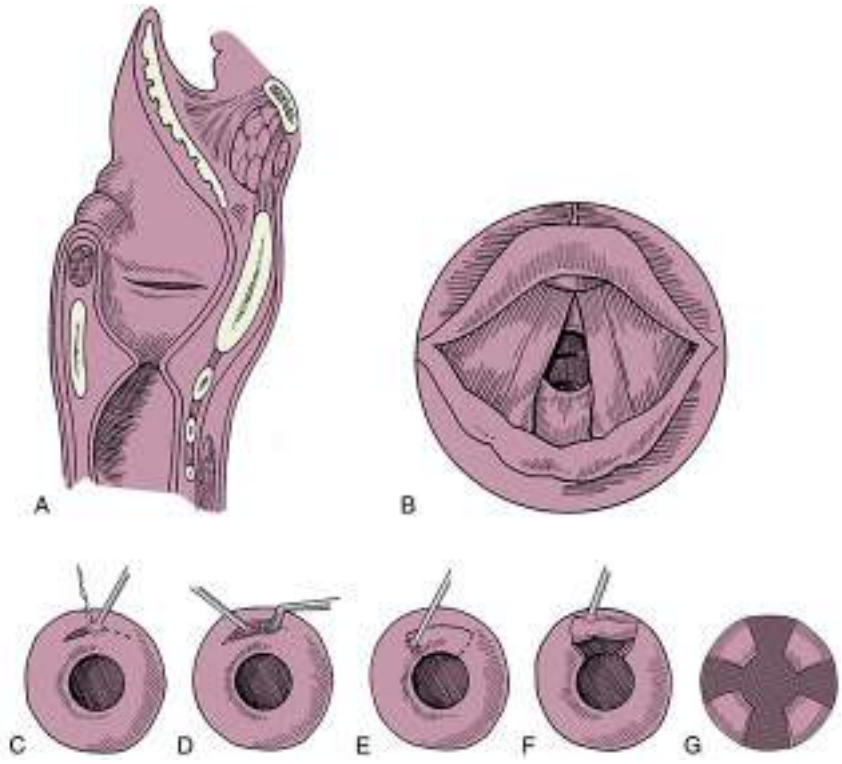

FIG. 10.18 **A,** Sagittal view of circumferential subglottic stenosis. **B** to **G,** Tracheal lumen after laser excision of a wedge-shaped area at four quadrants. It is not essential to excise four wedges; two or three wedges may be adequate for some patients. ***B*** to ***F,*** From Bluestone CD, Stool SE [eds]: *Atlas of Pediatric Otolaryngology*. Philadelphia: WB Saunders; 1995, p 509.

iv) The clavicular periosteum around the clavicular insertion is incised and elevated as a myoperiosteal flap (Fig. 10.24).

v) This flap is mobilized into the defect until tension-free closure can be achieved (Fig. 10.25).

vi) The flap is then sutured to the anterior edges of the cricoid and trachea over a Montgomery T-tube (Figs. 10.26 and 10.27).

vii) A Penrose drain is left in place.

viii) The wound is closed in multiple layers, and a compressive dressing is applied.

9. Common errors in technique

a. Airway management

1) Requires constant communication with the anesthesia team

2) All possibilities of airway management are discussed and prepared for, including emergency tracheostomy.

3) Avoids "loss of the airway"

b. Laser use

1) The surgeon needs to feel comfortable with using the laser, appropriate settings, laser safety precautions, and what to do in case of laser airway fire.

c. Laryngeal exposure

1) Optimal laryngeal exposure allows for improved understanding of the extent of stenosis and how much needs to be done.

a) Use largest laryngoscope possible to accommodate the patient's anatomy.

b) Use of angled telescopes provides a "three-dimensional" view of stenosis and surgical field.

d. Common errors in technique

1) Inadequate exposure of the laryngotracheal complex

2) Inadequate mobilization into the cervical area

3) Too much tension at the anastomosis

4) Excessive use of electrocautery over the tracheal surface leading to thermal injury and malacia

Postoperative Period

1. Postoperative management

a. Postoperative management of patients depends upon the type of surgery and the presence of a tracheostomy.

1) If the patient has a pre-existing mature tracheostomy tube, outpatient surgery is a possibility.

2) However, for all other patients undergoing airway surgery,

close observation in an intermediate or intensive care unit is necessary.

3) Patients with newly placed tracheostomy tubes will also require tracheostomy care and teaching.

b. The head of the bed is kept elevated 30 degrees to diminish the possibility of gastric reflux and to facilitate ventilation.

c. Humidified air is administered by face or tracheotomy mask, as appropriate.

d. Delivery of oxygen through hoses with a T-attachment of the tracheostomy tube is not recommended because they exert traction on the tracheostomy tube and elicit pain and cough.

1) Furthermore, such traction may break the peristomal sutures and lead to gross contamination of the wound with tracheal secretions.

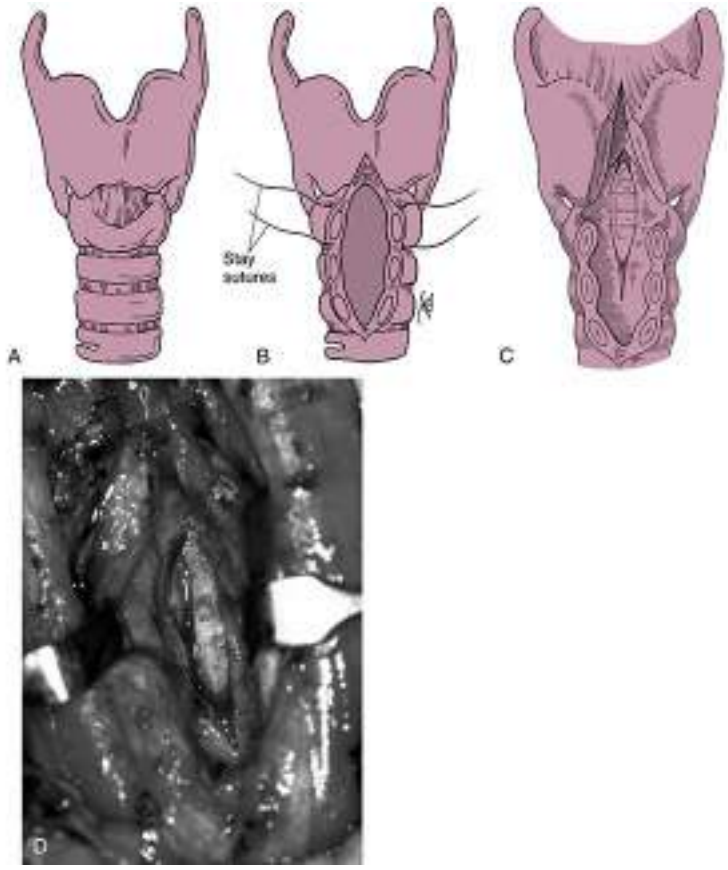

FIG. 10.19 **A** to **D,** Free cartilage graft (spindle shaped) to the posterior cricoid. The graft *(g)* is secured with Kirschner wires. A

and ***B,*** From Bluestone CD, Stool SE [eds]: *Atlas of Pediatric Otolaryngology*. Philadelphia: WB Saunders; 1995, p 467.

e. If the patient requires an open surgical repair, he or she should not be fed for the first 24 hours after surgery to diminish the possibility of nausea and vomiting, which may stress the endolaryngeal repair.

    1) A nasogastric tube for suctioning of stomach contents during the initial postoperative period and subsequent feeding can be considered, but it is associated with its own trauma and induces gastroesophageal reflux.

f. If a newly placed tracheostomy tube was necessary for airway maintenance, it may be downsized or changed to a cuffless tube no less than 72 hours after the procedure.

    1) This allows the formation of a tract, which greatly facilitates insertion of the next tube.

g. When an external approach was used, such as a laryngofissure, it is prudent to keep a cuffed tracheostomy tube in place for 5 to 7 days to prevent massive subcutaneous emphysema and contamination of the cervical wounds when air and secretions are insufflated through the endolaryngeal wound.

h. The tracheostomy tube should not be removed until the patient can breathe with the tracheotomy tube capped and still able to complete the physical activities he or she wishes to perform without dyspnea or restriction of activities for at least 24 hours.

i. Flexible laryngoscopy is an invaluable tool to ascertain the adequacy of the airway, as well as to monitor the healing process.

j. Patients who need a long-term tracheotomy tube or T-tube stent should be trained in the care of these artificial airways.

k. The patient's family must be aware of the possible complications and be proficient in emergency maneuvers, such as removal and reinsertion of the tracheostomy tube. In the case of T-tube stents, the companions should be taught how to remove the stent and insert a tracheostomy tube.

2. Complications

a. Airway

- The most dreaded complication after any kind of laryngeal surgery is loss of the airway.
- Airway compromise may ensue secondary to edema or hematoma within the soft tissues of the larynx, as in patients managed with endolaryngeal surgery without a tracheostomy, or may be due to plugging or accidental decannulation of the tracheostomy tube or T-tube.

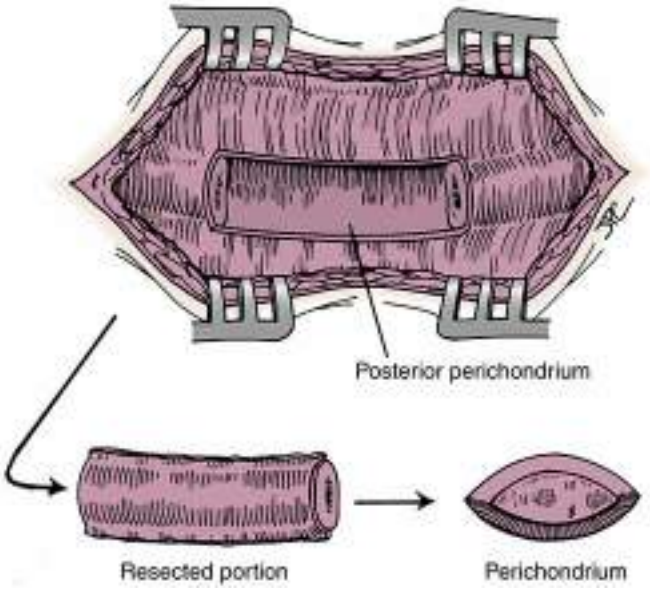

FIG. 10.20 Rib cartilage is carved to fit the anterior chondrotomy, as described by Zalzal and Cotton. From Bluestone CD, Stool SE [eds]: *Atlas of Pediatric Otolaryngology*. Philadelphia: WB Saunders; 1995, p 470.

  - The old dictum that prevention is the best treatment is most applicable during laryngeal surgery. Preventive measures have been addressed throughout this chapter.
- Patients in whom airway compromise develops after undergoing laryngeal surgery without a tracheostomy will benefit from humidified oxygen and should be provided with a surgical airway.
  - A tracheostomy is preferable to a cricothyroidotomy because the latter may produce more subglottic scar tissue and possibly complicate future management of the primary stenosis.

- Nevertheless, if an emergency airway is needed, cricothyroidotomy is the most expedient procedure.

- A mixture of 70% helium and 30% oxygen (heliox) may be used as a temporary measure.
  - Helium is less dense than nitrogen and flows with less friction and turbulence, thus diminishing the respiratory workload.
- Select patients can be managed with corticosteroids, racemic epinephrine, and humidified oxygen or heliox, under close monitoring, until the swelling resolves.

- A plugged tracheostomy tube is managed by removing the inner cannula, which may produce a patent outer cannula, by displacing or perforating the plug with a suction catheter or, ultimately, by removing and replacing the tracheostomy tube.
- During the early postoperative period, reinsertion of the tracheostomy tube after accidental or therapeutic decannulation is facilitated by traction on the traction sutures (see Chapter 19 – tracheostomy chapter).

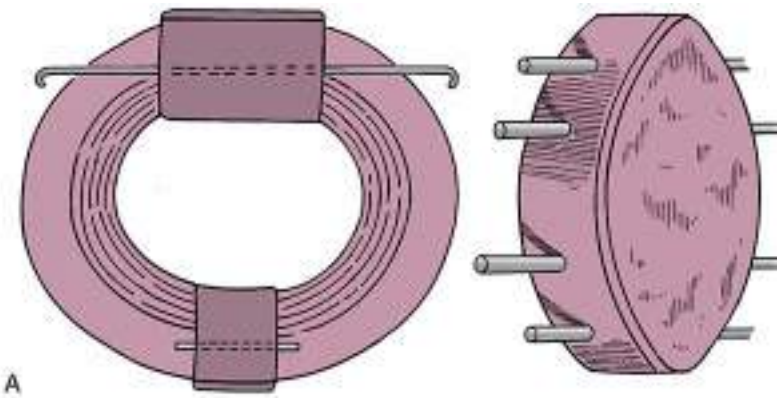

FIG. 10.21 **A,** Placement of wires through the free cartilage graft. An axial view of the anterior and posterior cartilage shows the graft in place. **B,** Placement of wires through the free cartilage graft.

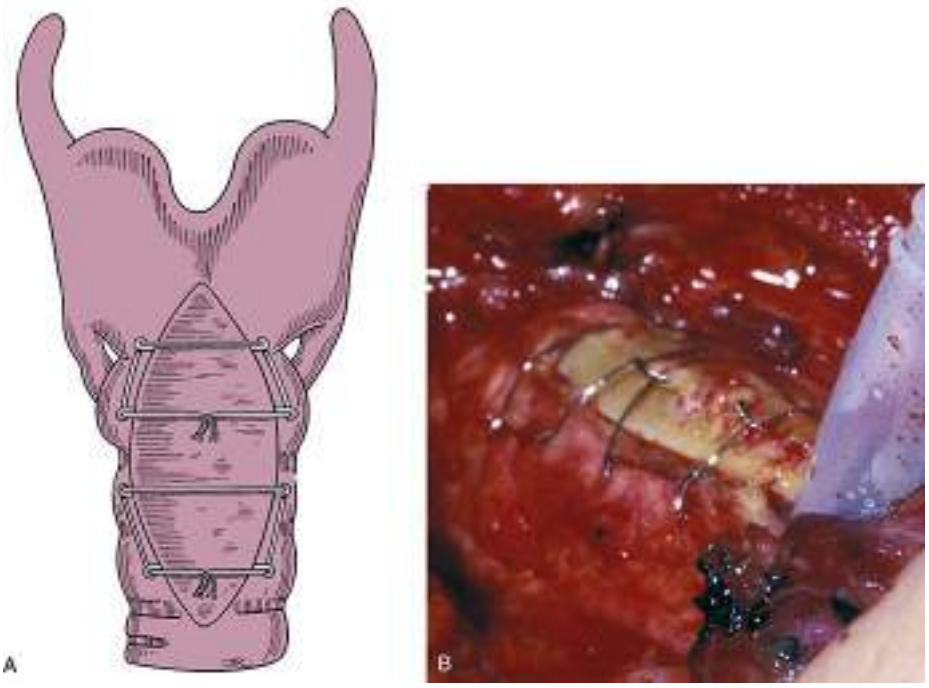

FIG. 10.22 **A,** Illustration and **B,** clinical photograph demonstrating the wiring technique on a free cartilage graft to reconstruct an anterior tracheal defect.

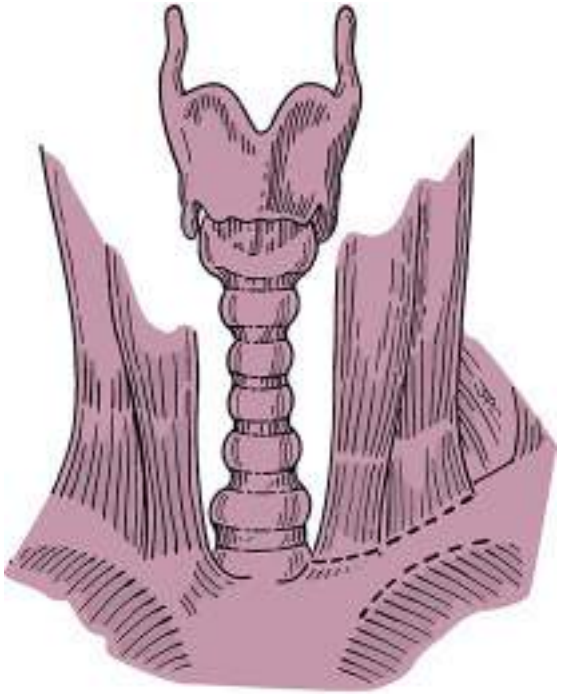

FIG. 10.23 Surgical exposure of the sternoclavicular head of the sternocleidomastoid muscle and the area of the stenosis.

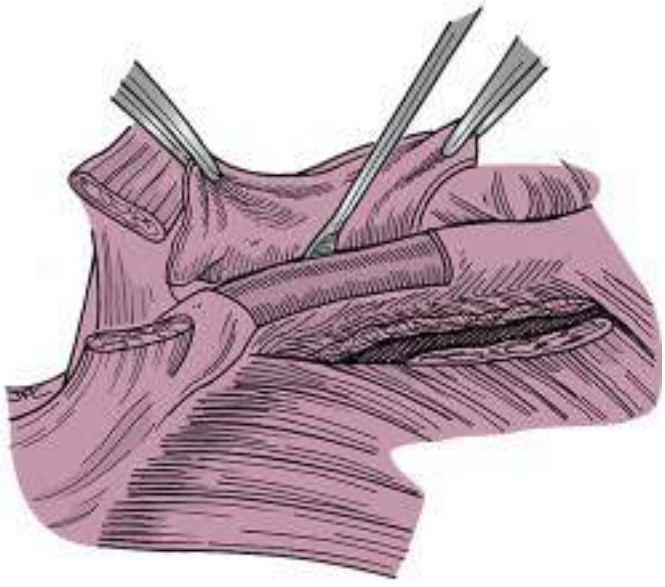

FIG. 10.24 The periosteum is elevated en bloc with the sternoclavicular head of the sternocleidomastoid muscle.

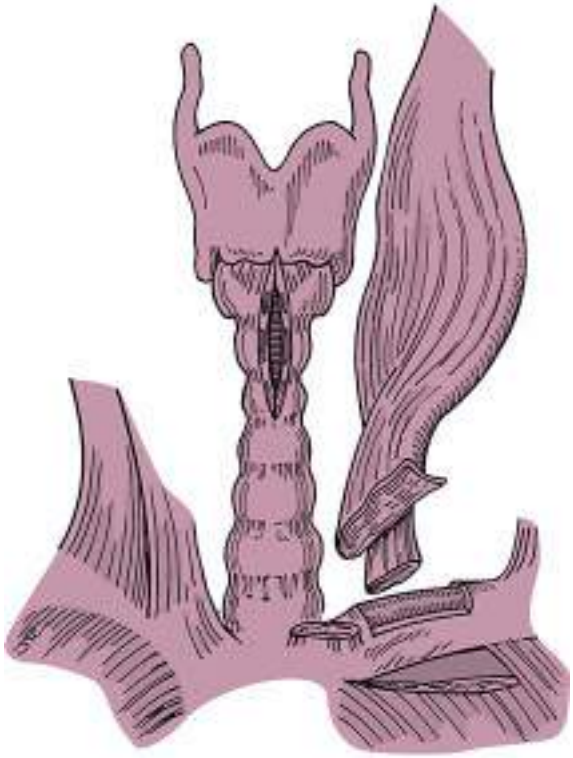

FIG. 10.25 The myoperiosteal flap is elevated. Branches of the thyrocervical trunk supplying the inferior aspect of the sternocleidomastoid muscles are usually sacrificed to enhance mobility of the flap.

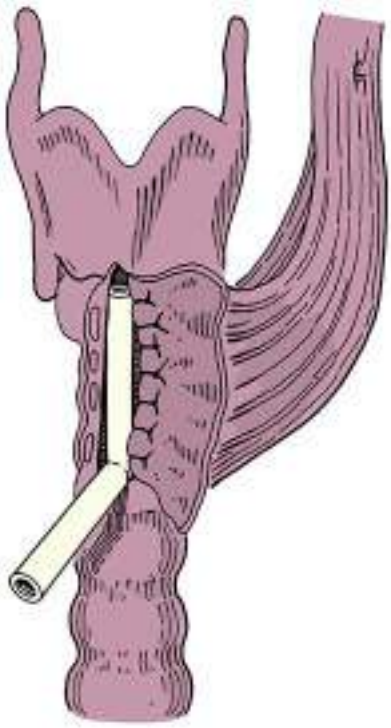

FIG. 10.26 The myoperiosteal flap is sutured to the defect. A Montgomery T-tube maintains the shape of the lumen and secures the airway.

  - The stay sutures bring the tracheal window close to the skin and thus provide better visualization of the opening and prevent a false passage.
- A suction catheter or endotracheal tube introducer may be used as a guide if the traction sutures break or the patient has a very thick neck that impairs direct visualization of the tracheal window.

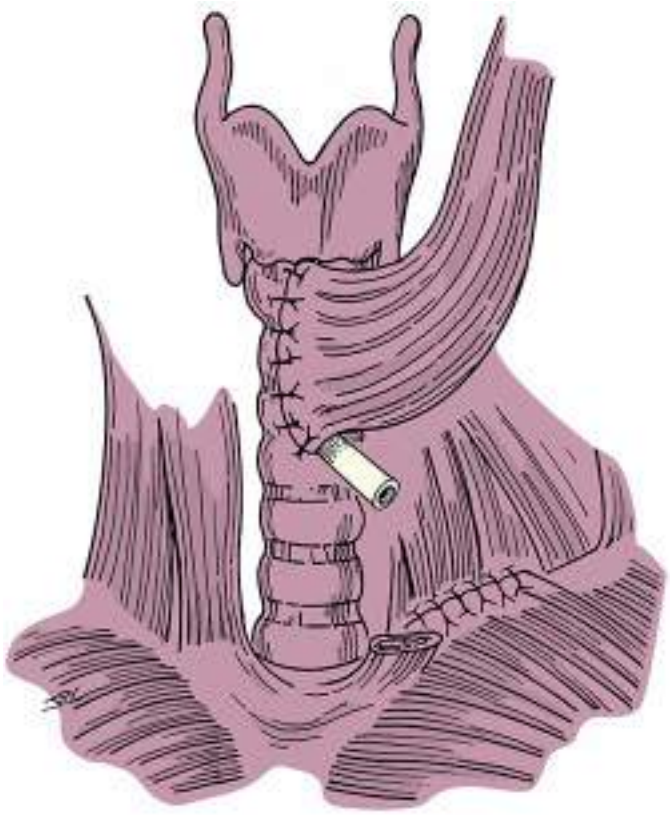

FIG. 10.27 The myoperiosteal flap has been sutured to the defect.

- If a flexible laryngoscope or bronchoscope is rapidly available, it provides direct visualization of the trachea and is a safer guide than any rubber catheter.

- Plugging of a T-tube stent with mucus deserves special consideration because it does not have the safety mechanism provided by a double cannula.
  - Even if the mucous plug can be displaced or perforated with a suction catheter, patency of the tube should be ascertained by direct examination with a flexible scope.
  - If the mucous plug cannot be removed with help of the laryngoscope, the T-tube should be removed and replaced with a tracheostomy tube, inserted as previously described.
  - The T-tube stent can be reinserted after the airway is stabilized.
    - Nevertheless, reinsertion has to be undertaken with the patient under general anesthesia and guided by visualization

through a direct laryngoscope.

b. Subcutaneous emphysema

- Subcutaneous emphysema is the result of insufflation of air into the soft tissues through a laryngeal wound during exhalation.
  - The air is usually reabsorbed without consequence.
  - Nonetheless, it has to be remembered that this air may also be accompanied by secretions (i.e., contamination), so antibiotics are recommended to prevent wound infection.
- Subcutaneous emphysema may be massive and associated with pneumomediastinum.
  - In infants, this may produce respiratory compromise, whereas in adults, subcutaneous emphysema, although unsightly, has no adverse consequences.

c. Infection

- Adequate wound drainage, via soft rubber drain or suction drain, is of utmost importance for the prevention of infection after open surgical procedures.
  - The drain should be kept in place until the tissue flaps have healed sufficiently to prevent accumulation of fluid.
- When postoperative wound infections occur, it may or may not be associated with a laryngocutaneous fistula.
  - The most significant factor influencing the outcome of any wound infection is adequate wound drainage.
  - If the rubber drain is still in place, it should be retained until there is minimal or no drainage.
  - Systemic antibiotics with a wide spectrum against oral flora (e.g., clindamycin) are administered to prevent sepsis.
- Bacterial tracheitis must be considered when patients exhibit increased productive cough or pain after surgery.
  - Diagnosis is confirmed with tracheoscopy.
  - Treatment options include nebulized antibiotics with or without steroid (e.g., ciprofloxacin/dexamethasone) and/or oral

antibiotic to cover common oral flora, including methicillin-resistant *Staphylococcus aureus* (MRSA) (e.g., clindamycin).

- If severe, close monitoring with in-patient treatment with intravenous clindamycin or ceftriaxone is needed.

d. Laser injury

- Adherence to the laser safety precautions outlined earlier in this chapter is paramount in preventing laser-related injuries.
- Airway fire is the most catastrophic complication, and multiple actions occur simultaneously:
  - Anesthesia gases are stopped, removing the oxygen source.
  - Endotracheal tube is removed.
  - A bulb syringe filled with saline solution should always be available during all laser cases and used to extinguish the fire.
  - Bronchoscopy is then performed to access tracheobronchial injury.
  - The patient is re-intubated and admitted to the intensive care unit for close observation.

e. Equipment malfunction

- Dilating balloon malfunction rarely occurs but could result in prolonged complete airway obstruction. In the case of inability to deflate the balloon, removal of the syringe from the insufflation device is recommended, with manual deflation.
  - Only as a last resort, the balloon can be punctured, allowing its deflation and removal.
    - If this is needed, the procedure should be followed by a bronchoscopy to confirm no portion of the balloon remains within the airway.
- There are different types of balloons, compliant and noncompliant. Noncompliant balloons can exert pressures that overcome the static resistance of the cricoid cartilage.
  - With inappropriate dilation diameter, cricoid fracture can occur.
- All balloons result in some degree of mucosa tear with inflation, as

do rigid dilators.

- Appropriate diameters will maximize treatment of stenosis while minimizing extent of mucosal injury.

3. Alternative management plan

   a. Advances in technology now allow for awake, in-office steroid injections for airway stenosis, particularly supraglotttic and subglottic. Repeated steroid injections may be helpful in decreasing the rate and severity of re-stenosis. Research in this area is ongoing.

Discussion

Evidence-Based Medicine Question

What is the long-term risk of a tracheostomy, and what is the best paradigm to manage airway compromise after decannulation?

Most patients do well after tracheotomy decannulation; however, at times, a patient is dyspneic. This mandates evaluation, including a complete endoscopic evaluation of the glottis, subglottis, and trachea. It is preferable to complete the examination while the patient is awake, thus providing a "dynamic airway evaluation." This allows the surgeon to observe the motion of the tracheal walls during activities such as deep breathing and coughing, which may lead to tracheal collapse and worsen breathing.

A proper glottal airway should have been confirmed before capping trial and decannulation. This is easily achieved by flexible nasolaryngoscopy in the office. Visualization through the tracheostoma (if still present) is performed, both looking retrograde to the infraglottic region and caudally to the trachea. In the office, visualization of the area between the glottis and subglottis is most challenging. This is critical because granulation tissue is one of the most common causes of airway obstruction in this area. If this tissue is obstructing the airway, the treatment is to remove or cauterize the granulation tissue or recannulate with a tracheostomy tube and, if necessary, with subsequent treatment in the operating suite.

To best assess whether the tracheostomy itself has resulted in tracheal

stenosis or tracheomalacia ("A-frame deformity"), one should perform a flexible bronchoscopy either in the office or in the operating suite. CT imaging is also helpful to ascertain whether the "stenosis" seen on endoscopy is due to thickening of the tracheal cartilage/mucosa (i.e., scar) or tracheomalacia. Imaging will provide more accurate information about the length of stenosis.

Tracheal stenosis presents as collapse or thickening of the cartilage and/or mucosa, which may occur after cuff overinflation with subsequent loss of capillary perfusion and tracheal cartilage sclerosis. This may be treated initially endoscopically as described in this chapter but may eventually require resection.

Tracheomalacia is more common than true tracheal stenosis after tracheostomy. It is the result of loss of the anterior tracheal wall through which the tracheotomy tube was placed, resulting in an A-frame deformity if the stenosis is at the level of the stoma. If the obstruction is distal, then it is more likely related to cuff overinflation and subsequent loss of capillary perfusion and thus cartilage necrosis/malacia. On imaging, the tracheal walls may appear to be of normal caliber. Treatment is challenging because endoscopic resection may not correct the problem, if the problem is related to weakness rather than the thickness of the wall. These patients may be treated with a tracheal T-tube, if they are amenable to having a stoma. If this is not feasible, then an open resection and anastomosis are usually required. Of note, there are no data showing that open or percutaneous tracheostomy has differing rates of tracheomalacia. Anecdotally, the incidence of tracheomalacia seems to be rising, but this may be due to more patients surviving their acute initial illness.

Editorial Comment

The management of laryngeal stenosis is complex and will depend on the presence and severity of symptoms, needs of the patient, age, and sites affected, among many other factors. Therefore its treatment ranges from observation, to dilatation (select cases of thin congenital webs), to endoscopic microsurgical techniques, or to major laryngeal reconstruction.

Review Questions

1. Acquired laryngeal stenosis may result from
   a. External or iatrogenic trauma
   b. Systemic diseases
   c. Infections
   d. Neoplasms
   e. **All of the above**
2. The area of the larynx most susceptible to stenosis is
   a. Epiglottis
   b. False vocal folds
   c. Glottis
   d. **Subglottis**
   e. a and b
3. Patients with laryngeal stenosis may present with
   a. Difficulty swallowing or aspiration
   b. Hoarseness
   c. Shortness of breath or dyspnea on exertion
   d. Stridor
   e. **All of the above**
4. Factors associated with laryngeal stenosis after intubation include
   a. Anatomic differences between the sexes
   b. Duration of intubation
   c. Endotracheal tube size
   d. Foreign body reaction to the tube

e. Mechanical pressure and friction

f. **All of the above**

5. Contraindications for laryngeal reconstruction include

a. Current smoker

b. Poor overall health

c. Uncontrolled anticoagulation

d. Uncontrolled diabetes

e. **All of the above**

7. The most common complication of tracheostomy is

a. Hematoma

b. Loss of airway

c. Pneumonia

d. **Tracheal stenosis**

e. Tracheoesophageal fistula

8. The management of congenital stenosis includes

a. Observation

b. Reconstructive surgery

c. Tracheostomy

d. b and c

e. **All of the above**

Transoral CO_2 Laser Microsurgery for Cancer of the Larynx

Johan Fagan

Introduction

Transoral CO_2 laser microsurgery is a well-established treatment for cancer of the larynx, particularly for T_1 or T_2 glottic cancer. Alternative treatment options include radiation therapy or hemilaryngectomy for glottic cancer and supraglottic or supracricoid laryngectomy for supraglottic cancers. The advantages of using CO_2 laser with an operating microscope include microsurgical precision, excellent intraoperative detail, and a dry surgical field. Swallowing and speech outcomes exceed that of external surgical approaches and radiation therapy. Other advantages include patient convenience, savings both on direct and hidden patient costs, reserving radiation as potential therapy for recurrence or for second primaries, and that patients who recur are more likely to have larynx preservation.

Surgeons must familiarize themselves with the laser machine, its settings and delivery system, and its tissue effects before attempting to use it clinically and should hone their skills on animal tissue and then small tumors. They must also understand the safety aspects relating to CO_2 laser surgery.[1,2]

Key Operative Learning Points

- Surgeons without prior experience using a laser should start with simpler cases (e.g., smaller cancers of the aryepiglottic fold, supraglottis, or medial wall of the piriform fossa).

- Spot size, focus, power, and mode (super pulse [SP]/pulsed/continuous) are important to achieve the desired effects and may be altered during an operation for different tissues or to achieve coagulation, cutting, or vaporization effects.
- Check the alignment of the aiming beam with the laser beam.
- Avoid past-pointing, as this may cause laser fires. Be aware of reflection of the laser beam off of instruments and scopes, and ensure that the backstop is correctly positioned to protect the endotracheal tube.
- Apply constant traction to tissues to define dissection planes and facilitate dissection.
- Maintain a relatively slow, smooth hand-speed.
- Use Ligaclips, not diathermy, for large vessels to avoid postoperative bleeding.
- Minimize tissue injury by employing super pulse (SP) as opposed to continuous mode.
- One may have to resect structures (e.g., suprahyoid epiglottis) to improve access.
- Debulking the cancer allows one to create space within which to move tissues around.
- Distinguish the cancer from normal tissue by transecting it and checking pliability (cancer tissue is rigid) and colors of tissues (cancer chars and is brown/black when transected) (Fig. 11.1).
- Bread slice (Fig. 11.2; see also Fig. 11.1) the cancer to determine its depth and to ensure an adequate deep resection margin.
- Do not lose orientation of specimens; pin specimens to cork that is placed in formaldehyde and make a detailed drawing for the pathologist and in the patient's notes of the precise location of resected specimens.
- What constitutes an adequate resection margin is controversial and might determine whether to return a patient to the operating room for an additional resection, whether to advise close surveillance, or whether to recommend adjuvant radiation therapy. Factors include

tumor site, size, function (voice and swallowing), patient fitness, extent of the initial resection (e.g., onto cartilage or carotid), not knowing precisely where the positive or close margin is located, and reliability of follow-up.

- Pathologists are reticent to do frozen sections on very small resections (e.g., T_1 glottic cancer).
- A surgeon's impression of the adequacy of a resection as seen through the microscope is important; one may adopt a watchful waiting approach even when the cancer is reported to be "present at the margin" with the knowledge that cells are denatured and killed at the margin by the laser.
- Follow laser safety procedures (Table 11.1).

Preoperative Period

Preoperative assessment is directed at the patient's general fitness for surgery, counseling about risk factors, the ability to cope with a degree of aspiration (supraglottic cancer resections), and to determine whether the cancer is amenable to endoscopic laser resection.

History

1. History of present illness
   a. Risk factors: Smoking
   b. Pulmonary status: Aspiration, smoking
   c. Pointers to synchronous primaries
2. Past medical history
   a. Previous squamous cell carcinomas
   b. Previous radiation to head and neck
3. Medical illness
   a. Ability to deal with aspiration and dysphagia
   b. Fitness for surgery

4. Medications
   a. Anticoagulants
   b. Allergies to antibiotics
5. Mental and social status
   a. Ability to overcome challenges related to speech and swallowing
   b. Ability to give informed consent
   c. Employment and hobbies: May be affected by speech or swallowing impairment

TABLE 11.1

Laser Safety Precautions and Management of Laser Fires

Safety Precautions (Surgical)—Develop a Check LIST Which Includes

- Place laser warning signs outside the operating room.
- Cover windows and securely close doors while the laser is "on" or in "standby" mode.
- Personnel and patients must use eye protection specific for CO_2 laser; it should also be available at entrances to the room; standard prescription eyeglasses are sufficient for CO_2 laser; side-guards are recommended.
- Tape the patient's eyes shut and cover them with moist pads.
- Do not use alcohol or flammable cleaning prep solutions in the operating room.
- Use flame retardant materials and drapes.
- Keep an open container filled with water or saline immediately available to douse a laser fire.
- Place moistened swabs/sponges adjacent to the path of the laser beam to protect surrounding tissues and structures.
- Minimize the possibility of a "blow-torch effect" by carefully protecting endotracheal tubes with wet cloth or neuro patties.
- The locking key to laser machine should be accessible only to persons trained in the use of laser; it should not be stored in or on the laser machine but kept in secure location; some lasers have electronic keypads.
- Keep the laser turned off or in "standby" mode unless in use.
- Instruments should have brushed, beaded, or sand-blasted surfaces to prevent reflection of the laser beam.

Safety Precautions (Anesthetic)

- "Nonflammable" endotracheal tubes may be used. (All tubes are flammable.)
- Fill the cuff of the endotracheal tube with saline colored with methylene blue.
- Maintain inspired oxygen (FiO_2) as low as clinically feasible (<30% FiO_2).
- Wait a few minutes for the oxygen concentration in the airways to drop before approving activation of the laser.
- Avoid nitrous oxide if possible.

Laser Airway Fire

- Turn off laser at emergency switch.
- Turn off all anesthetic gases.
- Remove swabs and flammable materials from the airway.
- Immediately remove the endotracheal tube.
- Pour saline into the airway.

With permission from Apfelbaum JL, Caplan RA, Barker SJ, et al: Practice advisory for the prevention and management of operating room fires: an updated report by the American Society of Anesthesiologists Task Force on Operating Room Fires. Anesthesiology 118(2):271-290, 2013.

Indications

- Biopsy and debulking of cancer causing airway obstruction
- Biopsy cancer located deep in ventricle or false vocal cord by cutting through false vocal cord
- Resect cancer of the larynx
- Treat sequelae of CO_2 laser or radiation (e.g., laryngeal stenosis, edema, glottic web).

Contraindications

1. Patient factors
   a. Medically unfit
   b. Inability to give informed consent
   c. Inability to overcome challenges relating to speech and swallowing
2. Tumor factors
   a. Unresectable (e.g., invading thyroid cartilage)
   b. Distant metastases
   c. Unacceptable morbidity
3. Surgical factors
   a. Inadequate expertise
   b. Inadequate surgical access

Preoperative Preparation

1. Evaluations by
   a. Surgeon
   b. Anesthesiology (if airway is compromised)
   c. Speech and swallowing therapist
2. Discontinue anticoagulation drugs (except for minor resections, e.g., T_1 glottic cancers).

Operative Period

Anesthesia

The surgeon and anesthesiologist must agree on how to maintain an airway for the specific patient. The principal challenges are to use an endotracheal tube that permits the surgeon to work in the confined space of the larynx and to eliminate the risk of laser fires.

- Airway options
  - Endotracheal intubation (nasal or oral)
  - Intermittent jet ventilation
  - Intermittent extubation with lasering during apneic intervals
  - Open airway
  - Spontaneous breathing with anesthetic gases administered through the suction port of the laryngoscope
  - Intravenous anesthesia
  - Tracheostomy
- Endotracheal tube: All tubes are flammable; therefore the problem is not the type of tube but perforating the tube when the O_2 concentration in the tube is too high. I use a regular plastic tube but protect it with a strip of wet cloth (Fig. 11.3) or with neuro patties. The cuff is filled with saline to flood the airway if the cuff is punctured.
- Avoid nitrous oxide if possible.
- Maintain inspired oxygen FiO_2 less than 30%.

Positioning

- Position the anesthetic machine at the patient's feet to create space at the patient's head.
- Position the patient supine with neck extended.
- Insert a gum guard to protect the upper teeth.

Perioperative Antibiotic Prophylaxis

- No antibiotics are necessary.

Monitoring

- Implement routine anesthesia monitoring.

- Maintain FiO_2 at less than 30%.

Instruments and Equipment to Have Available (Fig. 11.4)

Adequate exposure of the cancer is critical; hence a variety of laryngoscopes and pharyngoscopes with integrated suction channels to remove smoke is essential. Instruments must have mat or black surfaces to prevent reflection of the laser. Two suction systems are required, one attached to the laryngoscope to extract smoke from the surgical field and the other attached to the handheld suction tube.

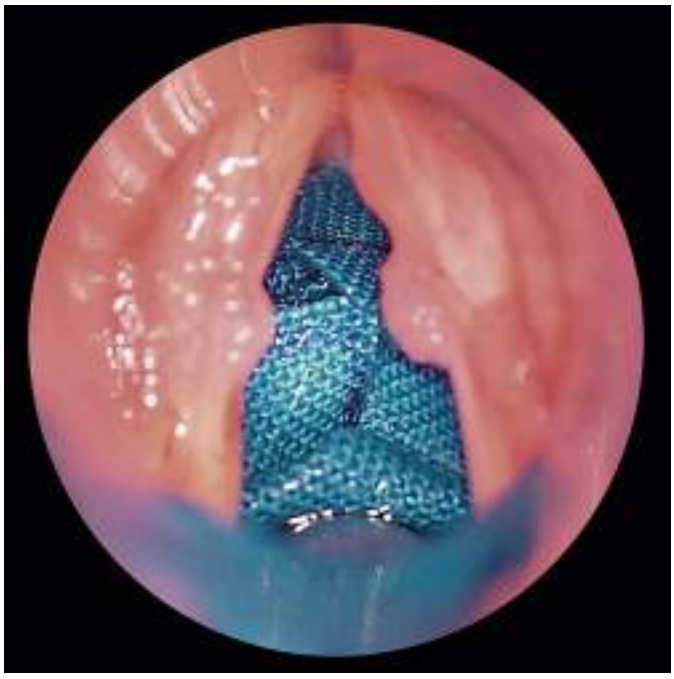

FIG. 11.3 Tube protected by strip of wet cloth. With permission from Fagan JJ, Steiner W: Transoral CO_2 laser microsurgery for cancers and other pathology of the upper aerodigestive tract. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/CO2%20laser%20transoral%20microsurgery%20_TLM_.pdf

FIG. 11.4 Basic set for CO_2 laser microsurgery: Laryngopharyngoscope (a), oropharyngoscope (b), laryngoscopes (c and d), light carrier (e), laryngoscope holder (f), graspers (g), insulated suction (h), microforceps (i), coagulation forceps (j), diathermy lead (k), and Ligaclip applicators to left and right (l). Courtesy of Karl Storz.

- Operating microscope with fitting for micromanipulator
- CO_2 laser machine with micromanipulator
- Rigid 0 degree endoscope to examine the subglottis if microscopic view is inadequate
- Safety glasses
- Distending laryngopharyngoscope to access the hypopharynx and supraglottic larynx
- Large laryngoscope to access endolaryngeal, upper tracheal, and hypopharyngeal lesions
- Small laryngoscope for difficult exposures such as anterior commissure, subglottis, and upper trachea
- Light carrier
- Laryngoscope holder
- Grasping forceps (different sizes)
- Microforceps (small vocal fold lesions)

- Coagulation forceps
- Suction tubes (insulated for diathermy)
- Diathermy cable
- Ligaclip applicators (left and right)
- Adjustable supporting plate for laryngoscope holder (not essential)

Key Anatomic Landmarks (Depends on Surgical Approach)

- Endoscopic (inside-out) laryngeal anatomy
- For cancer of the glottis
  - Vocal ligament
  - Thyroarytenoid muscle
  - Inner lamina of thyroid cartilage
  - Vocal process of arytenoid cartilage
- For anterior commissure ± subglottic cancer
  - Vocal ligament
  - Thyroid perichondrium
  - Inner lamina and inferior margin of thyroid cartilage
  - Cricothyroid membrane
  - Superior margin of cricoid cartilage
  - First tracheal ring
- For supraglottic cancer
  - Vallecula
  - Epiglottis
  - Pre-epiglottic adipose tissue
  - Superior laryngeal arteries
  - Superior rim of thyroid cartilage

- Arytenoids
- Aryepiglottic fold
- Pharyngoepiglottic fold

Prerequisite Skills

- Endoscopic anatomic knowledge of larynx
- Gain adequate access
  - Selection of appropriate laryngoscopes
  - Positioning of laryngoscopes
- Obtaining hemostasis
- Familiarity with CO_2 laser microsurgery techniques and safety
- Familiarity with operating microscope
- Anesthetist familiar with laser techniques (discussed later)

Operative Risks

- Dental, mucosal, and spinal hyperextension injury
- Airway fires
- Laser burns to face (if not properly covered with wet drapes)

Surgical Technique

- Place patient in supine position with neck extended.
- Check that the head is resting on the bed and not suspended in mid-air.
- Check for loose or crowned teeth.
- Insert gum guard.
- Panendoscopy
- Insert, position, and suspend laryngoscope.

- Surgical exposure is critical, and it may prove impossible to proceed due to poor access.
- Insert laryngoscope/laryngopharyngoscope/oropharyngoscope and expose the cancer.
- Different scopes may be required during an operation.
- Suspend scope with laryngoscope holder.
- It may be necessary for the assistant to press on the larynx, or to place tapes attached to the operating table across the neck to displace the larynx posteriorly for maximum exposure.

- Surround laryngoscope with moistened towels or cotton to avoid fire or burns to the patient's face.
- Bring in the microscope with focal length set at 400 mm.
- Detailed examination of laryngeal cancer (may need to use endoscope)
- Make a decision as to whether access is adequate, whether the cancer is resectable, and whether an endoscopic approach is appropriate.
- Attach the micromanipulator and focus the laser beam.
- Set the CO_2 laser according to the type of tissue to be lasered, the desired depth of the cut, the need for hemostasis, and the need to avoid excessive heating of tissue.
  - Laser power density (PD)
    - Watts
    - Laser spot size
  - Total duty cycle (time that laser interacts with tissues)
    - Continuous wave: Continuous emittance of laser energy
    - Pulsed settings: Discrete pulses; lengths, frequencies, and time intervals between pulses can be selected.
      - Single pulse: Single energy bursts every time foot pedal depressed
      - Repeat pulse: Repeated energy bursts while foot pedal depressed

- Super pulse (SP): Several thousand energy bursts of very high peak power laser pulses per second while foot pedal depressed. Bursts are spaced apart for tissue cooling between pulses and to reduce thermal damage.

- Keep in "safe mode" until ready.
- Attach suction to suction port of laryngoscope.
- Pack wet protective linen or neuro patty around the endotracheal tube.
- Plan surgical approach.
- Perform surgery under high magnification.
- Debulk if required.
- Bread slice. (Fig. 11.2).
- Resect the cancer in a piecemeal fashion.
- Orientate specimens for pathologist.

Glottic Cancer

The challenge is to strike the correct compromise between adequate resection and quality of the voice. Voice rest is not required after surgery except for superficial defects of the membranous cord.

TABLE 11.2

European Laryngological Society Classification of Endoscopic Cordectomy

Cordectomy	Type	Resected Tissue
Subepithelial	I	Epithelium
Subligamental	II	Epithelium, Reinke's space, vocal ligament
Transmuscular	III	Through vocalis muscle
Total	IV	—
Extended	Va	Contralateral vocal fold, anterior commissure
	Vb	Arytenoid
	Vc	Subglottis
	Vd	Ventricle

With permission from Remacle M, Eckel HE, Antonelli A, et al: Endoscopic cordectomy. A proposal for a classification by the Working Committee, European

Laryngological Society. Eur Arch Otorhinolaryngol 257(4):227-231, 2000.

Classification of Laser Cordectomy

The European Laryngological Society proposed a useful classification of endoscopic cordectomy in 2000 (Table 11.2, Fig. 11.5).[3]

One can anticipate an excellent speaking voice following Type I or subepithelial resection of T_{1s} and T_1 cancers of the membranous vocal fold. Following Type II cordectomy a "new cord" is formed by a scar band and results in a good, though not quite normal, quality voice, whereas Type III cordectomy generally leads to an adequate speaking voice. Type IV cordectomy, which extends onto thyroid cartilage, has a less predictable voice outcome, with some patients phonating using the false vocal cords.

Superficial Lesions of the Membranous Cord

Resection margins of less than 1 mm are acceptable; as with close follow-up, recurrences can be resected without adversely affecting oncologic outcome. Set the laser at its smallest spot size, low power (1.5 to 3 W) and continuous SP mode; this allows a very precise dissection with minimum lateral thermal injury to the tissues. Following the initial incision, the cut edge of the epithelium is grasped with microforceps, and the cancer is dissected off of the vocal ligament.

Deeper Lesions of Membranous Cord

With deeper cancers requiring Types II to IV resections, the objective is to do an adequate resection (>1 mm margin) and to maintain a speaking voice. Set the laser at its smallest spot size, power of 3 to 5 W, and SP mode. Use the bread-slice technique to determine the depth of the cancer and the deep resection plane, and remove it in sections (Figs. 11.6 to 11.8). It is generally easiest to remove the posterior segment first, especially if access to the anterior commissure is poor.

Bleeding may be encountered, especially when dissecting adjacent to or below the anterior commissure and lateral to the vocal process. Small vessels may be coagulated by defocusing the laser beam. Brisk bleeding

is controlled using monopolar or bipolar coagulation forceps.

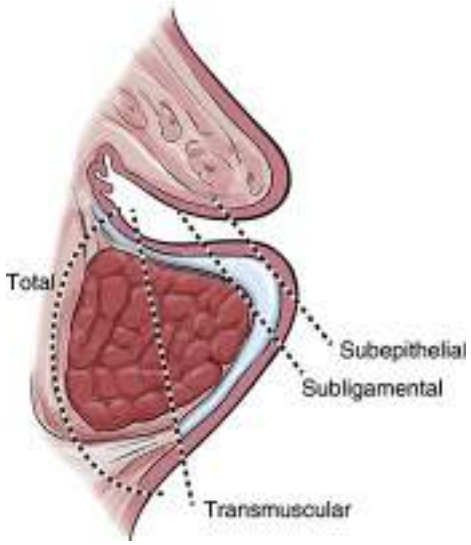

FIG. 11.5 Classification of cordectomy. With permission from Remacle M, Eckel HE, Antonelli A, et al: Endoscopic cordectomy. A proposal for a classification by the Working Committee, European Laryngological Society. Eur Arch Otorhinolaryngol 257(4):227-231, 2000.

Anterior Commissure

Although some surgeons consider involvement of the anterior commissure to be a contraindication for laser resection, I do not consider all anterior commissure cancers to be a contraindication for laser excision. The following need to be considered when managing cancers of the anterior commissure with the laser:

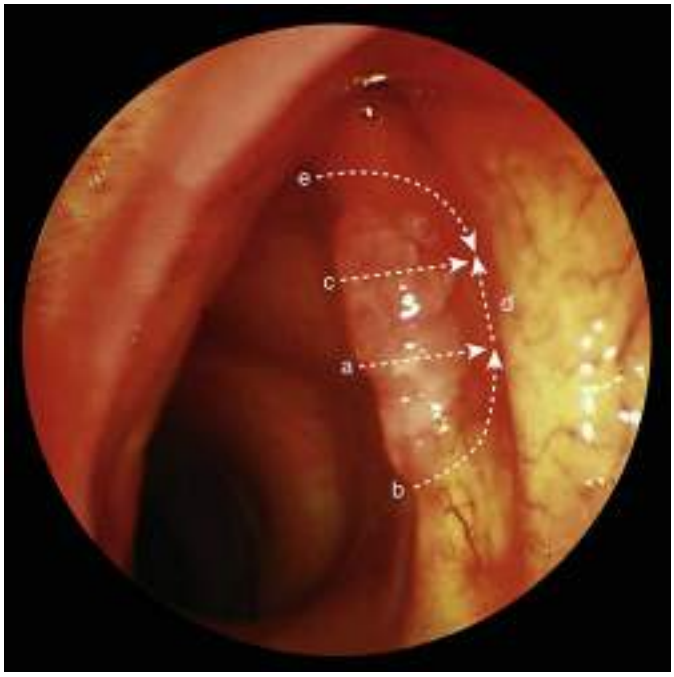

FIG. 11.6 Example of sequence of incisions for a partial cordectomy. a-e indicates example of sequence of laser incisions. With permission from Fagan JJ, Steiner W: Transoral CO_2 laser microsurgery for cancers and other pathology of the upper aerodigestive tract. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/CO2%20laser%20transoral%20microsurgery%20_TLM_.pdf

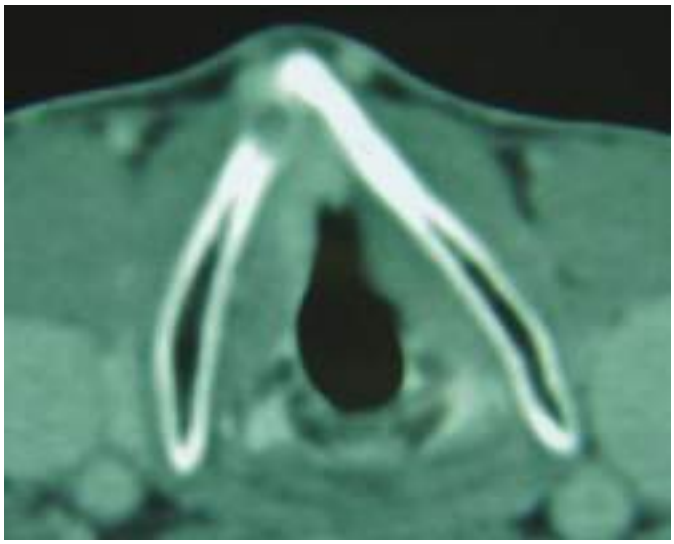

FIG. 11.9 Extension through the thyroid cartilage.

- Proximity to the thyroid cartilage: This raises the possibility of cartilage invasion and makes it impossible to obtain wide margins (Fig. 11.9). I do not routinely obtain imaging but follow the tumor during the resection and even resect cartilage with the CO_2 laser if necessary (Fig. 11.10). Once the vocal ligaments have been freed from the cartilage with the laser, the surgeon strips the tissues in a plane deep to perichondrium up to the inferior margin of the cartilage and then defocuses the laser and "sterilizes" the cartilage of any residual cancer cells (Fig. 11.11).
- Webbing of the anterior commissure: This results in poor voice quality and occurs when the anterior ends of both vocal cords are denuded of mucosa or resected. This can be avoided by doing a two-stage resection, initially resecting only up to the midline and completing the resection of the second vocal cord cancer approximately a month later. It may be difficult to correct a web. Simply dividing the web with laser invariably leads to a new web. One can divide the web with the laser and endoscopically place a silastic keel between the vocal cords to allow the cut edges to reepithelialize.

Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/CO2%20laser%20transoral%20microsurgery%20_TLM_.pdf

Supraglottic Cancer

Supraglottic cancer is resected using a distending laryngopharyngoscope (see Fig. 11.6), graspers, and Ligaclip applicators to clip the superior laryngeal vessels that traverse the pharyngoepiglottic folds. The laser is set at higher power (>5 W), slightly larger spot size, and on SP mode to both cut and coagulate. Surgery is done under high magnification, maintaining a distance of >5 mm from the edge of the cancer. Antibiotics are not required. Resecting the suprahyoid epiglottis is associated with only transient and minor difficulty with swallowing and aspiration that improve once the postoperative pain resolves. With cancer of the infrahyoid epiglottis and false vocal cords, aspiration is minor when compared to open supraglottic laryngectomy. The nasogastric tube is generally removed within a few days.

- Insert a distending laryngopharyngoscope with the anterior blade in the vallecula, and open it widely.
- Determine the extent of the cancer and the adequacy of access, and plan the resection.
- Excise the suprahyoid epiglottis for exposure and to remove the suprahyoid component of the cancer.
  - Make a curved incision in the vallecula (Figs. 11.12 and 11.13).
  - Bisect the suprahyoid epiglottis in the midline in a sagittal plane, cutting through the cancer if necessary (requires higher power setting to cut through the epiglottis).
  - Cut transversely across the epiglottis at the level of the hyoid.
  - Remove the left and/or right segments of the suprahyoid epiglottis.
- Readjust the position of the distending laryngopharyngoscope to improve access to the infrahyoid cancer.

- Incise the pharyngoepiglottic folds, taking care to identify the branches of the superior laryngeal vessels. Resist the temptation to coagulate the superior laryngeal artery with electrocautery; rather, apply two Ligaclips before dividing the vessel with the laser.

FIG. 11.13 Supra- *(purple)* and infrahyoid *(green)* incisions for laser supraglottic laryngectomy. With permission from Fagan JJ, Steiner W: Transoral CO_2 laser microsurgery for cancers and other pathology of the upper aerodigestive tract. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/CO2%20laser%20transoral%20microsurgery%20_TLM_.pdf

- Pre-epiglottic dissection
  - Cut transversely into the avascular pre-epiglottic adipose tissue, preserving a layer of adipose tissue over the anterior aspect of the cancer as a margin.
  - Palpate with the suction to determine the position of the hyoid bone and the superior edge of the thyroid cartilage.
  - Cut down onto and expose the thyroid cartilage.
- Bisect the infrahyoid epiglottis in a sagittal plane, cutting through the cancer if necessary. (Use a high power setting to cut through the epiglottis.)
- Follow the cancer (e.g., through the thyrohyoid membrane); thyroid

cartilage may also be resected.

- Remove the cancer in as many segments as is required, taking care to maintain their orientation for the pathologist.
- A frozen section may be used.
- Secure hemostasis with monopolar suction cautery or coagulation forceps, preferably with bipolar.

Cancer of the Hypopharynx

Cancer of the piriform fossa may extend medially into the paraglottic space, cricoid, and cricoarytenoid joint; anteriorly into pre-epiglottic space; and laterally to invade thyroid cartilage and behind the posterior edge of the thyroid lamina to the soft tissues of the neck and the carotid sheath.

At diagnostic endoscopy, assess:

- Depth and mobility of the cancer
  - Cancers clearly limited to mucosa are easily resected.
  - Deeply invasive cancers of the lateral wall need additional CT and/or MRI imaging, as cancer invading soft tissue around the carotid artery is not amenable to laser excision.
- Whether cancer on the lateral wall extends behind the thyroid lamina
  - Proximity of carotid sheath
  - Delay neck dissection by 2 weeks to avoid thru'-and-thru' defect into the neck.
- Distal extent, as one must avoid circumferential resection at the narrow cricopharyngeus region because this may cause a stricture.

Resection Technique

- Use high magnification through laryngoscopes and a distending laryngopharyngoscope (see Fig. 11.6) using graspers and Ligaclip applicators to clip the superior laryngeal vessels that traverse the pharyngoepiglottic folds.

- Maintain a distance of 5 to 10 mm from the mucosal edge of the cancer.
- Set the laser at a higher power (>5 W), slightly larger spot size, and on CW mode so as to both cut and coagulate. Reduce power when dissecting posterior to the thyroid lamina in the region of the carotid sheath.
- If the carotid artery is exposed, the vessel is either left uncovered or sealed with fibrin tissue glue.
- The cancer is excised in segments, taking care to orientate the specimens for histology.
- With major resections, insert a nasogastric feeding tube under direct vision to avoid the tube transgressing the cancer bed and entering the soft tissues of the neck, or arrange for a percutaneous endoscopic gastrostomy (PEG)
- Provided a neck dissection is not done simultaneously, antibiotics are not required.

Common Errors in Technique

- Inadequate access: Access is all-important and requires the employment of a range of laryngoscopes, repositioning the patient during the procedure, and external manipulation of the larynx by an assistant.
- Attempting to remove the cancer as a single tissue block: Because one is working within a very cramped space, the cancer must first be debulked if necessary and then removed piecemeal to ensure adequate deep resection margins.
- Losing orientation of tissue fragments

Postoperative Period

Postoperative Management

- The principal risks in the initial 24 hours are airway obstruction, bleeding, and aspiration.

- Airway management is a matter of clinical judgment. If in any doubt, the patient should be admitted to a high care unit. If the patient was difficult to intubate in the operating room, then high-risk patients should have a tracheostomy.
- Analgesia
- Feeding: This may require nasogastric tube feeding until swallowing is possible without aspiration.

Complications

Patients have surprisingly little pain but commonly have to clear their throat for a few weeks due to secretions from the surgical bed.

Early

- *Dental:* Protect the teeth with a gum guard, check for crowns or implants, and explain the risks to the patient.
- *Oropharyngeal trauma:* Minor tears of the tonsillolingual mucosa are common.
- *Lingual nerve:* Prolonged upward traction on the tongue can cause transient sensory change due to traction lingual nerve injury.
- *Bleeding:* This is most likely to emanate from the superior laryngeal arteries following resection of supraglottic cancer. To avoid this, always apply Ligaclips to the vessels, rather than relying on electrocautery. Should bleeding occur, then the patient should be returned to the operating room. Apply Ligaclips to the superior laryngeal vessels; do not cauterize major vessels.
- *Surgical emphysema:* This occurs mainly in the setting of surgery in the subglottic region and is treated conservatively.
- *Airway obstruction:* This is uncommon; hence prophylactic tracheostomy is rarely indicated.
- *Aspiration:* This does not occur with cordectomies but may complicate supraglottic laryngectomy and resection of the base of the tongue. It is most likely to occur in the elderly and infirm or following resection of

supraglottic cancers. It is unusual to be long-standing and generally is managed with effective analgesia, chest physiotherapy, dietary modification (avoiding liquids), and involving a speech and language therapist. Initial management includes pain control, thickened foods (rather than liquids), and temporary nasogastric tubes or PEG feeding.

- *Laser burns:* This occurs when the tissues are not properly protected with wet drapes.
- *Airway fire:* This is an extremely rare event and is entirely preventable.

Late

- Poor voice quality
- Granuloma: This occurs particularly where cartilage is exposed (e.g., anterior commissure and vocal process).
- Chondronecrosis: This rarely occurs when cartilage is exposed, especially after chemoradiation.
- Pharyngeal stricture: This occurs very rarely but may occur following circumferential excision of cancer of the hypopharynx.

Alternative Management Plan

Always discuss with patients the nonsurgical options such as (chemo)radiation therapy. Consider open surgical approaches (e.g., laryngofissure, vertical hemilaryngectomy, supraglottic, supracricoid, and total laryngectomy) in patients with anatomic problems that preclude the use of laser resection and in patients who have failed (chemo)radiation or previous laser surgery.

Evidence-Based Discussion

After Billroth, in Vienna, 1864, described his technique of total laryngectomy, the operation became entrenched as the only way of curing cancer of the larynx. When Justo Alonzo, of Montevideo, introduced partial laryngeal surgery in the United States in 1947, the operation was not accepted by the academic leaders largely due to the

influence of Halstead at the Johns Hopkins Hospital and the concept that unless the cancer and its underlying organ were excised "en bloc," the cancer would recur.

When Stuart Strong and Geza Jako, in Boston, 1972, adapted the Zeiss microscope (which had been previously used in otologic surgery) for use in laryngeal surgery and then found a way through clever engineering to attach a CO_2 laser, a very successful means of operating on early lesions of the glottis was introduced. This approach eliminated the laryngofissure from surgeons' thoughts when confronted with a patient with an early cancer of the vocal cord. It also proved to be an inexpensive and equally successful alternative to radiation therapy both oncologically and functionally.

Wolfgang Steiner, then of Gőttingen, introduced yet another application of CO_2 laser surgery when he used the laser to successfully resect cancers involving the supraglottis and the hypopharynx. Heinrich Rudert, then of Kiel, was also a pioneer in the field. Steiner and Rudert taught these techniques to scores of surgeons from all parts of the world, with the hands-on and live surgery courses they gave in their departments.

While many ENT surgeons from the United States have studied with surgeons from the "German School," the technique of laser supraglottic surgery has not been embraced as widely or as enthusiastically as its application for cancer of the glottis.

Eugene N. Myers

Editorial Comment

Transoral CO_2 laser microsurgery requires experience, surgical aptitude, careful case selection, and clinical judgment as to whether adjuvant radiation therapy is indicated in cases of questionable or close surgical margins to achieve good results.

Johan Fagan

- Access the review questions online at http://www.expertconsult.com

Review Questions

1. In CO_2 laser excision of glottic cancer

   a. Anterior commissure cancer is a contraindication

   b. Close margins always require adjuvant radiation

   c. **Paraglottic space invasion is a relative contraindication**

   d. Type III resections generally have a normal voice

   e. Aspiration is a common complication

2. In CO_2 laser transoral microsurgery

   a. The cancer should be resected in one tissue block

   b. A frozen section is useful to check margins for T_1 glottic cancers

   c. **Maintain inspired oxygen at FiO_2 less than 30%**

   d. A preoperative CT scan is always indicated with glottic cancer

   e. The superior laryngeal artery can be cauterized for hemostasis

3. Nerves potentially at risk with CO_2 laser transoral microsurgery include all of the following, *except*

   a. Lingual nerve

   b. Superior laryngeal nerve

   c. Recurrent laryngeal nerve

   d. Hypoglossal nerve

   e. **Accessory nerve**

Horizontal Partial Laryngectomy

Jonas T. Johnson, and Meghan T. Turner

Introduction

Cancer of the larynx arises from three subsites in the larynx: the supraglottis, glottis, and subglottis. Subglottic primaries comprise less than 5% of cancers of the larynx. The incidence of supraglottic versus glottic primaries varies, depending on the relative prevalence of alcohol and tobacco abuse and by geographic area. The optimal treatment of cancer of the larynx depends on primary tumor staging and the functional status of the larynx at the time of diagnosis. It is widely accepted that early stage (T1 and T2) cancers are treated equally well by either primary radiation or surgery. Advanced staged cancers, however, were originally thought to be best treated with total laryngectomy along with adjuvant chemoradiotherapy when indicated.[1]

However, in the 1980s a paradigm shift evolved in the treatment of advanced cancer of the larynx. Many began advocating for "organ preservation therapy" (OPT) with definitive radiotherapy versus concurrent chemoradiotherapy in order to improve laryngectomy-free survival, following the results of the VA Laryngeal Cancer Group Study.[1] Hoffman et al. analyzed the effects of this paradigm shift on outcomes and found that OPT has resulted in decreased overall survival for patients with cancer of the larynx in recent decades, particularly for those with T3 cancers.[2] Consequently, it is now recognized that certain patients are better treated with primary surgery. The desire to preserve the functions of the larynx and improve survival has fueled a renewed interest in conservation surgery of the larynx.

Conservation partial laryngectomy is defined as the removal of a portion of the larynx with preservation of its respiratory, sphincteric, and vocal functions. Both endoscopic and open techniques have been

developed for highly selected patients. Endoscopic techniques are discussed in Chapter 11. Open techniques are separated into two categories: horizontal partial laryngectomy and vertical partial laryngectomy. Vertical partial laryngectomy is discussed in Chapter 13. This chapter focuses on horizontal partial laryngectomy techniques.

For half a century, the only type of horizontal laryngectomy was supraglottic partial laryngectomy, which could only be performed on rare cancers confined only to the supraglottic larynx. In 1990, Laccourreye et al. described a new type of horizontal partial laryngectomy that removed both the true vocal cords and the entire thyroid cartilage.[3] Since then, several modifications of horizontal partial laryngectomy have been described to remove glottic and supraglottic cancer. These modifications allow for resection of the superior, inferior, and lateral extensions of the cancer into the base of the tongue, piriform sinus, paraglottic space, and subglottis, as well as the use of remnant structures in the reconstruction.[4] Surgeons must understand these techniques, as well as the indications and contraindications, in order to provide optimal treatment for patients with cancer of the larynx, who are likely to fail OPT and who are better treated by surgery.

Today, supracricoid partial laryngectomy (SCPL) with cricohyoidopexy (CHP) or cricohyoidoepiglottopexy (CHEP) is the most widely performed horizontal partial laryngectomy procedure because of to its reproducible oncologic and functional results in carefully selected patients.[3-5] Supratracheal partial laryngectomy has been described; however, the results are less reproducible.[4] This chapter will focus on supraglottic and supracricoid partial laryngectomy. If properly selected, most patients are decannulated, tolerate a regular diet, and enjoy improved overall and laryngectomy-free survival.

Key Operative Learning Points

1. Supraglottic laryngectomy has application limited to cancers of the supraglottic larynx and exophytic cancers of the base of the tongue confined to the vallecula (Fig. 12.1).

2. The hyoid bone, at least one functional (innervated) cricoarytenoid unit, the cricoid cartilage, the recurrent laryngeal nerves, and the internal branches of the superior laryngeal nerves must be preserved for

successful restoration of phonation and swallowing.

3. The ability to preserve the epiglottis determines the type of reconstruction: CHEP is performed for limited glottic cancers when the suprahyoid epiglottis can be preserved, and CHP is performed for glottic and supraglottic cancers where the epiglottis is involved and must be removed.

4. Extension to the base of the tongue, subglottis, or hypopharynx can make resection with negative margins impossible without an extended procedure, which downgrades function.

Preoperative Period

History

1. History of present illness

   a. Presenting symptom

      1) What was the initial presenting symptom: dysphonia, dysphagia, or odynophagia?

   b. Assess the current functional status of the larynx.

      1) Respiration

         a) Does the patient have dyspnea at rest or orthopnea?

         b) Does the patient have dyspnea on exertion?

      2) Phonation

         a) Does the patient communicate well or is he or she difficult to understand?

      3) Deglutition

         a) Does the patient experience aspiration with liquids or solids?

         b) Has the patient had pneumonia in the past year?

         c) Has the patient lost more than 10 pounds in the past year?

2. Past medical history

a. Prior treatment

1) Has the patient had prior direct laryngoscopy with biopsy, CO_2 laser excision, surgery, radiotherapy, or chemotherapy?

b. Medical illness

1) Does the patient have recurrent bronchitis, pneumonias?

2) Does the patient have chronic obstructive pulmonary disease (COPD) or a cardiac history?

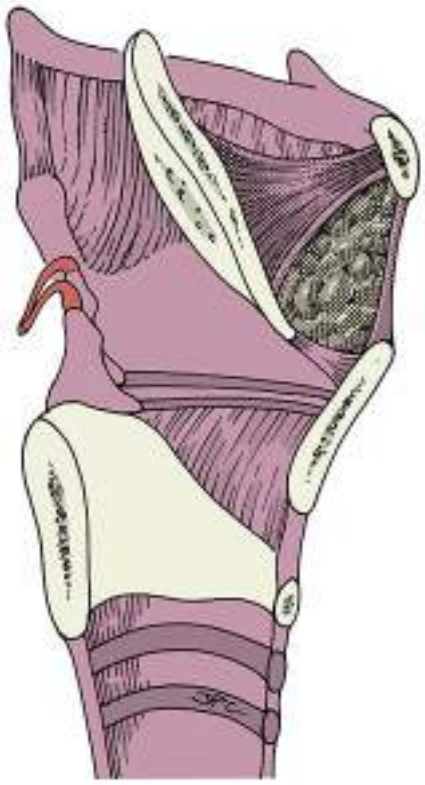

FIG. 12.1 The pre-epiglottic space *(shaded area)* is bounded anteriorly by the thyrohyoid membrane. Superiorly, it is contained by the hyoepiglottic ligament. Cancer limited to the pre-epiglottic space is not a contraindication to supraglottic laryngectomy. However, extension of the cancer anterior to the pre-epiglottic space must be recognized and satisfactorily excised to ensure clear surgical margins.

3) Does the patient have cirrhosis with bleeding varices or other gastrointestinal bleeding?

4) Consider using the Charleston Comorbidity Index or the Karnofsky Performance Status to identify those patients suited for surgery.[4,5]

5) What is the patient's respiratory reserve; can the patient climb two flights of stairs?

c. Surgery

1) Is there a history of thyroidectomy or anterior cervical discectomy and fusion (possible superior laryngeal nerve injury)?

2) Is there a history of prior neck surgery?

d. Family history

1) Do any first-degree relatives have cancer?

e. Social history

1) Tobacco use

a) Assessment of pack-year history and current use

b) Prior attempts to stop smoking and pharmacologic interventions

2) Alcohol use

a) Daily volume versus drinks per week, alcohol abuse, and current use?

b) Prior attempts to stop drinking, symptoms of withdrawal/seizures?

3) Occupation

4) Does the patient rely on his or her voice at work?

f. Medications

1) Daily inhalers and/or oxygen for COPD?

2) Does the patient take heart failure or antiplatelet medications?

Physical Examination

1. Flexible laryngoscopy

a. This is the most important part of the examination. It allows for detailed evaluation of the primary cancer, including the subsites and key anatomic structures involved. It also allows for assessment of the effect of the cancer on laryngeal function and helps screen for synchronous second primary cancers.

b. Cancer extending to the anterior commissure should be evaluated. If present, the surgeon should suspect invasion of the thyroid cartilage, which makes the patient unlikely to be cured by primary radiation therapy (RT).

c. Careful assessment of the true vocal folds and cricoarytenoid joint mobility helps determine the patient's candidacy for surgery. Atrophy of the true vocal fold suggests involvement of the ipsilateral cricoarytenoid joint and/or recurrent laryngeal nerve.

d. Subglottic extension is best assessed in the operating room through direct laryngoscopy using angled telescopes.

2. Videostroboscopy

a. This is indicated for cancer involving the true vocal cords and identifies the extent of mucosal involvement. Stroboscopy may help in planning the margins of resection and predict which patients will require removal of an arytenoid cartilage.

3. Behavior

a. Assessment of patient compliance with postoperative surveillance and rehabilitation is crucial. Patients who do not participate in intense swallowing therapy are unlikely to overcome the expected postoperative aspiration and may require placement of a percutaneous gastrostomy tube and/or prolonged tracheostomy.

4. Assessment of voice quality, respiration, and aspiration

5. Oral cavity and oropharynx

a. Screen for synchronous primaries and look for extension of the cancer that may be a contraindication to horizontal partial laryngectomy.

6. Laryngotracheal complex

a. Fixation to the anterior soft tissues suggests extra-laryngeal spread

and requires a total laryngectomy.

b. Fixation to the spine makes the cancer unresectable.

7. Palpation of the thyroid gland

a. Extension to the thyroid gland requires a total laryngectomy with thyroid lobectomy or total thyroidectomy.

8. Presence of cervical lymphadenopathy

a. Clinically detectable lymphadenopathy may require a comprehensive neck dissection, depending on the extent of metastasis, whereas the clinically negative neck requires a selective neck dissection.

Imaging

1. CT

a. Larynx

1) Thin-cut 1 mm axial CT scan through the larynx with coronal and sagittal reconstructions can detect extension of the cancer to pre-epiglottic and paraglottic spaces (see Figs. 12.1 and 12.2) as well as thyroid cartilage invasion with 75% accuracy. Adding analysis of gross radiographic signs of anterior commissure involvement (GRACI) signs improve accuracy in staging to 96%.

b. Neck

1) CT evaluation of cervical lymph node metastases is more sensitive than physical examination. Lymph nodes greater than 1 cm in the axial dimension that are round, hypodense, or demonstrate loss of the fatty hilum are considered suspicious for metastatic cancer.

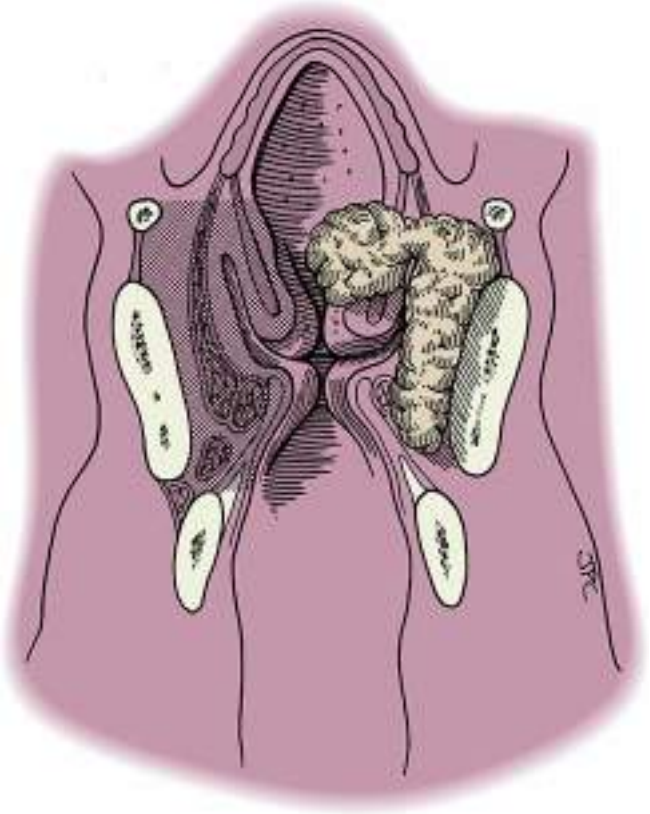

FIG. 12.2 The paraglottic space *(shaded area)* describes the submucosal soft tissue of the larynx contained by the thyroid cartilage externally. Cancer of the supraglottic larynx may spread submucosally through the paraglottic space. If the cancer extends inferior to the plane of the true vocal cord, as demonstrated in this illustration, supraglottic laryngectomy would be contraindicated because the surgeon would cut across the cancer at the level of the vocal cord.

c. Chest

1) This is the most sensitive test to rule out synchronous cancers of the lung, the most common second primary in patients who have cancer of the larynx.

2. MRI

a. Neck

1) MRI can evaluate the extent of involvement of the base of the tongue and identify which patients will require extended horizontal partial laryngectomy versus total laryngectomy.

Indications

1. Treatment of highly selected glottic cancer with the following characteristics:

   a. T1-T3 glottic cancer that extends onto the supraglottis or entirely involves both vocal folds, but spares one arytenoid

   b. T3 glottic cancers that have infiltrated the paraglottic space, causing vocal fold fixation without fixation of the cricoarytenoid joint

2. Treatment of highly selected supraglottic cancers with the following:

   a. T2 supraglottic cancers that extend to the true vocal fold

   b. T3 cancers that have infiltrated the paraglottic space, causing vocal fold fixation without fixation of the cricoarytenoid joint

3. Treatment of highly selected cancers with subglottic extension:

   a. T2 or T3 cancers with less than 10 mm of anterior subglottic extension are unlikely to invade the cricoid cartilage and will still allow for negative margins. These patients remain candidates for SCPL with CHP or CHEP.[4,5]

4. T3 glottic and supraglottic cancers with suspected invasion of the inner cortex of the thyroid cartilage.[5]

5. Patients who failed primary RT and meet all of the previously noted criteria.

Contraindications

1. Patients with general medical comorbidity, who are unable to undergo anesthesia or withstand postoperative aspiration

   a. Inability to climb two flights of stairs

   b. Karnofsky Performance Status less than 80[4]

2. Primary characteristics of the cancer making horizontal partial laryngectomy impossible:

   a. Interarytenoid/posterior commissure involvement

b. Involvement of both arytenoid cartilages

c. Cricoarytenoid joint involvement

d. Cricoid cartilage involvement

e. Subglottic extension greater than 10 mm

f. Massive invasion of the inferior paraglottic space extending to the apex of the piriform sinus or piriform sinus involvement

g. Greater than 2 cm of base of tongue involvement

h. Extralaryngeal spread of the cancer

Note that advanced age was previously a relative contraindication to horizontal partial laryngectomy. However, recent literature indicates that age is of limited importance.[4,5]

Preoperative Preparation

1. Preoperative pulmonary function tests and arterial blood gases (ABG) can help in evaluating the severity of COPD; however, there is no defined parameter by which patients are selected for horizontal partial laryngectomy. Weber et al. report using the patient's ability to climb two flights of stairs as helpful in selecting appropriate candidates.

2. Perform operative direct laryngoscopy with biopsy using angled telescopes (30- and 70-degree), with palpation of the cricoarytenoid joint to assess mobility. Fixation is a contraindication to horizontal partial laryngectomy. Biopsy should also be performed in order to provide the histologic diagnosis of cancer. Operative examination and biopsy can be performed prior to the day of surgery or immediately prior to surgery with frozen section diagnosis (if one has a reliable pathologist). Biopsies done at outside institutions should be reviewed by in-house pathologists to confirm the diagnosis.

Consider preoperative evaluation of speech and swallowing as well as nutritional evaluation. This is not essential and can be done successfully in the immediate postoperative period by the appropriate team.

Positioning

1. The patient should be in the supine position.

2. The patient's head should be centered and at the very top of the OR table.

3. Tape the endotracheal tube to the left lower lip for laryngoscopy.

4. Place a shoulder roll for neck dissections.

5. Make sure the upper lip, mastoid process, border of trapezius, and the clavicles are visible.

Perioperative Antibiotic Prophylaxis

1. Augmented penicillins are recommended for prophylaxis in cases of clean-contaminated head and neck surgery. Perioperative (24 hours) dosing is adequate in those cases where the aerodigestive tract is entered as in open partial laryngeal surgeries.

2. Clindamycin is an alternative in patients who have a history of penicillin allergy.

Monitoring

- The decision to use intraoperative nerve monitoring (IONM) is based on the surgeon's preference, as there is no evidence for or against nerve monitoring in partial laryngeal surgery.
- Disposable electromyography probes or IONM can be used to confirm identification and preservation of the hypoglossal nerve, the external branches of the superior laryngeal nerve, the recurrent laryngeal nerves, or the spinal accessory nerve.

Instruments and Equipment to Have Available

- Direct laryngoscopy set with Lewy arm
- Video tower with 30- and 70-degree laryngeal endoscopes

- Basic neck dissection set
- Headlight
- Reinforced endotracheal and tracheostomy tubes
- Three 2-0 nonabsorbable sutures on large diameter, tapered needles for pexy sutures

Key Anatomic Landmarks

- Epiglottis
- Vocal cords
- Base of the tongue
- Thyroid cartilage
- Piriform sinuses

Prerequisite Skills

- Transoral CO_2 laser excision (see Chapter 11). The ability to offer less invasive endoscopic resection of early glottic and supraglottic cancers should be a requisite skill for surgeons performing open conservation laryngeal surgery. In this way, patients will not be overtreated and develop aspiration if less radical techniques would suffice.
- Selective, comprehensive, and radical neck dissection (see Chapters 63–66). Definitive treatment of the neck should be performed at the time of surgery as indicated.
- Paratracheal lymph node dissection (see Chapter 67). The ability to perform this procedure is of absolute necessity for patients with cancers that have subglottic extension.
- Total laryngectomy (see Chapter 16). Some patients may not be candidates for partial laryngeal surgery based on operative examination of the cancer. For patients who have had prior radiation treatment, the borders of the cancer may be indistinct due to radiation changes to the mucosa, submucosal spread, multifocal nests of a

persistent tumor, or deep soft tissue extension of a tumor that requires subtotal or total laryngectomy. These patients may be better treated with total laryngectomy and, if offered partial laryngeal surgery, should understand that they may require salvage with total laryngectomy when doubt exists as to the extent of the cancer. Patients undergoing partial laryngectomy must consent to the possibility of converting the operation to a total laryngectomy.

FIG. 12.3 Mucosal incisions in the larynx are made under direct visualization. Inferiorly, the incision is made directly through the ventricle at the level of the true vocal cord. Posteriorly, the mucosal incision is made across the face of the arytenoids, unless extension of the cancer requires an extended procedure.

Operative Risks

1. Injury to the internal branch of the superior laryngeal nerves
2. Injury to the recurrent laryngeal nerve

3. Injury to the hypoglossal nerve

4. Injury to the lingual artery

Surgical Technique

Supraglottic Laryngectomy (Via *Transhyoid or **Lateral Pharyngotomy Approach)

- Tracheostomy (transverse incision incorporated into the apron incision)
- Apron flap
- Neck dissections as indicated
- Identify and free the hyoid bone laterally.
- Transect the strap muscles.
  - Transect the infrahyoid strap muscles (if the lingual surface of the epiglottis is free of cancer).*
  - Transect the mylohyoid and infrahyoid strap muscles to include the hyoid bone in the specimen (if the lingual surface of the epiglottis is involved).**
- Open the vallecula (Fig. 12.3).
  - Traverse the pre-epiglottic space, enter the pharynx in the midline, and identify the epiglottis (if the lingual surface of the epiglottis is free of cancer).*
  - Enter the pharynx opposite to the cancer (if the lingual surface of the epiglottis is involved).
- Incise and elevate the perichondrium along the superior edge of the thyroid cartilage.

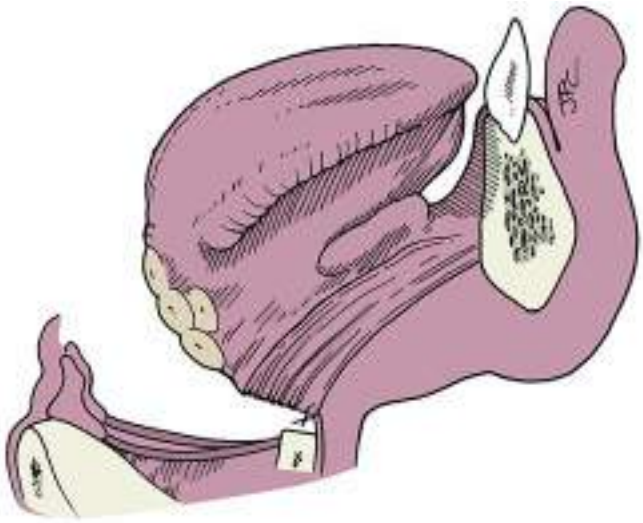

FIG. 12.4 The external perichondrium of the cricoid cartilage is reapproximated to the fibroaponeurotic layer of the base of the tongue. This positions the base of tongue posteriorly over the glottis.

- Incise the aryepiglottic fold at the level of the ventricle (see Fig. 12.3).
  - Do not cut the true vocal cords or arytenoid cartilages!
- Connect the endolaryngeal incision to the cartilage incision, and incise the thyroid cartilage at the ventricle under direct vision.
  - Do not disrupt the attachment of the anterior commissure to the thyroid cartilage.
- Remove the specimen, examine the margins, and take frozen sections as necessary.
- Place the nasogastric tube into the pharynx.
- Reconstruct the pharynx (Fig. 12.4).
  - Place three sutures from the perichondrium of the cricoid cartilage to the fibroadipose layer 12-15 mm anterior to the base of the tongue.
  - Do not suture to the tongue mucosa!
- With tension relieved, tie the sutures firmly and close the lateral aspects of the pharyngotomy mucosa separately.
- Irrigate the wound, and place suction drains.

- Suture the strap muscles to the platysma of the apron flap around the tracheostomy to prevent postoperative subcutaneous emphysema and contamination of the dissected neck(s) (Fig. 12.5).

1. Common errors in technique

   a. Positive margins

      1) This occurs more often with unrecognized invasion of the base of the tongue, piriform sinus, pre-epiglottic space, or subglottic extension. It is prevented with up-to-date imaging, direct laryngoscopic examination immediately prior to surgery, careful planning of the pharyngotomy to allow for endolaryngeal incisions to be made under direct visualization, and intraoperative frozen section analysis.

   b. Inappropriate approximation of the mucosa of the base of the tongue to the glottis

      1) The base of the tongue must be "set back" over the larynx by suturing the cricoid perichondrium to the fibroadipose aponeurosis of the tongue 12 to 15 mm deep to the mucosa. This creates a "roof" over the glottic larynx and reduces postoperative aspiration (see Fig. 12.5).

   c. Recurrence in the contralateral neck

      1) All patients with supraglottic cancers should undergo bilateral neck dissection. Recurrence rates in the contralateral neck can be reduced from 20% to 9%, with bilateral selective neck dissections in the clinically N0 neck.

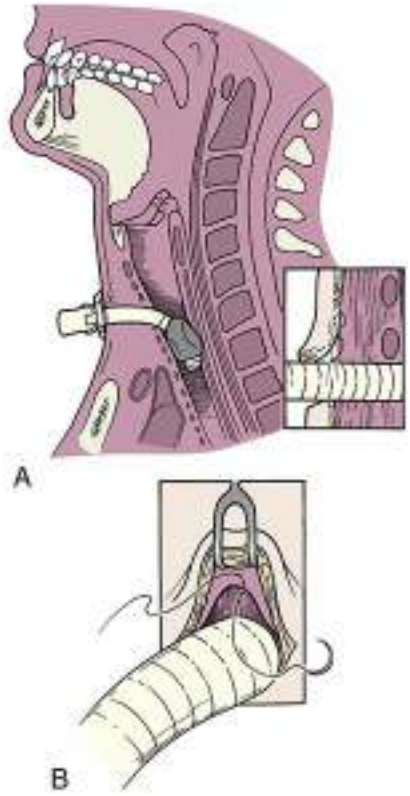

FIG. 12.5 **(A)** At the completion of the procedure, the tracheostomy site must be isolated from the potential dead space created through flap elevation and neck dissection. **(B)** Failure to isolate the tracheostomy from the potential space created by the neck dissection may result in transmission of contaminated air or secretions from the trachea underneath the cervical flap, resulting in subcutaneous emphysema and wound infection.

Postoperative Perlod

Postoperative Management

1. Patients are transferred to a monitored hospital bed managed by staff skilled in immediate postoperative tracheostomy and wound care.

2. Continuous pulse-oximetry is routine.

3. Patients are kept NPO, with the nasogastric tube kept on low wall suction initially. Once bowel sounds are detected, feedings and medications can be administered via the nasogastric tube.

4. Avoidance of postoperative emesis is crucial, because vomiting may disrupt the reconstruction. This is done with cautious advancement of feeding and antiemetic medication.

5. Deflating the cuff of the tracheostomy is attempted on postoperative day 3. Aspiration signifies that laryngeal edema is decreasing, and the cuff is often reinflated. The patient is then encouraged to expectorate secretions.

6. Flexible laryngoscopy is then performed with the cuff deflated on postoperative day 5 to assess laryngeal edema and aspiration. If edema is improved and aspiration not severe, an uncuffed no. 4 tracheostomy tube is placed. If aspiration is evident, the cuffed tube is replaced.

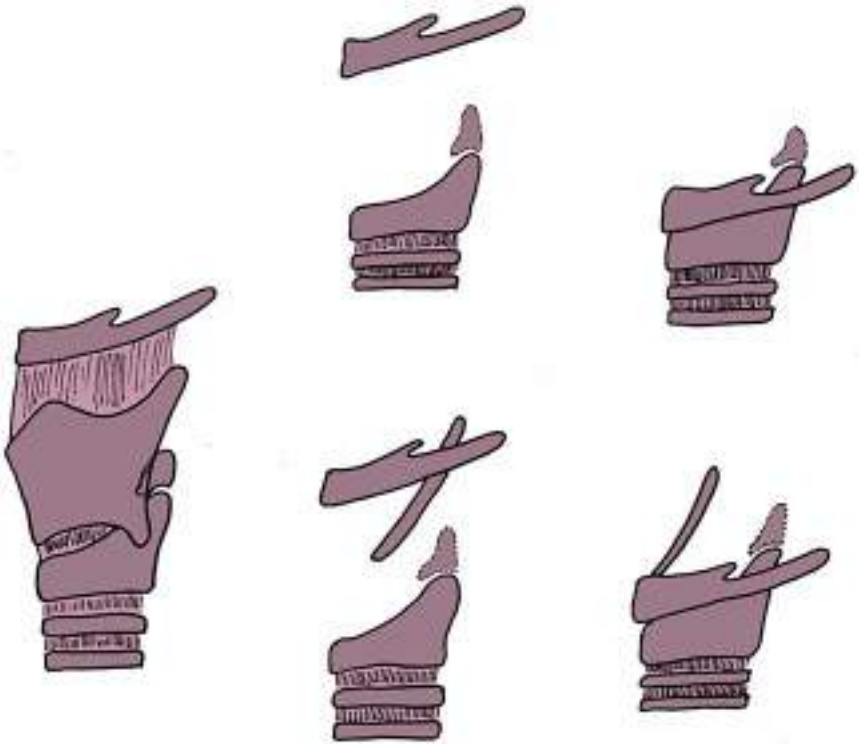

FIG. 12.6 The impaction sutures are tied tightly so that they approximate the cricoid complex to the hyoid bone. Care is taken to ensure adequate impaction and that the space previously taken by the thyroid cartilage and thyroid membrane is obliterated. Reprinted with permission from Pinel J, Cachin Y, Laccourreye H, editors. *Cancers du Larynx [Indications, Thérapeutiques, Résultats]*. Paris: Librairie Arnette, SFORL; 1980.

7. Once an uncuffed tracheostomy tube is tolerated in periods of recumbence and overnight, the tracheostomy tube is capped. If capping is tolerated for more than 24 hours, a laryngoscopy is performed to assure airway patency, and the patient is decannulated (usually postoperative days 12 to 14).

8. Swallowing therapy begins with placement of the speaking valve or cap. It includes exercises related to elevation of the base of the tongue, laryngeal elevation, and adduction. Therapy then includes supraglottic swallow techniques and the swallow/cough technique.

9. Registered calorie counts are begun with resumption of oral feeding. Approximately 2 to 3 days of therapy are necessary to resume adequate feeding, allowing patients to return home with assurance of adequate hydration and alimentation for healing.

10. Wasserman et al. found that aggressive inpatient dysphagia management and swallowing therapy achieve safe and functional swallowing prior to discharge without the excessive costs of PEG placement and home health services that are required with earlier discharge.

Complications of Supraglottic Laryngectomy

1. Acute complications

   a. Medical complications

      1) These include cardiac ischemia, bleeding ulcer, delirium tremens, and pneumothorax secondary to ruptured pulmonary blebs and are averted with proper patient selection and preoperative preparation.

   b. Aspiration pneumonia

      1) This is the most frequent complication. All patients are expected to aspirate.

      2) Aspiration can be minimized with proper surgical technique, offsetting the tongue base when closing the supraglottic laryngectomy, and placing well-approximated pexy sutures in

CHP/CHEP.

3) Proper patient selection, constant expectoration, aggressive pulmonary toilet, early ambulation, regular coughing, and intense swallow therapy with pre- and postswallow maneuvers to eliminate aspiration from autodigestive tract are crucial for prevention.

c. Hemorrhage

1) This complication is most often the result of inadequate hemostasis along the musculature and mucosa of the base of the tongue. Careful attention to hemostasis in this poorly visualized area should prevent this complication.

2) Hemorrhage due to vessel blowout is prevented by the placement of active suction drains in the neck and early recognition of salivary fistulae. Contamination of major vessels by saliva requires urgent surgical intervention.

d. Subcutaneous emphysema

1) Poor reapproximation of the strap muscles to the subplatysmal flaps around the tracheostomy site results in buildup of subcutaneous emphysema and secretions in the wound when the patient coughs, resulting contamination of the dissected neck.

2) This complication may be prevented by meticulous closure of the wound and the application of pressure dressings (Fig. 12.6).

e. Neck infection

1) This complication can be prevented by administering perioperative antibiotic prophylaxis for all patients and by carefully closing the dead space between the apron flap and the strap muscles (see Fig. 12.6).

f. Ruptured pexy sutures

1) This complication has been described in patients with postoperative nausea or uncontrolled acid reflux. It is treated by returning the patient to the operating room and revising the closure.

2. Late complications

a. Airway obstruction with failure to decannulate

1) Arytenoid edema is the most common cause. It is managed with steroids and observation. Edema often resolves with time, allowing the patient to be decannulated at the first postoperative office visit.

2) Mucosal flaps created during resection can scar and obstruct the neolarynx. Some surgeons describe treating this with endoscopic CO_2 laser excision of obstructing mucosa.[4]

b. Delayed deglutition

1) Most often this occurs due to poor patient selection or poorly performed surgery.

2) Patients at greater risk include patients of advanced age with pre-existing dysphagia and aspiration, noncompliant patients, and previously radiated patients. Patients undergoing extended procedures that involve removal of some of the base of the tongue also have this problem. Such patients may benefit from early PEG tube placement.

c. Regional recurrence

1) This complication occurs when there has been a failure to adequately treat the neck. Bilateral neck dissection should be performed in patients with supraglottic cancers or supraglottic extension of glottic cancer. Central neck dissection with removal of paratracheal nodes should be performed for cancers with involvement of the subglottis.

d. Delayed decannulation

1) Some patients cannot tolerate decannulation prior to discharge and are not managed with aggressive inpatient swallowing therapy. The majority of these patients have significant postoperative edema after supracricoid laryngectomy, as detected on flexible laryngoscopy. Such patients are discharged to rehabilitation facilities with a nasogastric tube in place. These patients are then reevaluated at their first office visit with fiberoptic laryngoscopy. Most can be decannulated, are seen the same day by the swallowing therapy team, and are sent home on an oral diet.

Alternative Management Plan

1. Radiation is considered an alternative to surgery for early laryngeal cancer.

2. Transoral partial laryngeal resection has replaced horizontal partial laryngectomy in most centers.

Discussion

Evidence-Based Medicine Questions

What is the overall survival and laryngectomy-free survival difference between conservation horizontal laryngeal surgery and organ preservation therapy for early T1–T2 cancers and T3 cancers, respectively?

In the VA laryngeal cancer study, 332 patients with advanced stage laryngeal cancer were randomized to treatment with chemoradiation therapy (CRT) and surgery with adjuvant RT. The majority of patients had T3 primaries. The 2-year overall survival was 68% in both groups, when patients who failed CRT were treated with salvage laryngectomy. The laryngeal preservation rate was 64%.[1] Surgical series show improved overall- and laryngectomy-free survival. Dufour et al. studied a series of 118 patients with T3 cancers treated by SCPL. The 3-year and 5-year actuarial-survival rates were 84% and 74%, respectively. The rate of local control at 3 and 5 years was 93.5% and 91.4%, respectively. Survival was significantly linked to local control. The laryngeal preservation rate was 89.8%.[5] Rizzotto et al. reported 5-year overall and disease-free survival rates of 95.6% and 90.9%, respectively, in a series of 399 patients.[4]

Editorial Comment

The primary objectives of treating patients with laryngeal cancer are to offer the best chance of cure and to preserve function relating to speech, swallowing, and airway. Even though total laryngectomy offers all of these benefits, it does have the major drawback of a permanent laryngostoma and having to manage and pay for speaking valves.

Therefore, a surgeon should always consider conservation horizontal laryngeal surgery before simply opting for total laryngectomy in suitable patients.

Review Questions

1. For which TNM stage cancers has mortality risen most drastically since the initiation of organ preservation therapy with concurrent chemoradiotherapy?

   a. **T3N0M0**

   b. T2N1M0

   c. T1N2M0

   d. T4N1M0

2. When performing selective treatment of the ipsilateral neck for supraglottic cancers, what is the recurrence rate in the untreated contralateral neck? What is the recurrence rate in those necks treated by bilateral selective neck dissection?

   a. **20% and 9%, respectively**

   b. 40% and 20%, respectively

   c. 40% and 10%, respectively

   d. 30% and 15%, respectively

3. What amount of involvement of the base of the tongue contraindicates horizontal partial laryngeal procedures?

   a. 1 cm

   b. **2 cm**

   c. 3 cm

   d. 0.5 cm

4. What amount of subglottic extension can be accommodated by

supracricoid laryngectomy?

a. 15 mm

b. 20 mm

c. **10 mm**

d. 5 mm

5. What maneuver is necessary in preventing intractable aspiration after supraglottic laryngectomy?

a. Preservation of the epiglottis

b. Preservation of the hyoid bone

c. **Creating a roof for the neolarynx**

d. Approximation of the mucosa of the base of the tongue to the perichondrium

Vertical Partial Laryngectomy

David Eibling

Introduction

Vertical partial laryngectomy (VLP) is used for cancers extending to or crossing the anterior commissure. Hence the resection as typically performed entails removal of several millimeters of the contralateral vocal cord as well as the midline portion of the thyroid cartilage. This procedure is not actually a "hemi" laryngectomy as it has been termed traditionally, since: the cricoid ring remains intact, the hyoid bone is uninvolved, and usually typically only a portion of the arytenoid is resected.

"Frontolateral partial laryngectomy" or "vertical partial laryngectomy" is a more accurate designation for the procedure.The procedure removes all or a portion of one vocal cord, usually in continuity with the anterior commissure and its ligamentous attachment to the thyroid cartilage. The removal of at least the vocal process (or even the entire) ipsilateral arytenoid is required. In addition, sufficient tissue must be retained or brought in as local flaps to maintain an adequate airway, and the voice is always adversely affected.

The technique was popularized in the United States by Dr. Joseph Ogura's group in the early 1970s (see Additional Sources for original references). At that time, imaging and radiotherapy techniques were not as precise as they are currently; hence many surgeons preferred surgical excision to radiotherapy for cancers encroaching on the anterior commissure. Detection of persistent disease following radiotherapy is often delayed, requiring a total laryngectomy. A report from our department indicated that more larynges were preserved by initial partial laryngectomy for early glottic cancer than with radiotherapy with surgical salvage.[1]VPL is performed for bulky or extensive early-stage

glottic carcinoma, which have a reduced chance of cure with radiotherapy.[2]

The widespread use of transoral endoscopic laser surgery, increased numbers of surgeons competent in performance of supracricoid laryngectomy, improved imaging, precise targeting of radiation therapy, and more recently the introduction of robotic surgery have decreased the use of VPL in the treatment of glottic cancer.

Laccourreye et al. compared outcomes of a series of patients with early glottic carcinoma managed with supracricoid laryngectomy with VPL, noting improved disease-free and survival benefit with the group treated with supracricoid laryngectomy.[3]

As noted previously, many recently trained otolaryngologists have no experience with VPL in their residency. Nonetheless, the procedure remains standard in locales that do not have access to these newer modalities or for surgical salvage in selected cases following laser resection or radiation for early glottic cancers.

Key Operative Learning Points

1. VLP for early glottic cancer has largely been replaced by endoscopic laser excision or supracricoid laryngectomy.

2. It is ideal for bulky glottic cancers that involve the anterior commissure and are confined to no more than one-third of the contralateral vocal cord with less than 1 cm of subglottic extension (Fig. 13.1).

3. As in other partial laryngectomy surgical procedures, accurate staging and careful attention to details of the procedure are paramount, especially if it is to be used as a salvage procedure.

Preoperative Period

History

1. History of present illness

   a. Hoarseness is almost always the presenting symptom for early

glottic cancer. Symptoms of otalgia, dyspnea, or dysphagia suggest a more advanced stage, and prompt careful evaluation is needed to ensure that the appropriate surgical procedure is selected.

b. The history, laryngeal photographs, and imaging from referring otolaryngologists are helpful but do not replace real-time examination in both the clinic and the operating room.

c. Diagnosis is achieved with appropriate examination and biopsies. If a biopsy was performed at another institution, most surgeons require that the pathology slides be obtained for re-review by in house pathologists.

d. The site and stage of the cancer must be accurately determined.

2. Past medical history

a. Prior treatment: Was this cancer previously treated by endoscopic excision or radiation therapy? Prior radiation therapy is not a contraindication, although postoperative wound complications may be more likely.[4]

b. Medical illnesses: Many patients with cancer of the head and neck have significant comorbidities, which must be identified prior to scheduling surgery.

1) Is the patient able to tolerate a surgical procedure?

2) Is the patient able to tolerate aspiration; a common consequence of the surgery?

c. Surgery—particularly any prior laryngeal or tracheal surgery

d. Eliciting a history of substance abuse is important, particularly a history of alcohol dependence, which may lead to postoperative alcohol withdrawal syndrome if not recognized preoperatively. Smoking has been demonstrated to impair healing; hence patients should be encouraged to stop smoking.[5] Nicotine withdrawal can be managed with transdermal nicotine release patches in the perioperative period.

Physical Examination

1. Awake fiber-optic or telescopic laryngeal endoscopy: Awake

endoscopy is the most important part of the examination, as it affords accurate assessment of vocal cord mobility as well as an estimate of the location, size, and extent of the cancer.

2. Oral cavity: It is important to rule out second primary cancers.

3. Neck: Palpation of the neck may reveal adenopathy or direct extension of cancer into the soft tissue anteriorly.

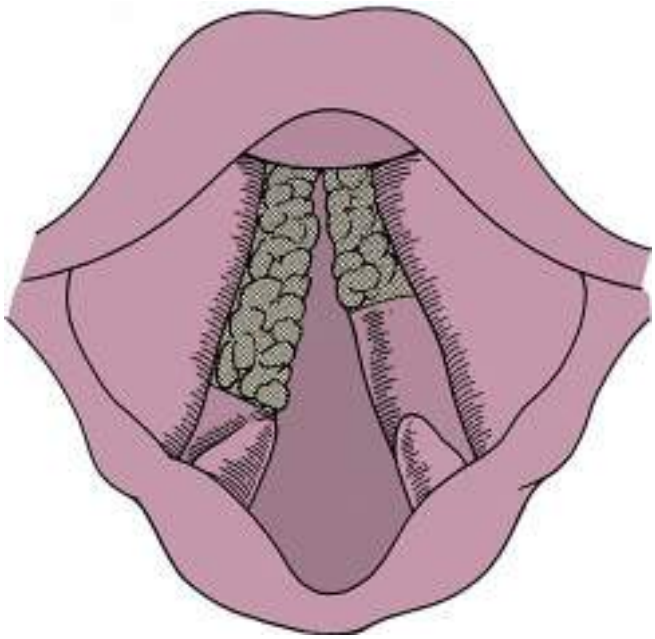

FIG. 13.1 Maximal size of a cancer that can be removed by frontolateral hemilaryngectomy involving entire left vocal cord and the anterior third of the right cord.

Imaging

1. Although theoretically not necessary, most surgeons favor imaging to assist with staging the patient with a bulky cancer of the glottis, particularly since more than one-third of clinically staged T2 glottis cancers are found to be more extensive on pathologic examination.[6]

2. Thin-cut axial computed tomographic images of the larynx may provide important information regarding tumor extension beyond the confines of the endolarynx. A chest radiograph or computed tomography (CT) scan is required to rule out a second primary cancer of the lung.

Indications

1. T1-2 cancer of the glottis

2. Impaired mobility or fixation of the vocal cord suggests invasion into the vocalis muscle and possibly a higher stage. Extension to the arytenoid and anterior commissure may require resection of additional tissue, such as more than half of the contralateral vocal cord, which may impair adequate glottic reconstruction (see Fig. 13.1).

3. The cancer does not extend onto the cricoid cartilage (1 cm anteriorly, 0.5 cm posteriorly).

4. Vertical partial laryngectomy (VPL) is an ideal salvage procedure for early cancers not controlled by primary radiotherapy or CO_2 laser. However, extensions of the standard procedure may lead to undesirable morbidity, particularly in previously treated patients.

Contraindications

1. Medical comorbidities with increased risk relating to general anesthesia and inability to tolerate mild aspiration. In these situations radiation therapy would likely be the preferred modality.

2. Cancer extending beyond the limits of resection to involve more than one-third of the contralateral vocal cord, entire ipsilateral arytenoid, or mucosa on cricoid cartilage.

Preoperative Preparation

1. Discontinue anticoagulants 3 to 5 days preoperatively.

2. Mark the side of the cancer on the skin, and confirm with preoperative endoscopy prior to incising the skin.

3. Administer perioperative antibiotics.

Consent

1. The patient must understand that the quality of his or her voice will

never be normal, and that it may be substantially worse than preoperatively.

2. VPL may lead to swallowing impairment due to inadequate laryngeal closure during deglutition. Patients must know that swallowing function may worsen with time due to age-associated loss of pharyngeal muscle tone and lung function.[7]

3. If excessive tissue is removed, the airway may be borderline or inadequate, even to the extent of requiring a long-term tracheostomy.

4. Many surgeons specify in the consent process that if the extent of the tumor is found to be greater than anticipated at the time of surgery, a total laryngectomy will be performed at the same sitting.

Operative Period

Anesthesia

General anesthesia is preferred.

Positioning

Supine: The patient is positioned the same as any anterior neck procedure, with the head extended on a shoulder roll.

Perioperative Antibiotic Prophylaxis

First generation cephalosporin if not allergic to penicillin

Clindamycin if allergic to penicillin

Monitoring

Routine EKG, pulse oximetry, capnography, Foley catheter for monitoring

Instruments and Equipment to Have

Available

1. Basic head and neck set

2. Cuffed tracheostomy tube: Some surgeons place a temporary flexible endotracheal tube through the tracheostomy site and replace it with the tracheostomy cannula at the end of the procedure. Others place a cuffed tracheostomy tube initially to avoid changing tubes later.

3. Oscillating or sagittal power saw to cut cartilage

Key Anatomic Landmarks

1. Thyroid cartilage midline: The incision through the cartilage is usually several millimeters lateral to the midline on the side *opposite* to the cancer.

2. The anterior commissure is a critical landmark for partial laryngeal surgery, as well as its relationship to the cancer being key for surgical planning.

3. Cricothyroid membrane: The inferior margin of the resection is the superior edge of the cricoid; hence the inferior edge of the cricothyroid membrane must be identified early.

4. Posterior edge of the thyroid ala: A strip of cartilage is retained posteriorly that connects the inferior and superior cornua of the thyroid cartilage.

BOX 13.1 Steps in Hemilaryngectomy

Indications

T1 and T2 bulky cancers of the membranous true vocal cord

T1 and T2 cancers that cross the anterior commissure

Normal or slightly impaired vocal cord mobility

No or minimal involvement of the supraglottis

Subglottic extension less than 5 mm posteriorly and 10 mm anteriorly

Contraindications

Extensive involvement of the body of the arytenoid

More than one-third of the contralateral vocal cord involved (consider supracricoid partial laryngectomy)

Technical Points

Administer perioperative antibiotics.

Re-endoscope the patient; make endoscopic incisions across the vocal cords if possible to accurately define the margin of resection.

Use a headlight.

A tracheostomy may be made before or after anesthesia is induced.

Make a horizontal skin incision over the thyroid ala.

Elevate flaps superiorly and inferiorly while avoiding the tracheostomy tract.

Incise the perichondrium from the thyroid notch down the midline over the cricothyroid membrane.

Elevate the perichondrium with the attached overlying strap muscles.

Mark the cartilage incisions while retaining a 3- to 5-mm posterior strip.

Cut the cartilage with a sagittal saw.

Incise the perichondrium along the superior border of the thyroid ala.

Incise across the petiole of the epiglottis. This will provide a panoramic view of the glottis.

Incise the cricothyroid membrane along the superior aspect of the cricoid cartilage.

Extend the incision(s) across the contralateral true vocal cord (at previously marked margin). Be careful to preserve adequate contralateral vocal cord for reconstruction.

Using hooks, open the thyroid ala like a book.

STOP, and carefully evaluate the lesion and determine the area to be excised.

Excise the tumor and ipsilateral vocal cord by incising along the apex of the aryepiglottic fold down around the arytenoid or through the vocal process of the arytenoid, depending on the posterior extent of the tumor.

Orient and examine the surgical specimen, and select sites for frozen section examination of the margins. Mark the specimen to orient it for the pathologist.

Obtain hemostasis.

Suture the contralateral vocal cord to the anterior end of the remaining cartilage or to the external perichondrium.

Pull pyriform mucosa over posterior cricoid to add bulk to posterior glottis if arytenoidectomy is required.

If excessive resection of contralateral vocal cord is required, reconstruct by doing an epiglottopexy.

Insert a nasogastric tube for feeding.

Close the perichondrium with absorbable sutures.

Inferiorly based or bipedicled muscle flaps may be used to reconstruct the glottis to improve voice quality but are probably not necessary.

A cricopharyngeal myotomy is not required.

Close the wound in layers over a drain, making sure that the tracheostomy wound is separated from the primary incision site.

Apply a neck dressing.

Postoperative Care

Antibiotics are continued for 24 h postoperatively.

Nasogastric feedings can begin as soon as the patient has bowel sounds.

The tracheostomy tube cuff can be deflated when the patient tolerates his/her secretions.

Initiate swallowing when patient swallows saliva, often following

decannulation.

The larynx will appear abnormal, with areas of granulation tissue for 4 to 6 weeks, so repeat biopsies should be delayed until re-epithelization is complete.

Prerequisite Skills

1. Endoscopic as well as open head and neck surgical skills

2. Knowledge of the three-dimensional anatomy of the larynx and particularly the anterior glottis

Operative Risks

1. Airway risks are minimized by the routine placement of a tracheostomy.

2. Failure to recognize that the cancer has extended beyond the limits of resection is problematic, since extending the resection may result in an inadequate airway or chronic aspiration. The most likely preferred solution in most cases is to convert to either supracricoid laryngectomy or total laryngectomy.

Surgical Technique

- The side of the cancer should be marked on the skin of the neck before induction of anesthesia, noted at the preoperative briefing, and confirmed again at endoscopy.
- I often make an incision under endoscopic control in the contralateral vocal cord at the point of the contralateral margin, as this location may be difficult to visualize accurately when the larynx is open.
- I perform a tracheostomy at the beginning of the procedure in all patients. The tracheostomy should be placed sufficiently inferiorly in the neck to avoid contamination of the surgical wound with tracheal secretions during the postoperative period. The tracheostomy stabilizes the patient and eliminates having to work around an endotracheal tube in the operative field. It should be noted that

Laccourreye's group has not routinely used a tracheostomy and has reported no untoward consequences in 25 years of experience, although their surgical technique differs.[3]

- The steps in the procedure are presented in Box 13.1. The technique illustrated is that of thyroid cartilage resection, which is my preferred technique and also the preferred technique of our group.
- A horizontal incision is placed in a major skin crease over the thyroid ala (Fig. 13.2). An apron incision is not generally used because the likelihood of extending the procedure to a total laryngectomy is exceedingly low.
- Subplatysmal flaps are elevated superiorly and inferiorly while avoiding entry into the tracheostomy tract. If the surgical wound communicates with the tracheostomy, it should be separated with several absorbable sutures placed between the strap muscles and the subcutaneous tissue at the completion of the procedure to avoid contamination of the laryngectomy wound with tracheal secretions.

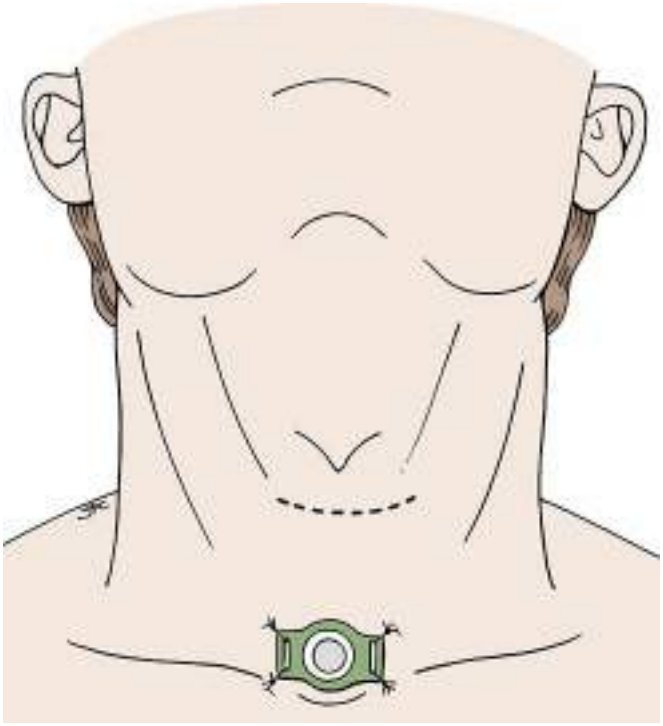

FIG. 13.2 Incision for VLP. Care should be taken to ensure separation of the tracheostomy incision from that required for the partial laryngectomy.

- The fascia is incised in the midline between the strap muscles and carried down to the level of the thyroid cartilage and inferiorly over the cricoid cartilage.
- The perichondrium is incised along the superior margin of the thyroid cartilage and then elevated with the attached overlying strap muscles to the posterior margin of the thyroid ala on the side of the tumor (Fig. 13.3). The perichondrium is incised along its attachment to the inferior portion of the thyroid ala to permit elevation laterally. Every attempt should be made to preserve the perichondrium because it is a component of the reconstruction.
- The cancer usually extends at least as far as the anterior commissure; hence the vertical incision in the thyroid cartilage must be made just lateral to the midline on the side *opposite* the cancer to ensure adequate resection of the anterior commissure as a deep margin of resection with the specimen.
- A posterior vertical cartilage cut is made on the side of the tumor, retaining a 3- to 5-mm-wide bridge of cartilage between the inferior and superior cornua of the thyroid cartilage (Fig. 13.4).
- The saw cuts should be made using a powered oscillating saw with a small right-angled blade through cartilage only and not through the underlying mucosa.
- Entering the ventricle on the contralateral side through the cartilage cut (immediately deep to the cartilage cut), the larynx is exposed by cutting across the petiole of the epiglottis. This maneuver facilitates visualization of the entire glottis and of the incision in the vocal cord made at endoscopy to mark the limits of resection (Fig. 13.5).
- The cricothyroid membrane is then incised just above the cricoid cartilage (Fig. 13.6). The true vocal cord is transected to connect the inferior and superior incisions. The contralateral vocal cord is cut at right angles (Fig. 13.7A and B) to avoid sacrificing excessive tissue.

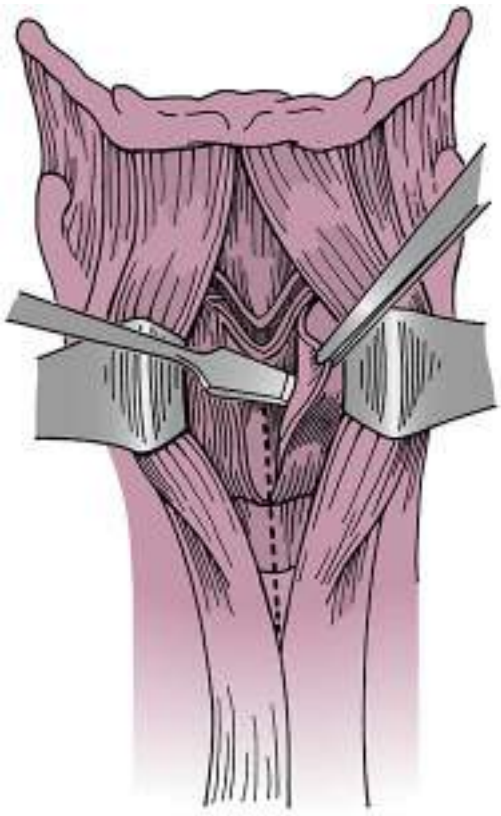

FIG. 13.3 Elevation of the perichondrium with the overlying strap muscles.

- Once the contralateral vocal cord (or the anterior commissure) has been divided, the cartilage halves are spread open like a book, and, using scissors, the incision is extended across the false vocal cord on the involved side. This is done by placing one blade of heavy Mayo scissors within the lumen and above the ipsilateral thyroid ala; several incisions are made to open the larynx for visualization of the posterior extent of the cancer.
- The inferior incision is extended posteriorly along the superior margin of the cricoid cartilage on the side of the cancer while taking care to ensure that an adequate margin has been resected inferior to the cancer (Fig. 13.8).
- The incisions are extended, and the specimen is resected. The entire arytenoid may need to be included with the resection. There will be some bleeding in this part of the procedure, and it is important to achieve hemostasis for complete visualization of the lesion.
- At the completion of the resection, hemostasis is obtained and the

specimen is carefully oriented and marked for the pathologist and examined using frozen sections to confirm negative margins.

- Pyriform mucosa should be advanced over the posterior portion of the cricoid to resurface the posterior larynx, particularly if the arytenoid has been resected.
- The contralateral true vocal cord (TVC) must be reattached to the anterior surface of the cartilage with nonabsorbable sutures, except in the unlikely situation in which the ligamentous attachment of the contralateral anterior commissure has been left intact (Fig. 13.9).
- If it is apparent that much of the least involved vocal cord required resection, the surgeon has a number of options. One is to convert the procedure to a supracricoid laryngectomy (see Chapter 12). Our favorite option is to use the epiglottis to reconstruct the larynx (epiglottopexy) (Fig. 13.10A and B); the epiglottis provides both structural support to prevent glottic stenosis as well as a mucosalized anterior glottis. Although this technique preserves an adequate glottic airway, it results in a breathy voice and occasionally unacceptable aspiration. A third alternative is to use a keel, a technique with which I have no experience. The final option is a total laryngectomy. A nasogastric tube is inserted and secured for postoperative feeding.

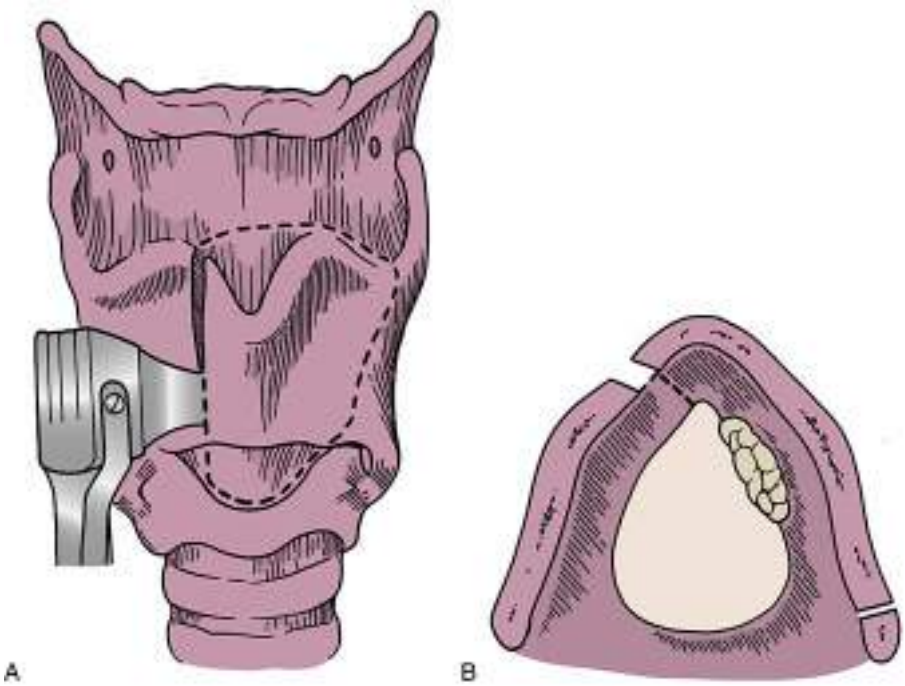

FIG. 13.4 **A,** Incision of cartilage for a left frontolateral hemilaryngectomy and **B,** the planned incision in the vocal cord. To remove the entire anterior commissure, note the incision in the cartilage just to the right of the midline. A 3- to 5-cm-wide strip of cartilage is maintained posteriorly. Redrawn from Pearson BW, Donald PJ: Larynx. In Donald PJ [ed]: *Head and Neck Cancer: Management of the Difficult Case*. Philadelphia, PA, WB Saunders, 1984, pp 93-148.

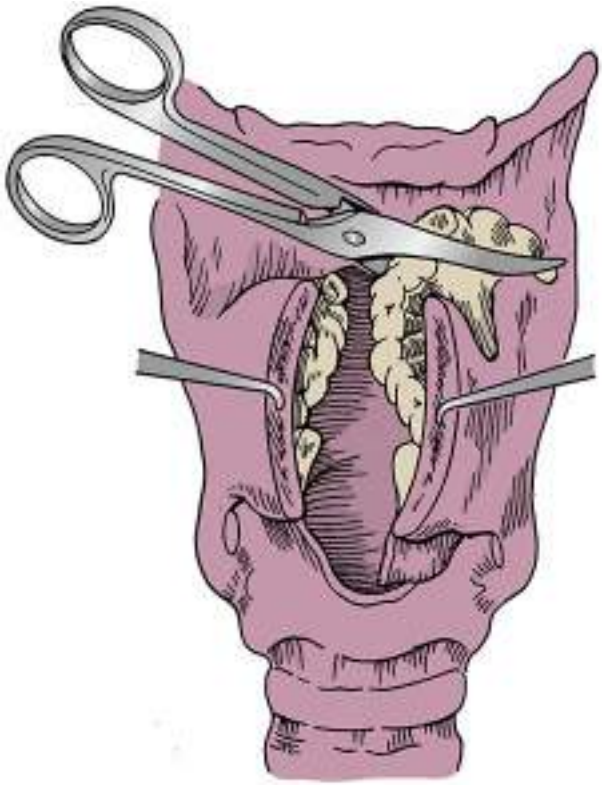

FIG. 13.5 Scissors are used to extend the incision across the pre-epiglottic space and the false vocal cord to expose the cancer.

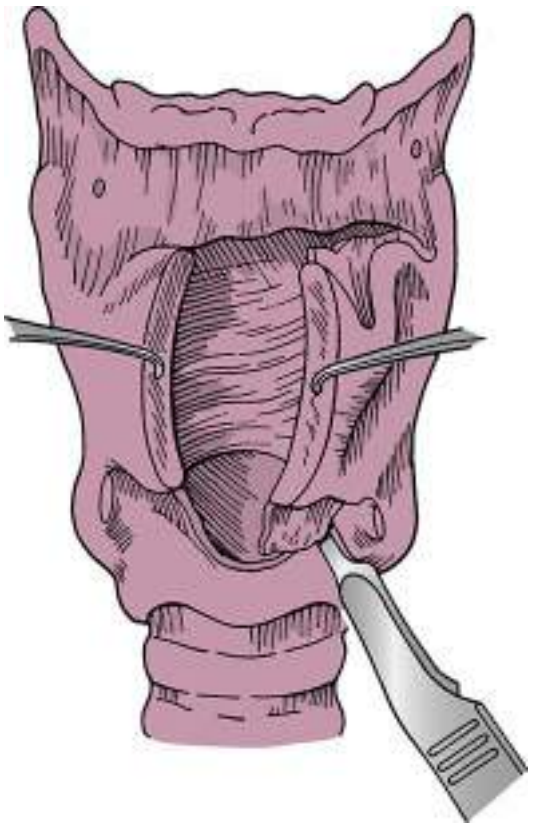

FIG. 13.6 The cricothyroid membrane is opened just superior to the cricoid cartilage to verify that the cricoid is not involved.

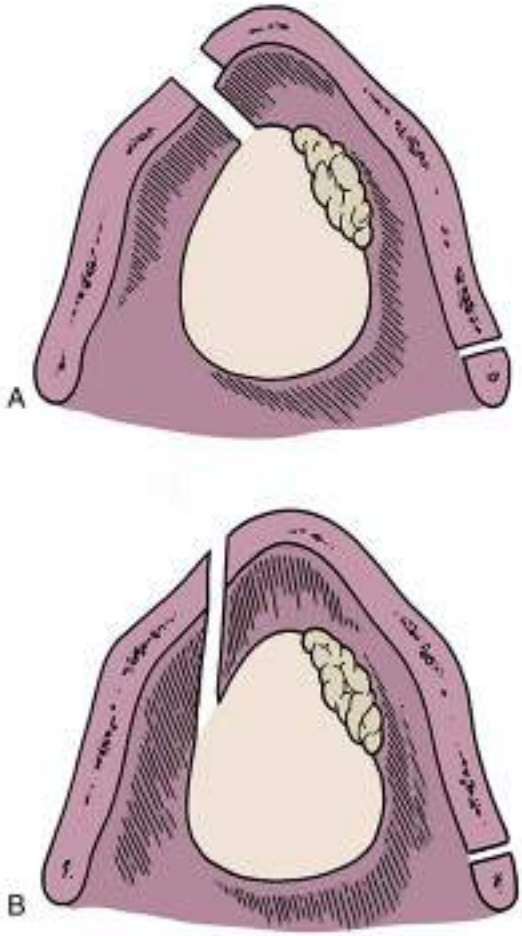

FIG. 13.7 Proper **(A)** and improper **(B)** angles of the cut through the vocal cord. Note the excess sacrifice of tissue caused by improper angulation of the incision through the vocal cord.

- The anterior perichondrium and the strap muscles are closed with absorbable sutures.
- A suction drain is placed subcutaneously in the neck.
- The neck incision is closed, with care taken to ensure that the wound does not communicate with the tracheostomy incision.

Common Errors in Technique

1. Wrong-side surgery: Since the cancer is not visualized until after the larynx is opened, there is a risk of opening the wrong side. As a precaution, the skin of the neck should be marked preoperatively on the

correct side, and the side should be confirmed by laryngoscopy prior to the procedure. Posting preoperative photographs also may be helpful to ensure proper orientation.

2. Cutting the cartilage and vocal cord at an incorrect angle: This error sacrifices excessive normal vocal cord tissue and creates substantial difficulties in reconstruction (see Fig. 13.7).

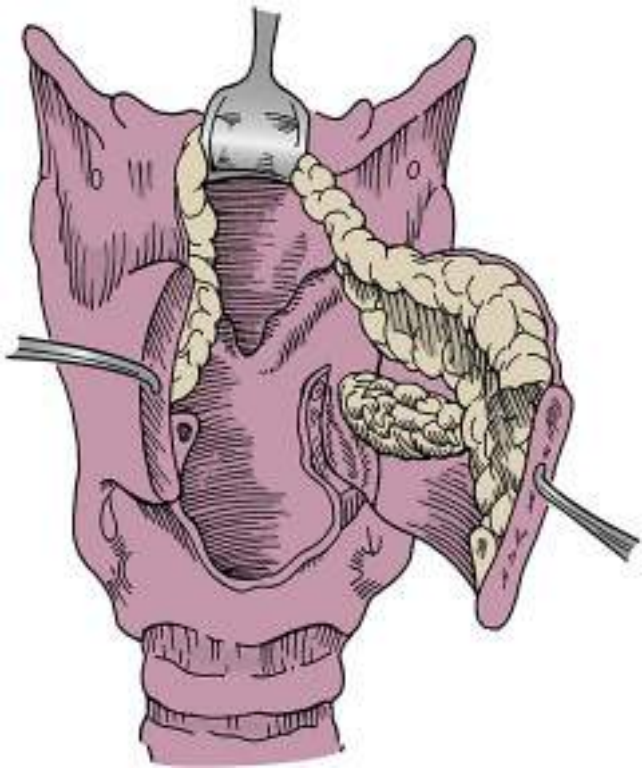

FIG. 13.8 Resection of the cancer by continuing the incision superiorly through the vocal process and vocal cord posterior to the cancer. The arytenoid may be taken at this step.

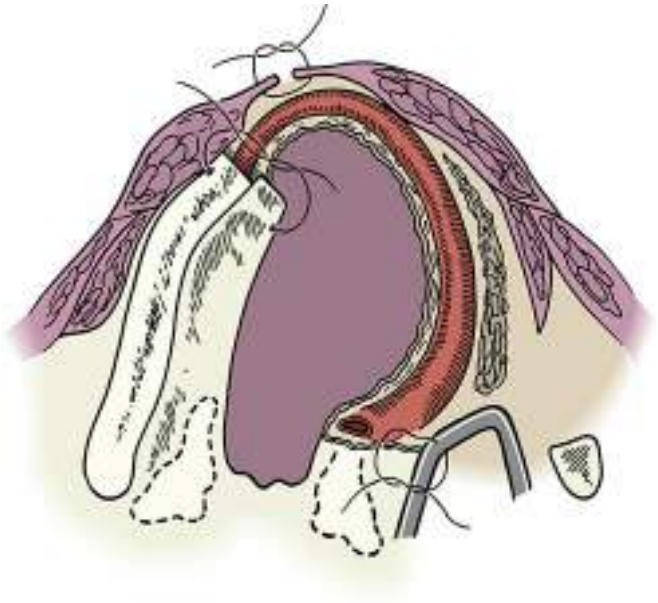

FIG. 13.9 Reattachment of the vocal cord remnant to the thyroid ala.

3. Failure to advance pyriform mucosa over the posterior glottis in cases where the entire arytenoid is resected will lead to increased aspiration.

4. Inadvertent communication between the tracheostomy wound and the surgical site will lead to soiling of the partial laryngectomy wound with tracheal secretions, prolonged healing, and possible loss of cartilage due to infection.

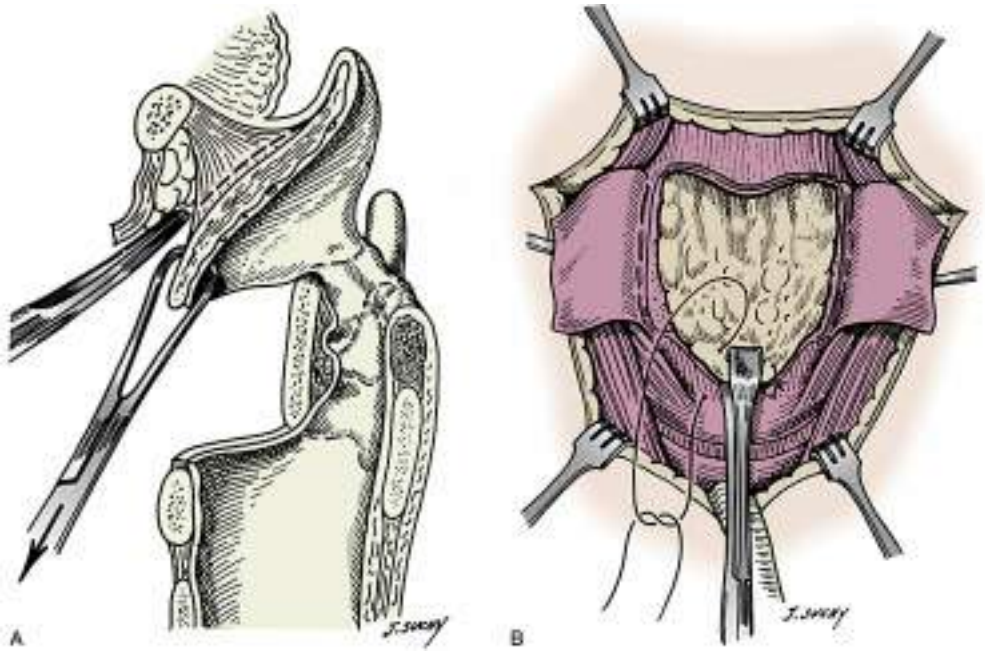

FIG. 13.10 Epiglottopexy to reconstruct anterior glottis.

A, The lingual surface of the epiglottic cartilage is undermined in the subperichondrial plane and pulled inferiorly. **B,** The epiglottis is sutured to the cricoid cartilage to reconstruct the anterior lumen of the larynx. This creates an open anterior glottis with a suboptimal and breathy voice.

Postoperative Period

Postoperative Management

1. The tracheostomy cuff should remain inflated for several days to reduce aspiration of secretions. Thereafter, test deflation of the cuff with downsizing, plugging, and decannulation can occur in an orderly sequence.

2. Nasogastric (NG) tube feeding should be administered until the patient has been decannulated and can swallow without aspirating.

3. Resumption of anticoagulants/antiplatelet drugs is required.

Complications

1. Hemorrhage: Although unusual, this can occur from larger vessels entering the posterior endolarynx. If bleeding occurs, the wound will need to be opened and the perichondrial closure taken down to access the bleeding site.

2. Wound infection: This is best prevented by isolating the tracheostomy incision from the surgical wound as described previously.

3. Vocal cord paralysis: Preservation of the posterior strip of thyroid cartilage and avoidance of dissection near the entry point of the recurrent laryngeal nerve posterior to the cricothyroid joint will prevent this complication

Alternative Management Plan

1. Endoscopic transoral laser excision of early glottic cancer has largely replaced VPL.

2. Total laryngectomy

3. Radiation therapy

4. Newer, more precise radiotherapeutic techniques enhance the ability of radiotherapy to control early glottic cancer that involves the anterior commissure. Accurate staging is a prerequisite, and close cooperation between the head and neck surgeon and radiotherapist is critical. If voice quality is a concern, radiotherapy is most likely the optimal choice.

5. Supracricoid partial laryngectomy with cricohyoidoepiglottopexy is used for more advanced cancer involving both vocal cords. Recovery is more delayed; however, the airway is better than that obtained following extensive resection of both vocal cords. Long-term swallowing function may be better than that obtained by extended VPL reconstructed with epiglottopexy.

6. In the future robotic VPL may be feasible utilizing newer flexible surgical robot devices that facilitate laryngeal surgical approaches that were not feasible with traditional multiarm robotic instrumentation.[8]

Discussion

Evidence-Based Medicine Question

Is vertical partial laryngectomy as effective as supracricoid partial laryngectomy in the management of advanced T2 glottic cancer?

In 2000 Laccourreye et al. compared outcomes of a series of patients with early glottic cancer managed with supracricoid partial laryngectomy with a group managed with VPL. He reported improved disease-free survival with the group treated with supracricoid laryngectomy.

Editorial Comment

Vertical partial laryngectomy (VPL), although now seldom used since the introduction of transoral CO_2 laser microsurgery, remains an important procedure for early glottic cancers in centers that lack radiation or laser facilities, and for surgical salvage of radiation or laser failures.

Review Questions

1. Landmarks for the position of the anterior commissure are

   a. 1 cm superior to the inferior border of the cricoid

   b. **Halfway between the inferior border of the thyroid cartilage and the thyroid notch**

   c. 3 cm anterior to the posterior edge of the thyroid cartilage

   d. 1 mm below the inferior aspect of the thyroid notch

   e. 1 mm above the inferior edge of the thyroid cartilage

2. The maximal subglottic extent of a tumor amenable to VPL is

   a. **1 cm anteriorly and 0.5 cm posteriorly**

   b. At the superior margin of the first tracheal ring

   c. 3 mm

d. 1 cm on the side of the tumor and 0.5 cm on the contralateral side

e. 6 cm above the carina

3. Early glottic cancer can be managed by

a. VPL

b. SPL

c. Transoral laser excision

d. Radiotherapy

e. **All of the above**

Supracricoid Partial Laryngectomy

Miriam N. Lango

Introduction

Historically, a variety of partial laryngectomies have been developed to preserve speech and avoid the permanent stoma associated with the classical total laryngectomy. The supracricoid partial laryngectomy was developed to manage selected glottic and/or supraglottic cancers.[1,2] The procedure can be modified based on the extent of supraglottic involvement; otherwise, supracricoid laryngectomy is distinguished by a standardized approach that has been associated with exceptionally low rates of local cancer recurrence.[1-4] However, proper patient selection is critical. Careful preoperative mapping of the extent of the cancer is necessary to determine whether this operation is appropriate. This procedure may not be undertaken without the patient providing consent for a total laryngectomy should it be needed based on intraoperative frozen section assessment of the resection margins, because as in all cancer operations, it is not acceptable to perform the operation and knowingly leave cancer behind.

Although a permanent tracheostomy is not needed, a tracheotomy is required for several weeks during the postoperative period. During the recovery, patients experience copious secretions through the tracheostomy, some of which lodge in the lungs potentially causing pneumonia. Patients with chronic obstructive lung disease from a long history of smoking may not be suitable candidates for this operation. Over time, the secretions lessen, as patients heal and swallowing function improves, and the copious secretions that were previously expelled through the tracheostomy are swallowed. Once the tracheostomy is removed, patients learn to use a voice, which although it does not resemble their voice prior to the cancer, is understandable. Ultimately, patients with a partial supracricoid laryngectomy report a better quality

of life than those who had their entire larynx removed. The final outcome makes the difficult road to recovery well worthwhile.

However, an alternative to a supracricoid partial laryngectomy should be strongly considered for patients with an active mental health or substance abuse issue or lack of motivation that would impede recovery and preclude rehabilitation therapy compliance. The recovery period after a total laryngectomy is usually far less arduous or protracted. Often, an oral diet may be resumed, without aspiration, within a matter of weeks. In addition, some patients favor an unrestricted oral diet over lung-powered vocalization. Such priorities and preferences should be considered in making treatment recommendations.

Key Operative Learning Points

1. T1-T2, selected T3N0 glottic and/or supraglottic squamous cell carcinomas with involvement of the anterior commissure or petiole of the epiglottis are often good candidates for a supracricoid partial laryngectomy.

2. Glottic cancer with limited supraglottic extension may be reconstructed using a cricohyoidepiglottopexy (CHEP); cancers requiring resection of the epiglottis are reconstructed using a cricohyoidopexy (CHP).

3. Patients with cancer of the larynx after failure of narrow field radiation may be effectively salvaged using a supracricoid partial laryngectomy; however, the swallowing function of patients who received definitive wide field radiation or chemoradiation for cancer of the larynx is poor, and a total laryngectomy should be recommended for salvage.

4. The function of the residual larynx following a supracricoid partial laryngectomy depends on the preservation of at least one cricoarytenoid unit, which opposes the arytenoid against the residual epiglottis or base of the tongue during deglutition, thus protecting the airway.

5. Although select T3 laryngeal cancers with vocal cord fixation are suitable for supracricoid partial laryngectomy, concomitant fixation to the cricoid is a contraindication due to the inability to both preserve a functional cricoarytenoid unit and obtain negative surgical resection margins.

6. Reapproximation of the cricoid to the epiglottis or the base of the tongue is a key technical step and is contingent upon the proper placement of pexy sutures around the cricoid and hyoid; the repair is reinforced by the meticulous closure of the strap muscles.

7. A supracricoid partial laryngectomy is not undertaken in the absence of consent for a total laryngectomy, should it be come necessary.

Preoperative Period

History

1. History of present illness
   a. Hoarseness
   b. Stridor
   c. Shortness of breath
   d. Mass in the neck
   e. Weight loss
   f. History of pneumonia
2. Past medical history
   a. Prior treatment, especially radiation, and tumor stage
   b. Medical illness and functional status
   c. Prior laser surgery does not preclude supracricoid partial laryngectomy (SCPL)
   d. Social history of smoking and/or alcohol use; history of other substance use
   e. Family history
   f. Medications
      1) Antiplatelet drugs, thyroid hormone replacement
   g. Exercise tolerance

Physical Examination

A complete preoperative assessment is necessary to determine whether the patient is an appropriate candidate for a supracricoid partial laryngectomy. This assessment is necessary for patient counseling and involves a careful preoperative physical examination, including laryngoscopy, imaging, and mapping biopsies obtained during a laryngoscopy performed under general anesthesia. Nevertheless, intraoperative findings during the partial laryngectomy such as positive intraoperative frozen resection margins may require conversion to a total laryngectomy. An evaluation for a supracricoid partial laryngectomy starts initially with a careful physical examination.

A complete examination of the head and neck should be performed with particular attention to the following:

1. General health, vitality, appropriate and cooperative behavior, and evidence of frailty should be noted.

2. Pulmonary status should be assessed, as the patient has to cope with some aspiration

3. Voice quality, articulation, hoarseness, or stridor are noted.

4. In the oral cavity, exclude second primary cancers, and evaluate the mobility of the tongue

5. In the pharynx, exclude tonsil and base of tongue involvement by cancer

6. Evaluate the neck for the presence of cervical metastases

7. For laryngeal examination, laryngoscopy is mandatory.

Assess the following:

- Mobility of the vocal cords
- Mobility of the arytenoids
- Supraglottic and subglottic extension
- Arytenoid involvement

Imaging

1. Computed tomography (CT) scan with intravenous (IV) contrast,

magnetic resonance imaging (MRI) of the neck with gadolinium

2. 18F-fluorodeoxyglucose positron emission tomography-computed tomography (PET CT scan)

Although the accuracy of CT scans and MRI scans is limited in defining mucosal extension, they reliably demonstrate findings considered contraindications to supracricoid partial laryngectomy, such as extralaryngeal spread. The PET CT scan is more useful in restaging recurrent larynx cancers after radiation, providing important information regarding the presence of nodal disease and distant metastases.

Indications

1. T1, T2, selected T3, N0-1 glottic and supraglottic squamous cell carcinoma

2. Recurrent T1-T2, selected T3, N0-1 SCC after narrow field radiation

3. Motivated patient, able to participate in swallowing rehabilitation

Contraindications

1. Medical comorbidities with increased risk for general anesthesia

2. Inadequate pulmonary reserve

3. Prior wide field radiation for cancer of the head and neck

4. Preoperative dysphagia due to prior treatment or medical comorbidities

5. Anticipated need for postoperative radiation or chemoradiation

6. Anatomic contraindications

   a. Vocal cord immobility with arytenoid fixation

   b. Subglottic extension

   c. Invasion of the cricoid

   d. Invasion of the hyoid

   e. Extralaryngeal spread

7. Active mental health issues including anxiety or depression

8. Active substance abuse

9. Lack of motivation to participate in recovery and rehabilitation

10. Lack of support systems

Select glottic and supraglottic cancers classified as T3 stage may be effectively treated with a supracricoid partial laryngectomy. Cancers with pre-epiglottic space invasion may be managed with an SCPL, provided that the pre-epiglottic space involvement is not extensive. Vocal cord fixation alone is not a contraindication to SCPL, unless associated with arytenoid fixation. Paraglottic space invasion by a cancer of the larynx will usually produce fixation of the vocal cord, but the adjacent arytenoid will retain mobility. Resection of the arytenoid will usually yield a negative resection margin. In contrast, vocal cord immobility associated with arytenoid fixation is frequently a result of cricoarytenoid joint invasion by cancer; resection of the involved arytenoid rarely yields a negative surgical resection margin. Following radiation or chemoradiation, there may be fixation of the cricoarytenoid joint, even in the absence of direct invasion of the cricoarytenoid joint by cancer. Functional rehabilitation following SCPL is critically dependent on the well-preserved mobility of at least one cricoarytenoid unit.

Preoperative Preparation

1. Medical consultations as necessary

2. Consultation with radiation and/or radiation oncology if indicated

3. Review imaging

4. Informed consent including consent for total laryngectomy

5. Speech and swallowing therapy evaluation

6. Intraoperative examination with mapping biopsies

Operative Period

Anesthesia

1. General anesthesia

Positioning

1. Supine

Perioperative Antibiotic Prophylaxis

1. Ancef and Flagyl
2. Clindamycin if allergic to penicillin

Monitoring

1. Routine for general anesthesia

Instruments and Equipment to Have Available

1. Standard laryngectomy set
2. Standard tracheostomy set

Key Anatomic Landmarks

1. Relationship between the recurrent laryngeal nerve and the cricothyroid articulation (Fig. 14.1). The cricothyroid articulation is not well visualized until the cricopharyngeus and inferior constrictor are elevated off the posterior thyroid cartilage lamina and inferior cornu. The recurrent laryngeal nerve is immediately posterior to the cricothyroid articulation and is at risk of injury during disarticulation of the joint.

2. Relationship of the external and internal branches of the superior laryngeal nerve and the thyrohyoid membrane (see Fig. 14.1). For carcinoma of the glottis, entry into the larynx through the thyrohyoid membrane, below the level of the internal branch of the superior laryngeal nerve, will preserve sensation to the residual epiglottis and enhance swallowing postoperatively.

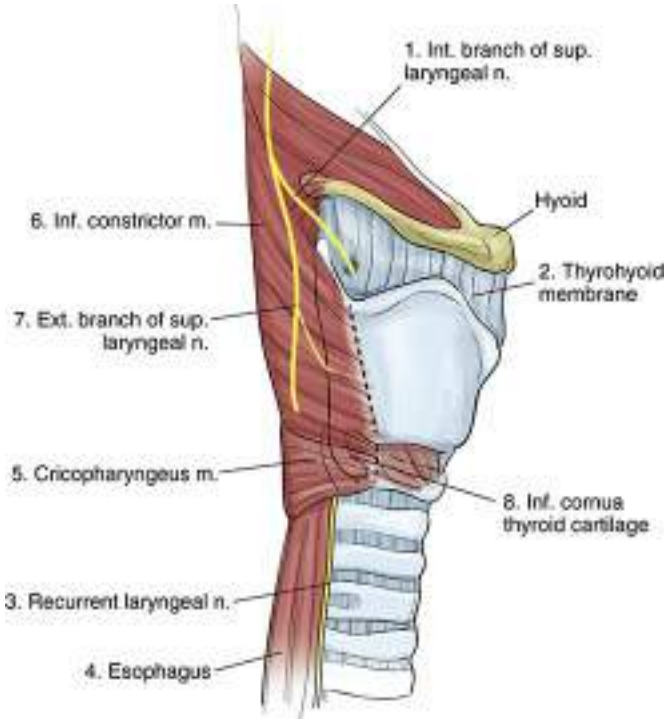

FIG. 14.1 Right side of the thyroid cartilage and trachea.

The inferior constrictor and cricopharyngeus muscle must be released from the posterior thyroid cartilage lamina and inferior thyroid cornu to expose the cricothyroid articulation. The recurrent laryngeal nerve is located just posterior to this articulation.

Prerequisite Skills

1. Expertise in performing total laryngectomy and thyroid surgery

Operative Risks

1. Intraoperative hemorrhage
2. Injury to recurrent laryngeal nerves
3. Injury to the superior laryngeal nerves
4. Injury to the hypoglossal nerves
5. Fracture of the cricoid
6. Dislocation of the arytenoid cartilage

Meticulous surgical technique and a working knowledge of the anatomy of the larynx will prevent most intraoperative complications. Great care is used to disarticulate the cricothyroid joint. Sutures placed to approximate the cricoid to the residual supraglottis or hyoid must be secured snugly to prevent dehiscence but not too tightly so as to damage the cricoid. The cricoid is susceptible to injury during manipulation, particularly after radiation. During the resection, the surgical incision anterior to the arytenoid will preserve a fully functional cricoarytenoid unit necessary for airway protection; inadvertent dislocation of the arytenoid cartilage cannot be salvaged. If both arytenoid cartilages are resected as part of the procedure, conversion to a total laryngectomy is necessary. Preservation of the strap muscles will help bolster the closure and provide the extra tissue used to separate the tracheostomy from the rest of the neck.

Surgical Technique

Prior to a definitive operation, a pan-endoscopy with biopsies should be performed to map out the extent of the cancer. Direct laryngoscopy and tracheoscopy and biopsy may demonstrate subglottic extension of cancer that was not appreciated on imaging studies and represent a contraindication to SCPL. Pan-endoscopy may be performed in a staged fashion or just prior to the open procedure. Pathologic review of biopsy specimens performed elsewhere requires pathologic confirmation prior to definitive surgery.

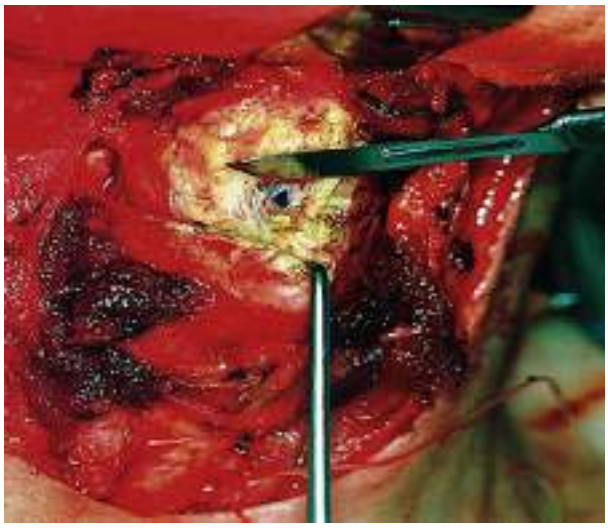

FIG. 14.2 For laryngeal carcinomas with minimal supraglottic involvement, entry into the larynx is accomplished by means of dissection through the pre-epiglottic space. An incision started just above the thyroid notch is extended through the pre-epiglottic space. The infrahyoid epiglottis is incised, resulting in laryngeal entry and direct visualization of the glottis. Placing a Deaver retractor in the mouth against the infrahyoid epiglottis may be helpful.

An apron incision, centered on the cricoids, is designed and subplatysmal flaps are elevated to 1 cm superior to the hyoid bone. Neck dissections are performed as indicated. The strap muscles are separated in the midline. The sternohyoid and omohyoid muscles are transected at the superior edge of the thyroid laminae. The deeper sternothyroid muscles are transected over the thyroid cartilage, and strap muscle flaps are elevated and retracted laterally. The thyroid isthmus is divided in the midline, and the thyroid lobes are dissected off of the trachea, preserving the superior thyroid neurovascular pedicle. Anterior pretracheal cervicomediastinal finger dissection is performed down to the carina. The inferior pharyngeal constrictor muscles are mobilized off the posterior edge of the thyroid cartilage. Transecting the superior cornua of the thyroid cartilage at their bases facilitates mobilization and delivery. The mucosa of the piriform sinus is mobilized from the inner aspects of the thyroid laminae. The cricothyroid joint is disarticulated sharply using a 15 blade angled medially and superiorly just beneath the inferior cornua of the thyroid cartilage to preserve the recurrent laryngeal innervation of the cricoarytenoid units. At least one functional cricoarytenoid unit is a prerequisite for a functional larynx (see Fig. 14.1).

The cricothyroid membrane is incised along the cricoid. The subglottic region is inspected to rule out the possibility of subglottic extension, which would preclude a supracricoid partial laryngectomy. Cancer may extend up to the level of the cricoid but not below this level to be considered operable using this technique. Frozen section margins must be negative. The endotracheal tube is passed through the cricothyroidotomy.

The means of entry to the larynx depends on the extent of supraglottic involvement by cancer. For cancers with minimal supraglottic

involvement, infrahyoid entry into the larynx through the pre-epiglottic space enables the epiglottis to be preserved (Fig. 14.2). Supracricoid partial laryngectomy is followed by impaction of the cricoid against the residual epiglottis and hyoid for the purpose of reconstruction. For supraglottic or combined supraglottic and glottis cancers, hyoid dissection (usually immediately below the hyoid) yields entry into the vallecula. The pre-epiglottic space is resected with the partial laryngectomy. Reconstruction is accomplished by means of impacting the cricoid and the residual hyoid.

Supracricoid Partial Laryngectomy With CHEP for Glottic Carcinoma

For glottic cancers with minimal extension to the supraglottis, entry into the larynx is achieved through the pre-epiglottic space (see Fig. 14.2). A Deaver retractor inserted into the mouth positioned against the infrahyoid epiglottis, can help prevent disorientation in the pre-epiglottic space. The cartilage of the infrahyoid epiglottis is then transected, and the airway is entered through the petiole. This opening is then extended laterally on the less involved side behind the superior aspect of the thyroid cartilage.

The incision is extended inferiorly to the cricothyrotomy, through the aryepiglottic fold, posterior aspect of the false and true vocal cords, but anterior to the ipsilateral arytenoid (Fig. 14.3). Once the thyrohyoidotomy and cricothyrotomy are connected, the thyroid cartilage may be fractured vertically at the level of the thyroid notch, opening the larynx "like a book." The final incisions are made under direct visualization. The paraglottic space is resected. The contralateral arytenoid may be resected as needed, but the mucosa over the posterior commissure and interarytenoid region must be preserved to prevent arytenoid fixation or glottic stenosis.

After frozen section margin clearance is secured, the arytenoid cartilages are repositioned in an anterior position using 4.0 Vicryl suture. Usually, the arytenoid mucosa does not reach the anterior cricoid arch, and the sutures securing the arytenoid in an anterior position are air knotted. The cricoid is then impacted against the hyoid using three submucosal 1 Prolene sutures with a TP-1 needle. The initial suture is

passed submucosally under the midline of the cricoid, looping around the hyoid under the epiglottis and the mucosa of the base of the tongue. Two additional sutures are placed 1 cm off the midline, taking care to avoid the hypoglossal nerves, and tied securely (Fig. 14.4). A low tracheostomy is only now created at the level of the neck incision, creating a tracheostomy that will not place tension on the impacted cricohyoid repair. During closure, skin flaps are advanced over the stoma and secured to isolate the neck contents from the tracheostoma. A 4.0 Vicryl suture is used to pull the piriform sinus mucosa anteriorly into a more physiologic position. A cricopharyngeal myotomy is not performed. The strap muscles are used to reinforce the pexy. The neck is closed in layers over suction drains.

Nutritional supplementation will require a nasogastric tube or a temporary gastrostomy. Typically, patients undergo decannulation prior to removal of the feeding tube. The cuff is deflated the day following surgery, and an uncuffed tracheostomy tube is placed during the first tracheostomy tube change. A decline in the volume of tracheal secretions suggests that the swallowing function is returning. When the patient is able to swallow saliva, a thickened liquid diet may be started, and a swallowing rehabilitation program is instituted.

Supracricoid Partial Laryngectomy With Cricohyoidopexy for Supraglottic Carcinoma

The management of a supraglottic squamous cell carcinoma or a glottic carcinoma extending to involve the supraglottis requires resecting the epiglottis and pre-epiglottic space to ensure complete removal of the cancer. Instead of entering the airway through the pre-epiglottic space, entry into the vallecula is accomplished by dissecting immediately below the hyoid. Placement of a Deaver retractor into the vallecula can assist with this maneuver. The epiglottic and inferior incisions across the aryepiglottic fold, posterior false, and true cords (Figs. 14.5 and 14.6) proceed in a fashion similar to that described previously. The repair impacts the cricoid and arytenoids against the base of tongue, rather than the residual epiglottis (see Fig. 14.4).

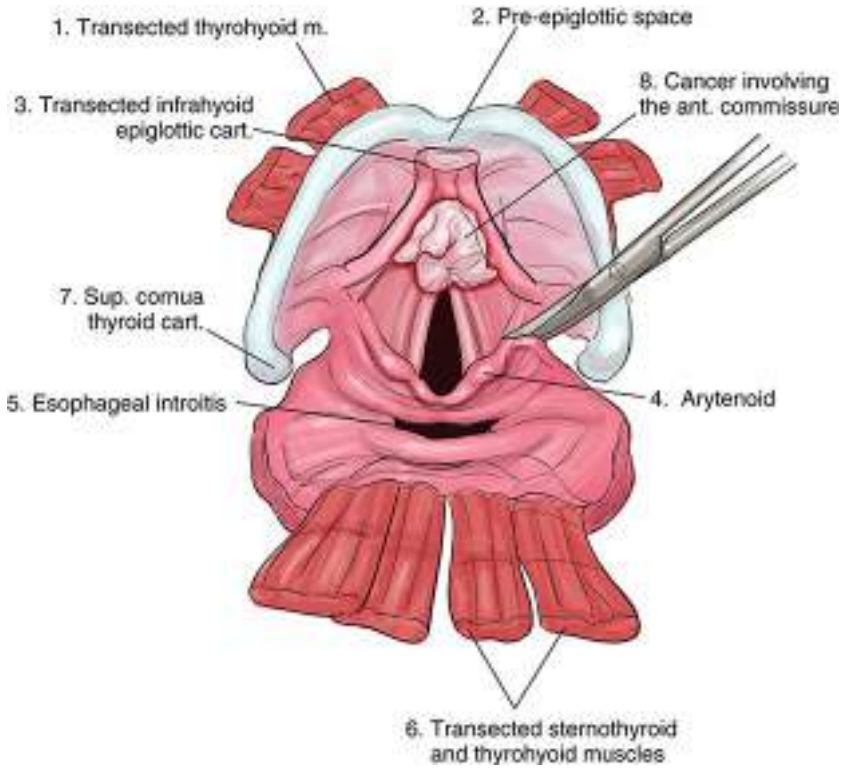

FIG. 14.3 Surgical view from the head of the table.

The infrahyoid epiglottis has been transected. The suprahyoid epiglottis is not visible under the superior edge of the wound. Surgical incisions are made just anterior to the arytenoid, through the aryepiglottic fold, false and true vocal cord. *1,* Transected thyrohyoid muscle; *2,* Pre-epiglottic space; *3,* Transected infrahyoid epiglottic cartilage; *4,* Arytenoid; *5,* Esophageal introitus; *6,* Transected sternothyroid and thyrohyoid muscles; *7,* Superior cornua thyroid cartilage; *8,* Cancer involving the anterior commissure.

Common Errors in Technique

1. Failure to save the strap muscles for use in reconstruction
2. Failure to save at least one cricoarytenoid unit
3. Improper placement of pexy sutures
4. Incorrect tension on pexy sutures
5. Incorrect placement of tracheostomy with tension on the impaction
6. Failure to separate the neck contents from the tracheostoma

Postoperative Period

Postoperative Management

1. Antibiotics should be continued postoperatively for 24 hours.
2. Diligent tracheostomy care
3. Encourage cough, deep breathing, and ambulation
4. Speech rehabilitation

Complications

1. Subcutaneous air
2. Wound infection
3. Dehiscence of pexy
4. Aspiration pneumonia
5. Tracheotomy dislodgement
6. Laryngeal stenosis
7. Cricoid fracture

Most complications may be avoided with meticulous surgical technique. Subcutaneous air is seen when the tracheostomy is not sutured to the muscle and skin flaps, allowing the entry of tracheal secretions into the neck. This results in wound infection. Proper placement of pexy sutures prevents dehiscence. Dysphagia after this procedure is common and expected. Patients with poor pulmonary reserve may develop aspiration pneumonia. Proper patient selection is necessary to decrease the frequency of this complication. Tracheostomy tubes should be secured with sutures and ties for 5 days prior to the first tracheostomy tube change. Inability to replace a dislodged tracheostomy tube is an emergency; oral intubation may be challenging due to swelling, profuse secretions, and limited extension of the neck. Laryngeal stenosis may follow dehiscence of a pexy or an extended resection of an arytenoid. Damage to the cricoid will lead to wound infection and rupture of the pexy, for which conversion to a total laryngectomy is usually necessary.

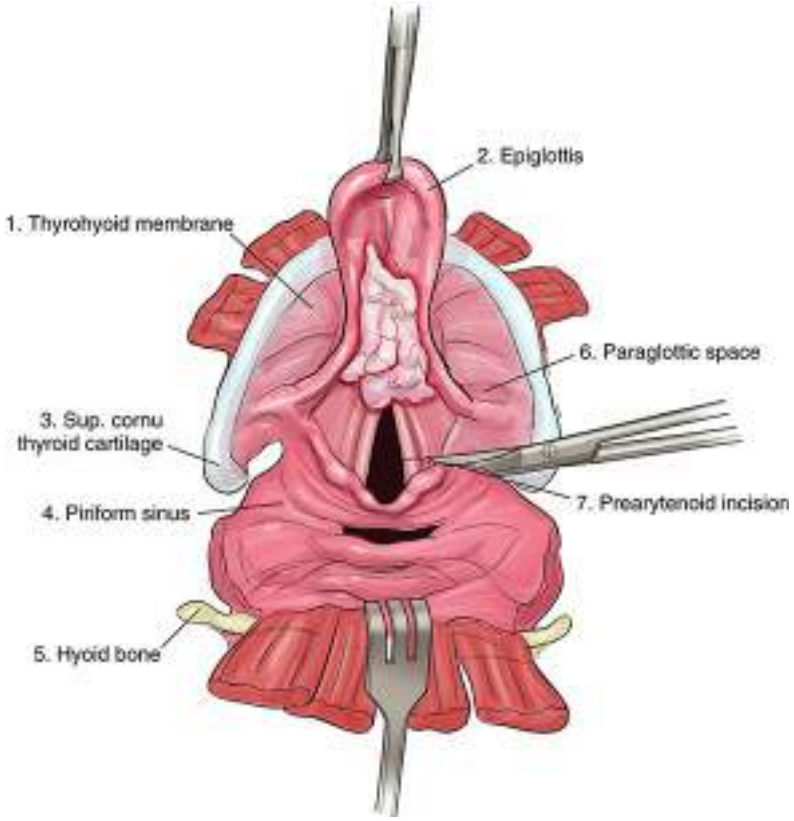

FIG. 14.5 Surgical view from the head of the table.

The infrahyoid epiglottis will be resected with the specimen. Surgical cuts are made just anterior to the arytenoid, through the aryepiglottic fold, false and true vocal cord. *1,* Thyrohyoid membrane; *2,* Epiglottis; *3,* Superior cornu thyroid cartilage; *4,* Piriform sinus; *5,* Hyoid bone; *6,* Paraglottic space; *7,* Prearytenoid incision. Reprinted with permission Brasnu DF: Supracricoid partial laryngectomy with cricohyoidopexy in the management of laryngeal carcinoma. *World J Surg 27*[7]:817-823, 2003.

FIG. 14.6 Infrahyoid dissection with resection of the supraglottis and glottis along with the paraglottic space and pre-epiglottic space. This defect will be reconstructed with a CHP.

Alternative Management Plan

1. Total laryngectomy

2. Radiation or chemoradiation

Long-Term Outcomes

Long-term complications include neck fibrosis and a variable degree of dysphagia. The vast majority of patients do not require a gastrostomy long term. However, patient selection is important. The local cancer control rates following a supracricoid partial laryngectomy for laryngeal cancer are extremely favorable relative to radiation alone. Indeed, the indications for SCPL have been expanded to include selected glottis and supraglottic squamous cell carcinomas classified as T3 and recurrent cancers after failure of radiotherapy. Local control and disease-related survivals remain favorable in several large series.[3-5]

The supracricoid partial laryngectomy procedure is a highly effective procedure to manage early stage and select T3 larynx cancers. The SCPL is also effective in managing recurrent early stage larynx cancers after failure of radiotherapy. Judicious and careful patient selection followed by flawless surgical technique and postoperative management will ensure optimal results (Video 14.1).

Editorial Comment

Selection of treatment of cancer of the larynx should be based on the approach that is most likely to result in prolonged, cancer-free survival. Larynx conservation surgery, which preserves speech and swallowing function, may be undertaken in selected patients. Even though total laryngectomy offers all of these benefits, it does have the major drawback of a permanent tracheostoma and having to manage and pay for speaking valves. Therefore a surgeon should always consider conservation laryngeal surgery in suitable patients before simply opting for total laryngectomy.

Review Questions

1. Indications for a supracricoid partial laryngectomy include all the following laryngeal squamous cell carcinomas *except*

   a. T2N0 supraglottic squamous cell carcinoma

   b. Transglottic squamous cell carcinoma

   c. Squamous cell carcinoma involving the anterior commissure

   d. **Squamous cell carcinoma involving the posterior commissure**

   e. rT1N0 glottic squamous cell carcinoma after radiation

2. Potential complications of a supracricoid partial laryngectomy include all of the following *except*

   a. Dehiscence of the pexy sutures

b. Cricoid fracture

c. Recurrent laryngeal nerve paralysis

d. **Dysphagia**

e. Aspiration pneumonia

3. Contraindications for a supracricoid partial laryngectomy include all the following *except*

a. **Prior wide field neck radiation**

b. Vocal cord immobility with arytenoid fixation

c. Oxygen dependent chronic obstructive lung disease

d. Involvement of the cricoid cartilage

e. Prior stroke with dysphagia

Supraglottic Transoral Robotic Surgery

J. Kenneth Byrd, and Umamaheswar Duvvuri

Introduction

Early supraglottic squamous cell carcinoma may be treated with either surgery or radiation as a single modality with equal results, based on retrospective evidence and extrapolation from larger studies comparing radiation to total laryngectomy. As treatment modalities shifted toward "organ preservation therapy" after the Veterans Affiars Larynx trial, both surgical innovation and a noted decrease in survival have prompted the resurgence of conservation surgical procedures, both open and endoscopic. Although open supraglottic partial laryngectomy (SGPL) is an excellent oncologic technique, it has been supplanted by endoscopic partial laryngectomy. Endoscopic laser partial laryngectomy has been shown to provide equivalent disease control compared with the open procedure[1], with good functional outcomes.

Transoral robotic surgery (TORS) was popularized in the mid-2000s by Weinstein and colleagues, who first reported TORS in a canine model and shortly thereafter published a series of three patients who underwent the procedure successfully.[2] Since then, the technique has been widely adopted and reported in the literature with success rates comparable to both open surgery and laser microsurgery.[3-7] Compared with open surgery, authors cite shorter operative times and lengths of hospitalization and avoidance or shortened duration of tracheostomy and enteral feeding. Compared with transoral laser microsurgery (TLM), TORS may also be associated with shorter operative times, provided that the patient's anatomy allows adequate exposure with available retractors and instrumentation.[8]

Key Operative Learning Points

- Superiorly based T1/T2 supraglottic tumors may be efficiently resected using TORS as an alternative to TLM, provided that the patient's anatomy allows adequate exposure.
- Careful patient selection is important to ensure that swallowing and airway are not compromised by surgery.
- The superior laryngeal artery must be controlled with cautery or clips when dissecting in the lateral pre-epiglottic space.
- Dissection becomes more restricted inferiorly.

Preoperative Period

Candidates for TORS supraglottic laryngectomy should undergo preoperative in-office laryngoscopy to assess vocal cord mobility and mucosal extent of the cancer. Contrasted computed tomography (CT) may be helpful to evaluate the base of tongue, pre-epiglottic space, laryngeal framework, and cervical lymph nodes. The classification system proposed by Remacle et al. for the european laryngological society (ELS) endoscopic laser supraglottic laryngectomy is applicable for TORS SGPL.[9] Patients with significant lung disease or poor performance status may be poor candidates for partial laryngeal surgery, especially more extensive ELS types, due to the probability of postoperative dysphagia and aspiration.

Robotic supraglottic laryngectomy is contraindicated in the presence of extralaryngeal spread, major invasion of the base of the tongue, and fixation of the arytenoid. Patients with significant involvement of the pre-epiglottic space or glottis may be better treated with an open approach to remove adjacent laryngeal framework as a margin and reposition the arytenoids, when necessary.

Patients should be counseled about the possible need for postoperative radiation or chemoradiation (CRT) due to cancer that may be found after neck dissection. In a large, multi-institutional European study, 51% of patients treated with TORS SGPL and neck dissection required adjuvant therapy.[7] Patients with N2 or N3 metastasis or obvious extracapsular spread on imaging should be counseled that long-term swallowing outcomes will be poorer if concurrent chemoradiotherapy is necessary after SGPL. These patients may be better served with definitive

chemoradiation, rather than surgery as a primary modality.

History

1. History of present illness
   a. A thorough history should be taken to assess for pain, dyspnea, dysphonia, stridor, dysphagia, and aspiration.
   b. The duration of symptoms is important to determine the rapidity of growth and impending airway compromise.
   c. The patient's ability to take adequate nutrition and any recent weight loss should be noted.
   d. Any prior treatment for the cancer should be elicited, including prior surgery, radiation, or chemotherapy.
2. Past medical history
   a. Other malignancies
      1) Prior cancer of the head and neck
      2) Cancer of the lung
   b. Comorbidities
      1) Chronic obstructive pulmonary disease or asthma
      2) Heart disease
      3) Other systemic disease: diabetes, renal disease
   c. Prior surgery of the head and neck, including carotid endarterectomy, tracheostomy
   d. Medications
      1) Aspirin
      2) Anticoagulants
      3) Nebulizers or steroids
   e. Social history
      1) Tobacco use—how much, how long?
      2) Marijuana

3) Alcohol or other substance dependence—how much, how long?

Physical Examination

1. General: Ambulatory status, dyspnea, overall health assessment

2. Oral cavity: Note the presence of factors that would prevent adequate transoral exposure

   a. Trismus

   b. Mallampati/tongue size

   c. Dentition

   d. Micrognathia

3. Neck

   a. Cervical lymph nodes

   b. Previous incisions

   c. Hyomental distance

   d. Range of cervical motion/extension

4. Voice/respiratory

   a. Stridor

   b. Wheezing

   c. Hoarseness

5. Flexible laryngoscopy

   a. Extent of tumor

      1) Suprahyoid versus infrahyoid epiglottis

      2) False vocal fold

      3) Glottis

      4) Hypopharynx

      5) Base of the tongue/vallecula

   b. Vocal cord movement should be assessed because fixation is a contraindication to TORS supraglottic laryngectomy.

c. Examine for synchronous primary cancers

Imaging

1. CT of the neck with contrast
   a. Pre-epiglottic space and/or extralaryngeal extension of tumor
   b. Cervical lymph nodes
2. CT of the chest
   a. Metastases or second primary lung cancer
   b. Evidence of COPD
   c. Superiorly located brachiocephalic artery should be noted if tracheostomy is planned
3. Positron emission tomography-computed tomography (PET/CT): For stage III/IV cancer, PET/CT may be performed to screen for distant metastatic disease in lieu of CT chest
4. Magnetic resonance imaging (MRI): Limited indication but may be useful if tongue base involvement is a concern

Indications

1. T1/T2 squamous cell carcinoma (SCC) of the supraglottis
2. Selected recurrent supraglottic or hypopharyngeal SCC
3. Glottic SCC
   a. Has been reported in small case series
   b. May be more widely adopted if smaller instruments become available

Contraindications

1. Inadequate intraoperative exposure
2. Fixation of the vocal cord

3. Extralaryngeal soft tissue involvement

4. Cartilage destruction

5. Bilateral glottic involvement

6. Poor cardiopulmonary reserve

7. Advanced neck disease necessitating postoperative concurrent chemoradiation (relative contraindication)

Preoperative Preparation

1. Swallowing evaluation
   a. Assess for dysphagia/aspiration.
   b. Significant dysphagia predicts poor postoperative swallowing.
   c. Instruction in supraglottic swallow preoperatively reduces postoperative dysphagia.
2. Dental evaluation if adjuvant therapy is likely to be needed
3. Anesthesiology
4. Discontinue aspirin and anticoagulants 1 week prior to surgery.
5. Continue respiratory medications for patients with COPD.

Operative Period

1. Anesthesia
   a. Plan for securing airway should be discussed prior to induction
   b. A small endolaryngeal tube is used to minimally obstruct working space.
   c. Nasotracheal intubation is not always necessary but may improve exposure.
   d. Bulky supraglottic tumors may require fiberoptic intubation or intubation by an Otolaryngologist
   e. Paralytic agents may aid in exposure of the larynx.

f. An arterial line may be necessary to safely monitor blood pressure due to positioning if significant comorbidities are present.

2. Positioning

   a. Supine

   b. Bed is turned 180 degrees from anesthesia

   c. Arms are tucked to allow robotic docking and suspension

   d. The da Vinci robot is docked at 30 degrees to the head of bed

   e. A 0-silk suture is placed through the junction of the anterior and middle thirds of the oral tongue for anterior retraction.

3. Perioperative antibiotic prophylaxis is not routinely indicated.

4. Routine anesthetic monitoring

5. Instruments and equipment to have available

   a. Feyh-kastenbauer (FK) retractor or Crowe-Davis retractor

   b. The 8-mm 0-degree endoscope is used with 5-mm instruments.

      1) Maryland retractor

      2) Monopolar cautery

      3) Alternatively, a needle driver may be used with a CO_2 laser fiber carrier.

   c. Bedside assistant aids in dissection, suctioning, and hemostasis

      1) Pediatric Yankauer and laryngeal suctions

      2) Bipolar cautery

      3) Endoscopic clip applicator

Key Anatomic Landmarks

- The supraglottis is the region of the larynx that extends from the laryngeal ventricle superiorly to the tip of the epiglottis.
- Subsites include the suprahyoid and infrahyoid epiglottis, the aryepiglottic folds, arytenoid, corniculate, and cuneiform cartilages, and the false vocal folds.

- The quadrangular membrane, epiglottic cartilage, and hyoepiglottic ligament act as barriers to prevent spreading to adjacent sites, but tumors may quickly involve the glottis via spread through the paraglottic space, which is continuous with the pre-epiglottic space.
- Cancer that penetrates the epiglottic cartilage may extend into the vallecula and base of tongue musculature, and evaluation of the pyriform sinuses for spread is important when the aryepiglottic fold is involved.
- The superior laryngeal artery runs deep to the nerve from the transoral perspective, deep to the mucosa near the pharyngoepiglottic fold in the pre-epiglottic space. The artery may be sizable and should be addressed definitively with clips or bipolar cautery.

Prerequisite Skills

- Transoral robotic surgery
- Endoscopic laryngeal surgery

Surgical Technique

- A tooth guard should be placed on the upper dentition. We have found that a thermoplastic splint cut and molded to the dentition is less bulky and more durable than the standard rubber or plastic tooth guard.
- Direct laryngoscopy is performed to map the cancer.
- If retraction of the oral tongue with a suture is needed for exposure, the lower teeth should also be covered with a tooth guard to prevent maceration of the ventral tongue.
- The FK retractor with the laryngeal or flat base of the tongue blade is inserted into the vallecula. Depending on the patient's anatomy, the 0- or 30-degree endoscope may be used.
- The Crowe-Davis retractor may be used in some patients as an alternative.
- The base of the da Vinci robot is brought in at 30 to 45 degrees to the foot of the operating table.

- A Maryland retractor and the monopolar cautery or laser manipulator are used for dissection, placed on either side of the camera to form an isosceles triangle of 30 to 45 degrees. The black lines on the ports, marking the pivot axes, should be near the level of the oral commissures.
- Fig. 15.1 demonstrates a tumor of the epiglottis appropriate for TORS resection.
- Dissection begins by making mucosal incisions 5 mm to 1 cm away from the tumor (Fig. 15.2).
- An incision into the vallecula to improve mobility of the tumor and for resection of the pre-epiglottic space, if necessary (Fig. 15.3)
- Rotation of the epiglottis back and forth may be necessary to make circumferential mucosal and deep incisions to avoid bisecting the specimen (Fig. 15.4). Alternatively, large cancers may be removed in several pieces with careful orientation for the pathologist.
- Repeated regrasping of the epiglottis should be avoided to limit disruption of the mucosa and cartilage.
- Laterally the superior laryngeal arterial supply should be positively identified and controlled with bipolar cautery or clips.

FIG. 15.1 A supraglottic squamous cell carcinoma involving the midline suprahyoid and infrahyoid epiglottis. The asterisk *(*)* denotes the center of the tumor.

FIG. 15.2 The monopolar cautery is used to incise the right aryepiglottic fold and pharyngoepiglottic fold a suitable distance from the visible tumor.

FIG. 15.3 The incision is continued into the vallecula to further mobilize the tumor and to resect the pre-epiglottic space to the hyoid bone, if necessary.

FIG. 15.4 The epiglottis is grasped and rotated to facilitate further dissection with the mucosal surfaces visualized.

- The anterior and ipsilateral incisions facilitate visualizing the full extent of the tumor (Fig. 15.5).
- When the specimen is fully mobilized superiorly and laterally, the inferior incision is made (Fig. 15.6).
- Communication with the bedside assistant is important to maintain orientation, particularly for small specimens.
- Circumferential frozen section margins are taken and analyzed by the pathologist while the patient is still in the operating room.
- The field is irrigated and inspected after a Valsalva maneuver to ensure hemostasis (Fig. 15.7). Hemostatic agent may be applied.

Common Errors in Technique

- The endotracheal tube may become dislodged by the robotic arms if not adequately secured.
- Improper docking causes arm collisions.
- Failure to identify and control the superior laryngeal artery leads to brisk intraoperative or postoperative bleeding.

FIG. 15.5 With the epiglottis freed by right-sided and vallecular incisions, the extent of left-sided tumor *(*)* is visualized.

FIG. 15.6 The contralateral inferior mucosal incision is made to further mobilize the tumor.

- Inadequate exposure due to positioning or anatomic factors may result in incomplete tumor resection and positive margins.
- The internal branch of the superior laryngeal nerve should be preserved for laryngeal sensation if tumor resection does not require sacrifice.

Postoperative Care

- Perioperative steroids are useful to prevent airway edema, particularly when the false vocal folds are involved.
- A single perioperative dose of steroids may suffice for epiglottectomy; however, consideration may be given to a full 24 hours of postoperative steroids if airway edema is a concern.
- Postoperative antibiotics are advocated by some but are not routinely used at our institutions.
- Most patients are kept in the hospital for observation and swallowing evaluation.
  - If the patient is managing his or her secretions the following day, a speech and language pathologist may assess swallowing at the bedside, with a modified barium swallow study, or Fiberoptic Endoscopic Evaluation of Swallowing (FEES).
  - If the patient is intolerant of secretions or is unable to sustain enough oral intake, a nasogastric tube is placed until follow-up.
- For limited resections, the surgeon may consider discharging a reliable patient without significant cardiopulmonary comorbidities after monitoring in recovery.
- The patient should be aware that delayed laryngeal edema may develop rarely and that prompt attention should be sought.

Complications

- Airway bleeding: return to operating room for intubation and operative control
- Dental injury
- Lingual nerve neuropraxia: temporary
- Delayed airway compromise due to edema
  - Intubation
  - Tracheostomy

- Aspiration
- Prolonged dysphagia
  - Nasogastric feeding up to 2 to 3 weeks
  - Gastrostomy if prolonged enteral feeding needed
- Airway stenosis

FIG. 15.7 Resultant defect from supraglottic partial laryngectomy involving the suprahyoid and infrahyoid epiglottis to the level of the laryngeal ventricles.

Alternative Management Plan

Patients with early stage supraglottic cancer may be treated with TLM, open partial laryngeal surgery, total laryngectomy, or (chemo)radiation therapy.

Discussion

Evidence-Based Medicine Question

What are the outcomes for TORS supraglottic laryngectomy?

Patients with T1-T2 N0 SCC of the supraglottis treated surgically had

81% to 86% disease-specific survival in the surveillance, epidemiology, and end results program (SEER) study of more than 2600 patients by Arshad et al.[10] Although no prospective trials compare TORS SGPL to TLM SGPL or open partial laryngectomy, oncologic outcomes in retrospective studies have been equivalent. In the literature, tracheostomy and enteral feeding practices vary greatly from study to study and likely depend on patient selection. When tracheostomy is performed, decannulation is generally possible within 2 weeks.[7] Temporary enteral feeding is typically accomplished with a nasogastric tube, rather than a gastrostomy; the largest published series of TORS-SGPL, a multi-institutional European collaboration, reports a 9.5% incidence of gastrostomy, which is comparable with other smaller series.[4,7] Early consultation with a speech and language pathologist and initiation of the supraglottic swallow may shorten the duration of temporary dysphagia. Preoperative speech evaluation may help to identify patients with pre-existing dysphagia who may benefit from early gastrostomy placement. Similarly the rate of complications varies based on report from 0% to 28% and includes bleeding, delayed airway compromise, and aspiration pneumonia.[4-7] Superior laryngeal artery bleeding can result in rapid loss of airway, requires a return trip to the operating room, and is best prevented by deliberate control at the time of resection.

Editorial Comment

TORS-SGPL has all the benefits of transoral CO_2 laser microsurgery, as well as improved access in patients in whom anatomic factors preclude good visualization of the tumor with the microscope. However, the high initial cost and recurrent costs of TORS are still a barrier to its introduction outside the developed world.

Johan Fagan

- Access the review questions online at http://www.expertconsult.com

Review Questions

1. Which of the following stage cancers is not a potential candidate for TORS?

a. T1N0M0 suprahyoid epiglottis

b. T2N1M0 epiglottis and aryepiglottic fold

c. **T3N2cM0 supraglottis with vocal cord fixation**

d. T2N0M0 aryepiglottic fold and pyriform sinus

2. What is an advantage of monopolar cautery over CO_2 laser for TORS SGPL?

a. Less thermal scatter

b. **Shorter operative time**

c. More working space

d. Smaller instruments

3. In TORS SGPL, which of the following arteries is commonly encountered and must be addressed?

a. Lingual artery

b. **Superior laryngeal artery**

c. Facial artery

d. External carotid artery

Total Laryngectomy

Anna Pou

Introduction

The most common location of laryngeal cancer is the glottis, followed by the supraglottis, with the least common site being the subglottis. The American Cancer Society estimates that more than 14,000 new cases of laryngeal cancer will occur in the United States in 2016, resulting in about 3620 deaths.[1] It occurs more frequently in males. Tobacco (cigarette smoking) is the primary risk factor for laryngeal cancer, and the incidence is falling about 2% to 3% per year because fewer people are smoking. Other causes include alcohol, human papilloma virus (HPV), and environmental factors, such as exposure to asbestos. The most common histologic type is squamous cell carcinoma and the prognosis depends upon the stage at the time of diagnosis. Treatment has changed over the past 25 years to include conservation laryngeal surgery—for example, endoscopic techniques such as transoral laser microsurgery, transoral robotic surgery, and organ preservation protocols. Total laryngectomy is employed primarily in patients with advanced laryngeal cancer, in cases of failed organ preservation treatment, and in those who cannot undergo conservation laryngeal surgery due to medical comorbidities. Depending on the stage of a tumor, patients may require adjuvant (chemo) radiation therapy. Total laryngectomy has a significant psychologic impact related to changes in voice, swallowing, and olfaction, in addition to living with a permanent stoma.[2]

Key Operative Learning Points

1. Accurate tumor staging is paramount for successful treatment.

2. Unilateral or bilateral neck dissections may be indicated, depending on

the staging of the neck and the location and extent of the tumor.

3. Control of the airway is of utmost importance. Some patients may require a preoperative tracheostomy for airway obstruction. If this is not required, intubation can generally be performed by direct laryngoscopy or flexible fiberoptic intubation.

4. Mapping of the tumor is required to plan the surgical approach so that the cancer is removed with appropriate margins.

5. Cover the edges of the tracheostoma by approximating skin to tracheal cartilage with half vertical mattress suture.

6. Identify the hypoglossal nerves bilaterally to avoid inadvertent injury to the nerves.

7. A watertight pharyngeal closure is required to prevent a pharyngocutaneous fistula.

8. If a tracheoesophageal puncture (TEP) is performed, a pharyngeal constrictor myotomy is necessary to prevent spastic speech.

9. Flap reconstruction is not a contraindication to primary TEP, provided that the party wall is not separated.

Preoperative Period

History

1. History of present illness
   a. Hoarseness is one of the most common presenting symptoms.
   b. Patients may also complain of pain in the throat, odynophagia, dysphagia, otalgia, and weight loss.
   c. If previously treated, the patient may have a recurrence of his or her initial presenting symptoms.
2. Past medical history
   a. Prior treatment with conservation laryngeal surgery, radiation therapy, or organ preservation protocol
   b. Medical illness: Severe chronic obstructive pulmonary disease

(COPD), cardiac disease, history of deep vein thrombosis (DVT)

c. Past surgical history

d. Family history of cancer of the head and neck

e. Social history: Tobacco use, alcohol abuse, environmental exposure to asbestos, marijuana use

f. Medications: Antiplatelet drugs, Warfarin

g. Allergies

Physical Examination

1. Voice quality

2. Dyspnea, stridor

3. Laryngeal examination with a mirror or a flexible fiberoptic laryngoscope. The latter is especially helpful, as it can be used as an educational tool and to follow a patient's progress. The location of the tumor and the mobility of the vocal cords are documented, as well as the presence or absence of aspiration and pooling of secretions.

4. Complete examination of the head and neck for second primaries

5. Neck: Presence of lymph node metastases; involvement of overlying skin of the anterior neck by tumor

6. Nutritional status; cachexia

Imaging

1. Computed tomography (CT) scan of the neck with contrast in selected cases to determine the extent of the tumor, including involvement of the pre-epiglottic space, thyroid cartilage, and lymph node metastasis

2. Chest x-ray (CXR) or CT to evaluate for lung metastases: Some may obtain a positron emission tomography–computed tomography (PET-CT) scan to evaluate for distant metastases and the extent of the primary tumor and the presence of lymph node metastasis.

Indications

1. Relative indications:
   a. Whether T3 laryngeal cancer should be treated by total laryngectomy or by chemoradiation is a matter of debate.
   b. Patients unfit for chemoradiation therapy
   c. Life-threatening aspiration due to neurologic disease
   d. Severe COPD precluding conservation laryngeal surgery
2. Absolute indications
   a. Most T4 tumors
   b. Invasion of the thyroid cartilage
   c. Extension of tumor into soft tissues of the neck
   d. Salvage laryngectomy for failed nonsurgical treatment
   e. Chondroradionecrosis refractory to conservative management
3. Contraindications
   a. Tumors amenable to conservation laryngeal surgery, radiation, or chemoradiation
   b. Medical comorbidities precluding general anesthesia
   c. Patient's refusal for total laryngectomy

Preoperative Preparation

1. Endoscopy under general anesthesia for tumor mapping and biopsy and to exclude a second primary cancer

2. If a biopsy was obtained at an outside institution, slides are reviewed at the treating institution to confirm the diagnosis.

3. If PET-CT was not obtained previously, one may be obtained as a baseline to follow treatment results and to rule out distant metastasis.

4. Patient is evaluated by medical and radiation oncology, and the case is presented at a multidisciplinary tumor board for consensus opinion

5. Referrals are sent to dental oncology, nutrition, speech therapist, social worker, and patient advocate as necessary.

6. Referral for spiritual and/or psychologic support if needed and patient agrees

Operative Period

Anesthesia

1. General anesthesia

2. The type of intubation depends on the tumor size and location and is discussed with the anesthesiologist prior to surgery: Oral endotracheal intubation (ETT), awake flexible fiberoptic ETT, local awake tracheotomy.

Positioning

1. Supine with shoulder roll to extend the neck

2. Arms are tucked at patient's sides

3. Bed is turned 90 or 180 degrees from the anesthesiologist to create space for the surgeons around the head of the bed

Perioperative Antibiotic Prophylaxis

The first dose should be given prior to the skin incision:

1. Clindamycin 900 mg IV plus gentamicin 5 mg per kg IV × 1 dose; followed postoperatively with clindamycin 900 mg IV q 8 hours × 3 doses (particularly in penicillin allergic patients)

2. Unasyn 3 gm IV q 6 hours × 4 doses

Monitoring

1. Continuous monitoring of blood pressure, pulse, and oxygen

2. Arterial blood gas when indicated

3. Hemoglobin and hematocrit when indicated

Instruments and Equipment to Have Available

1. Routine head and neck set with retractors

2. Monopolar and bipolar electrocautery

3. 14F red rubber catheter if primary tracheoesophageal puncture is to be performed

4. 1% lidocaine to inject into adventitia of carotid bulb if the patient develops profound bradycardia due to manipulation of the carotid artery

Key Anatomic Landmarks

1. Thyroid notch

2. Cricoid cartilage

3. Sternal notch

4. Carotid sheath

5. Esophagus

Prerequisite Skills

1. Knowledge of the anatomy of the anterior neck

2. Proficiency in soft tissue surgery

3. Understanding appropriate oncologic resection

4. Understanding intraoperative complications and how to address them

Operative Risks

1. Profound bradycardia due to manipulation of the carotid artery

2. Injury to the contents of the carotid sheath

3. Injury to cranial nerves, particularly cranial nerve 12

4. Positive surgical margins

5. Inadequate pharyngeal closure with resultant pharyngocutaneous fistula

6. Bleeding

Surgical Technique

1. Outline an apron (U-shaped) incision that starts at the level of the greater horn of the hyoid bone bilaterally and extends inferiorly to about 2 cm above the sternal notch, to incorporate the tracheostomy incision if present. The lateral limbs of the incision are placed along the anterior border of the sternocleidomastoid muscles (SCMs). Injecting the skin incision with 1% lidocaine with 1:100,000 epinephrine for hemostasis is optional.

2. Incise the platysma muscle along the above incision and raise a subplatysmal flap superiorly above the level of the hyoid bone and inferiorly to the level of the clavicles and sternal notch.

3. If neck dissection is to be performed, complete the neck dissection before proceeding to the laryngectomy operative steps below.

4. Using electrocautery, incise the fascia along the anterior border of the SCM.

5. The SCM is retracted laterally, and the contents of the carotid sheath are identified (Fig. 16.1).

6. The tissue anterior and medial to the carotid sheath is dissected down to the prevertebral fascia separating the laryngotracheal complex from the lateral neck; this is done along the entire length of the muscle (Fig. 16.2).

7. The omohyoid muscle is seen at this point, as well as the superior thyroid artery and superior laryngeal neurovascular bundle, which are clamped, ligated, and transected (see Fig. 16.2).

8. The infrahyoid strap muscles are transected inferiorly at the level of the stoma and elevated superiorly. This exposes the thyroid lobes and the

thyroid isthmus, which is divided (Fig. 16.3).

9. If a thyroid lobe is to be preserved, the thyroid is dissected off the lateral aspect of the trachea using electrocautery; if the thyroid lobe is to be removed with the specimen, the fascia overlying the capsule is transected and dissected posteriorly and laterally to preserve the blood supply to the parathyroid glands.

10. The hypoglossal nerves are identified bilaterally in order to avoid inadvertent injury.

11. The suprahyoid muscles are transected off of the body of the hyoid bone until the level of the mucosa of the vallecula is reached.

12. The greater horns of the hyoid are freed; it is useful to grasp the body of the hyoid with a penetrating towel clip or an Allis clamp for stabilization during this dissection (Fig. 16.4).

13. The larynx is rotated using double-pronged skin hooks, and the middle and inferior constrictor muscles are transected and mobilized off the posterior lateral aspect of the thyroid cartilage.

14. Using a cottle elevator, the pyriform sinus mucosa is elevated from the inner aspect of the cartilage and preserved. If this mucosa is involved with the tumor, it is not elevated.

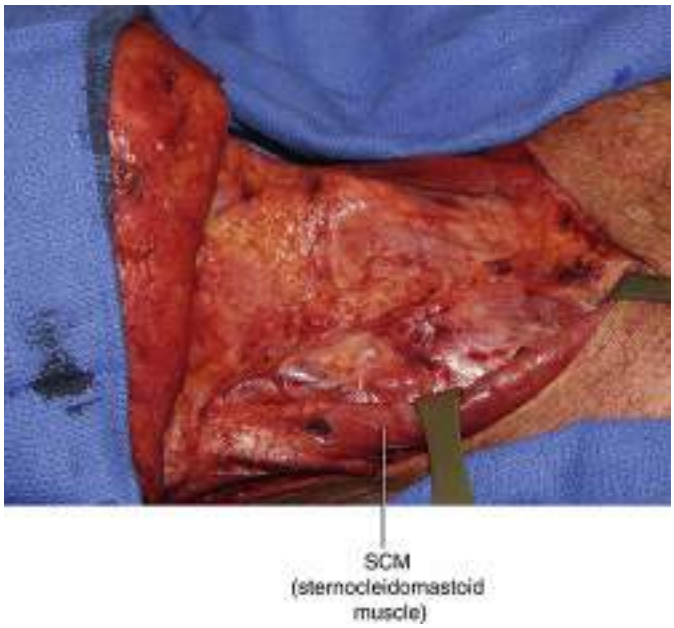

FIG. 16.1 The fascia along the entire length of the SCM has been incised and the muscle is retracted laterally.

15. The thyrohyoid ligament is transected in order to free the superior cornu of the thyroid cartilage.

16. The distal trachea is then mobilized by bluntly dissecting along its anterior aspect; this allows it to be pexied to the clavicular heads later in the procedure.

17. The trachea is transected between the anterior tracheal rings inferior to the tumor.

18. Using heavy curved Mayo scissors, the lateral aspect of the trachea is beveled to enlarge the stoma.

19. The stoma is secured to the anterior neck skin, and a reinforced ETT is placed in the distal trachea and connected to the anesthetic circuit in a sterile fashion.

20. The posterior membranous trachea is transected until the party wall is reached; care is taken not to separate the party wall inferiorly.

21. The proximal trachea is then bluntly elevated to the level of the cricoid cartilage (Fig. 16.5).

22. The surgeon then goes to the head of the bed to make the incisions in the larynx; a head light is needed at this point.

23. The pharynx is entered through the vallecula, pyriform sinus, or postcricoid mucosa, depending on tumor location and the surgeon's preference (Fig. 16.6).

24. The vallecula is entered by transecting the hyoepiglottic ligament, which leads one to the epiglottis, or by placing a suction tip into the vallecular mucosa and cutting down onto it.

25. The tip of the epiglottis is grasped with an Allis clamp (see Fig. 16.6).

26. After visualizing the tumor, mucosal incisions including a 1-cm margin are made with scissors. Care is taken to preserve the pyriform sinus mucosa if it is uninvolved.

27. If the mucosa of the pyriform sinus is entered instead of the vallecula, a suction tip is placed into the pyriform sinus and an incision is made

down through the mucosa; the larynx is more typically opened like a "book."

28. The specimen is examined for adequate margins by opening the larynx and fracturing it after incising through the posterior cricoid cartilage. Additional margins are taken when necessary.

29. The neck is copiously irrigated, and hemostasis is obtained.

30. Gowns and gloves are changed and clean instruments are used for the remainder of the case.

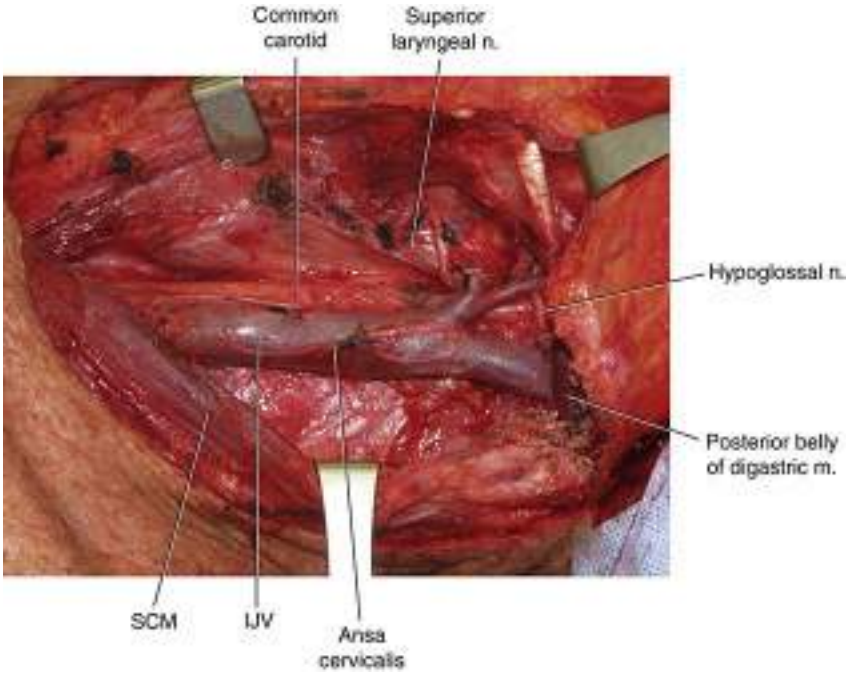

FIG. 16.2 The SCM is retracted laterally and the strap muscles are retracted medially with the laryngotracheal complex. The contents of the carotid sheath, hypoglossal nerve, part of the ansa cervicalis, and superior laryngeal nerve can be seen. During laryngectomy the carotid sheath contents are retracted laterally with the SCM.

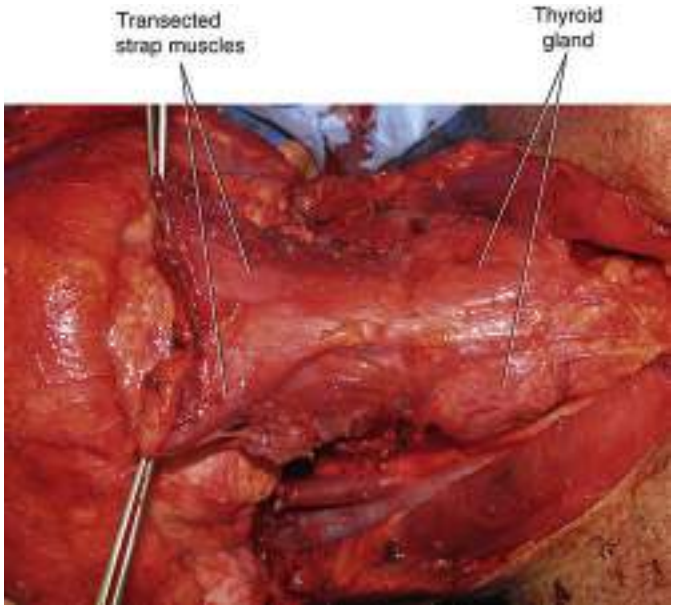

FIG. 16.3 The strap muscles are transected inferiorly and elevated exposing the thyroid gland.

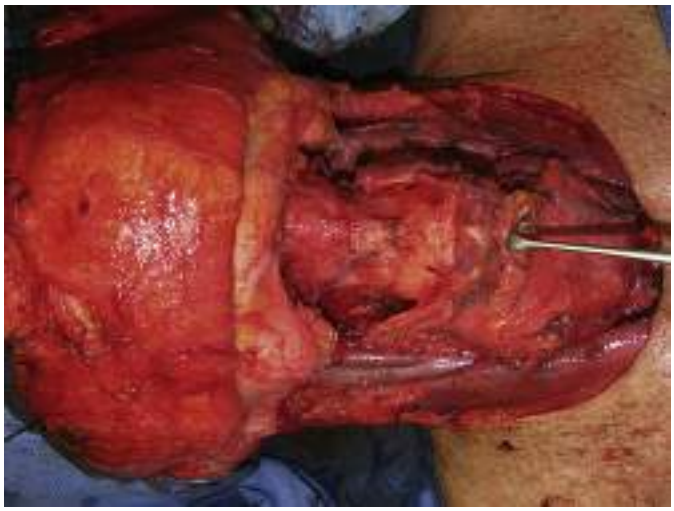

FIG. 16.4 The hyoid bone is skeletonized and freed from the surrounding tissue. It is grasped with an Allis clamp for stability.

31. An 18F nasogastric tube (NGT) is placed through the nose, through the pharynx, and into the esophagus. It is secured with a suture through the columella.

32. The proximal stoma is pexied to the clavicular heads bilaterally using a 2-0 Vicryl suture. The sutures are placed along the lateral aspect of the

trachea 2 to 3 rings distal to the cut edge. This prevents the stoma from "falling" into the chest.

33. The anterior aspect of the stoma is sewn to the skin using half vertical mattress sutures of 2-0 Vicryl to cover the edge of the cartilage (Fig. 16.7). The stoma should be 3 cm in size to prevent microstomia.

34. If a primary tracheoesophageal puncture is to be made, additional steps are done at this time.[3]

a. The party wall is buttressed to the back of the membranous trachea at its cut edge using 4-0 Vicryl sutures. Separation of the party wall is an absolute contraindication to a primary TEP.

b. A pharyngeal constrictor myotomy is performed by the surgeon placing a finger into the pharyngeal defect and cutting the muscles (middle and inferior constrictors and upper cervical esophageal) from the esophageal inlet to the base of tongue in a vertical fashion until the mucosa is reached. If an inadvertent pharyngotomy is made, it is closed with interrupted sutures inverting the mucosa.

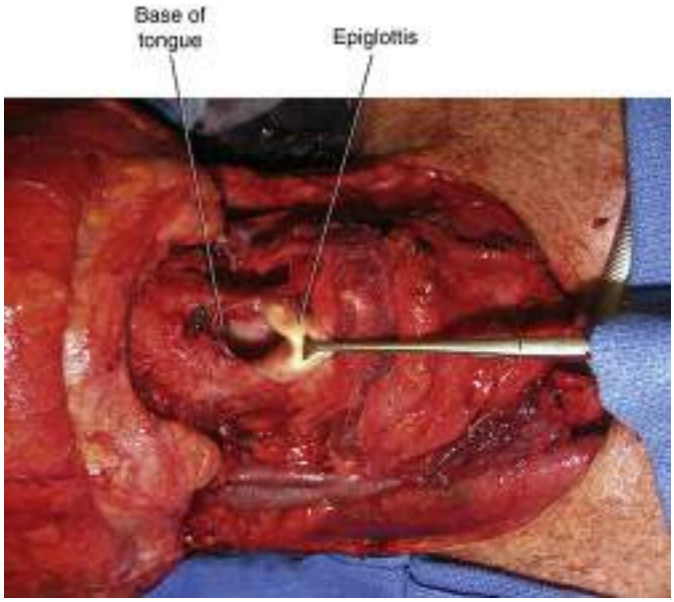

FIG. 16.5 After incising the trachea, it is dissected in the plane of the party wall to the level of the posterior aspect of the cricoid. The party wall and the remaining lobe of the thyroid are also visualized here.

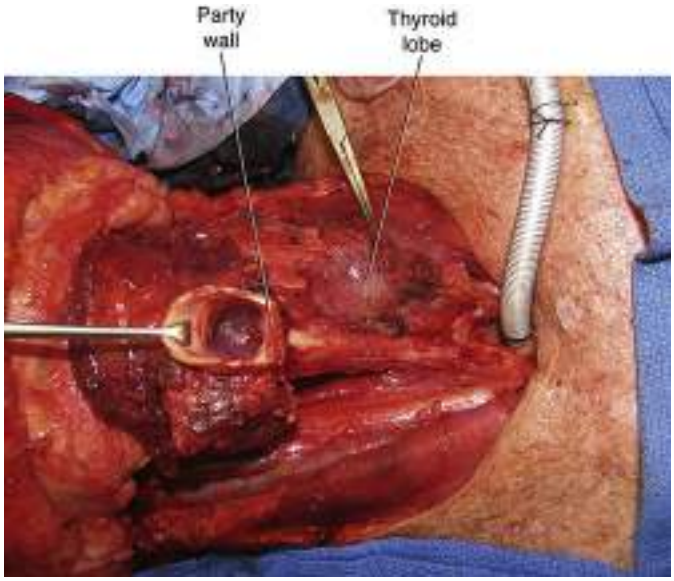

FIG. 16.6 After entering the valleculae, the epiglottis is grasped and tumor incisions are made under direct visualization.

c. To perform the puncture, a right-angled hemostat is placed in the pharyngeal defect against the posterior membranous trachea about 1 to 1.5 cm below the cut edge (Fig. 16.7). A #15 scalpel blade is used to make an incision over the tip of the right angle. The tips are pushed through the puncture, and a Foley catheter or red rubber catheter is grasped, pulled into the pharynx, and directed into the esophagus (Fig. 16.8A, B, C). It is secured to the skin with a 2-0 silk stick tie. The patient can be fed through the puncture site in lieu of a NGT.

d. The voice prosthesis can be primarily placed immediately following the TEP using a kit.

FIG. 16.7 The anterior stoma is then secured with half vertical mattress sutures and the pharyngeal constrictor myotomy is performed; the tracheoesophageal puncture is made 1 to 1.5 cm below the cut edge of the posterior membranous trachea.

35. The pharyngeal mucosa is closed using a running inverted suture of 3-0 Vicryl.[3] The mucosa can be closed in a vertical, horizontal, or "T" fashion, depending on the surgeon's choice and the amount of remaining mucosa (Fig. 16.9).

36. The pharyngeal closure is tested by introducing a bulb syringe filled with half-strength hydrogen peroxide into the mouth and filling the pharynx. Bubbles of hydrogen peroxide will be seen along the suture line if a leak is present.

37. 10-mm Jackson Pratt drains are placed on either side of the neck.

38. The superior skin flap is returned to its natural position, and the posterior aspect of the stoma is sewn to the skin using simple interrupted sutures of 2-0 Vicryl.

39. The platysma muscle is closed, and the incision is stapled.

40. A laryngectomy tube may be placed at the end of the case in order to maintain patency of the stoma if needed.

41. The patient is extubated in the operating room if in stable condition.

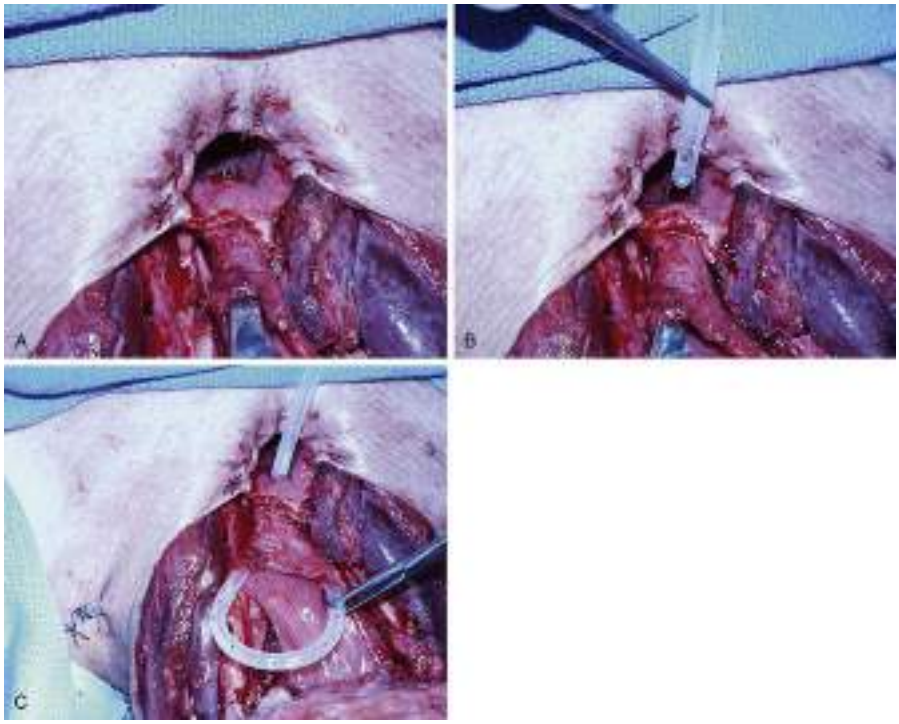

FIG. 16.8 **A,** #15 scalpel blade is used to make a horizontal cut over a right angled hemostat whose tips are pushed through the posterior wall. **B** and **C,** A red rubber catheter or a Foley catheter is grasped and pulled through the puncture site into the pharyngeal defect and then directed inferiorly into the esophagus.

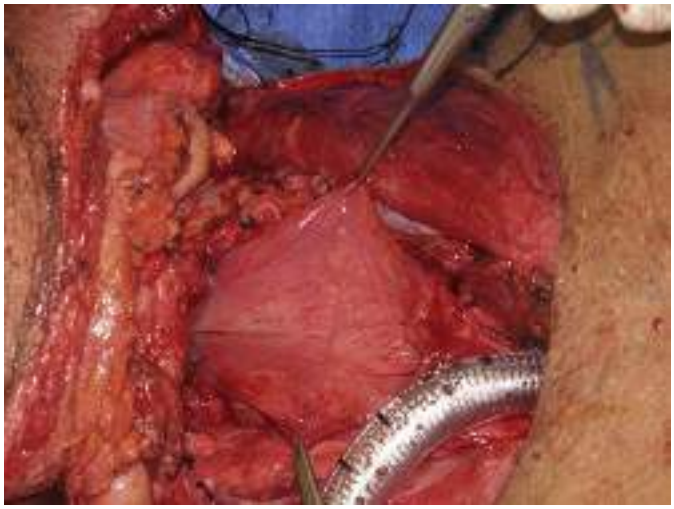

FIG. 16.9 The remaining pharyngeal mucosa is then closed by inverting the edges with a watertight closure to prevent fistula formation. If a primary TEP is performed,

it is done prior to pharyngeal closure.

Common Errors in Technique

1. Inadequate perioperative antibiotic coverage

2. Understaging the cancer

3. Removal of excess pyriform sinus mucosa

4. Suboptimal pharyngeal closure, resulting in a fistula or stenosis

5. Inadequate size of stoma

6. Separation of the party wall when performing a TEP

Postoperative Management

1. Patient is to be admitted to a step-down unit or to the intensive care unit for monitoring

2. Antibiotics are administered for 24 hours.

3. Continuous humidified room air or oxygen to stoma per tracheostomy collar

4. Regular tracheal suctioning

5. Clean crusts from stoma

6. Use laryngectomy tube if needed to keep stoma patent.

7. Antiemetics as required

8. Pain medication via Patient Controlled Anesthesia pump or routinely scheduled (morphine or dilaudid); oral pain medication when tolerating tube feeds and pain is better controlled

9. Start tube feeds per protocol.

10. Physical therapy to start day 1; refrain from neck extension until 10 days postoperatively

11. Stoma care teaching to patient and family to start postoperative day 1

12. Speech therapy to start teaching with electrolarynx prior to discharge

if indicated

13. Barium swallow on postoperative days 5 to 7 to evaluate for small fistula; if negative, start a liquid diet and advance as tolerated

14. If a fistula is present, continue tube feeds and start antibiotics.

Complications

1. Hematoma/seroma

2. Wound infection

3. Fistula formation

4. Dehiscence of stoma or neck incision

5. Pharyngeal stricture

6. Deep vein thrombosis

7. Chest infections

8. Complications regarding primary TEP

Alternative Management Plan

1. Primary radiation therapy or chemoradiation

2. Referral to palliative care for those refusing treatment

Evidence-Based Medicine Question

Does the use of pectoralis major myofascial flap (PMMF) in salvage total laryngectomy reduce the incidence of pharyngocutaneous fistula?

The use of PMMF in salvage total laryngectomy does reduce the incidence of pharyngocutaneous fistula. The incidence of postoperative pharyngocutaneous fistula is about 30%. In a recent study patients undergoing PMMF following salvage total laryngectomy had a 22% decrease in risk of fistula compared with the control group. In addition, there was no significant difference in fistula rate in those undergoing total laryngectomy, compared with those undergoing

pharyngolaryngectomy.[4]

Editorial Comment

Total laryngectomy is an excellent oncologic procedure for laryngeal cancer, and quality of life studies show similar outcomes compared with chemoradiation therapy. However, a favorable quality of life outcome requires attention to surgical detail to optimize speech and swallowing and attention to speech rehabilitation. In order to optimize speech outcome, patients need to be counseled preoperatively by the speech and language therapist. A capacious and relaxed pharynx should be created by doing a cricopharyngeal myotomy, avoiding a vertical pharyngeal closure, and having low threshold for augmenting a narrow pharynx with a pectoralis major flap, and the tracheoesophageal fistula should be correctly sited; the sternal heads of the sternocleidomastoids should be divided to create a flat tracheostoma.

Review Questions

1. Otalgia is a common complaint in patients with laryngeal cancer due to referred pain from

   a. **Jacobsen nerve**

   b. Arnold nerve

   c. Hypoglossal nerve

   d. Pharyngeal plexus

2. Indications for total laryngectomy include

   a. Vocal cord paralysis

   b. Laryngocele

   c. **T4 cancer with extension of the cancer into the muscles of the neck**

   d. T1 to T2 tumors

3. The most likely cause of fever, elevated white count, and erythema of neck skin postoperatively is

   a. Chyle leak

   b. Infected hematoma

   c. **Pharyngocutaneous Fistula**

   d. Inappropriate antibiotic use

4. The cranial nerve most at risk for injury during a total laryngectomy is the

   a. **Hypoglossal nerve**

   b. Spinal accessory nerve

   c. Marginal mandibular nerve

   d. Vagus nerve

5. Humidification to the stoma is important to prevent

   a. Mucous plug

   b. Crusting

   c. Tracheitis

   d. **All of the above**

6. A tight pharyngeal closure can lead to

   a. Pharyngeal stricture

   b. Fistula

   c. Dysphasia

   d. **All of the above**

Total Laryngopharyngectomy

Benjamin L. Hodnett, and Karen Pitman

Introduction

Total laryngopharyngectomy is employed for cancer of the hypopharynx. The hypopharynx forms the inferior part of the pharynx and is located immediately behind the larynx. It has three subsites—that is, postcricoid, posterior pharyngeal wall, and pyriform sinuses bilaterally. Total laryngopharyngectomy may also be performed for primary laryngeal tumors with extension to the aforementioned sites.

Total laryngopharyngectomy includes removal of the larynx as well as the hypopharynx and posterior pharyngeal wall, resulting in a circumferential defect. More extensive cancers involving the cervical esophagus require total laryngopharyngoesophagectomy. A laryngopharyngeal reconstructive procedure is required. Options include myocutaneous flaps (pectoralis major or latissimus dorsi) or fasciocutaneous free flaps (anterolateral thigh, radial forearm), jejunal free flaps, and gastric pull-up procedures.[1]

Lymphatic drainage is typically to levels II and III; however, retropharyngeal and bilateral drainage can occur. Paratracheal and paraesophageal metastases may also be present. Contralateral nodal metastases may occur in cancer of the medial wall of the pyriform sinus and bilateral nodal metastases may occur with cancer of the postcricoid region.[2] Therefore laryngopharyngectomy is generally accompanied by bilateral neck dissections.

Key Operative Learning Points

- Extent of resection should be determined preoperatively to plan for adequate reconstruction.

- 2-cm mucosal resection margins should be obtained due to the risk of submucosal spread.
- 3 cm of pharyngeal mucosa in the transverse plane is required for closure without flap reconstruction.

Preoperative Period

History

- Hypopharyngeal cancer may present at an advanced stage, as few symptoms may be present until the cancer is advanced.
- Presenting symptoms include progressive pain in the throat, dysphagia, odynophagia, dysphonia, referred otalgia, throat clearing, globus sensation, weight loss, and/or a mass in one or both necks.
- Dyspnea and hoarseness may represent invasion of the larynx or the recurrent laryngeal nerve.
- Dysphagia for solids and liquids implies an advanced cancer.
- Risk factors include the use of tobacco and alcohol, gastroesophageal reflux, and Plummer-Vinson syndrome.
- Plummer-Vinson syndrome is a rare condition generally appearing in women between the ages of 30 and 50. This syndrome consists of iron deficiency anemia, esophageal webs, dysphagia, weight loss, angular stomatitis, and atrophic glossitis.
- Preoperative nutritional evaluation should be performed on patients with hypopharyngeal or cervical esophageal cancer. Prealbumin, albumin, thyroid stimulating hormone, and iron levels provide information regarding nutritional status in conjunction with complete blood counts and basic chemistry. Referral to a nutritionist or dietician may be indicated preoperatively, as well as placement of enteral feeding access. Reconstructive options must be evaluated prior to placement of feeding access, as stomach and jejunum are potential donor sites.

Physical Examination

- Evaluation of the larynx and pharynx with flexible laryngoscopy is mandatory.
- Cancer may represent direct extension from the larynx or be a primary cancer of the hypopharynx.
- Vocal fold motion, patency of the airway, and pooling of secretions in the hypopharynx should be noted.
- Examination of the neck may reveal a mass either from regional metastasis or from direct extension of the cancer.
- Stridor is suggestive of involvement of the larynx.
- Poor nutritional status should be noted.
- Examination of the oral cavity and oropharynx should be performed to rule out synchronous primary cancers.
- Examination of the cranial nerves (hypoglossal, accessory) should be performed to evaluate extension of the cancer from the primary site or regional metastases.
- Paralysis of the vocal folds can occur as a result of invasion of the paraglottic space or cricoarytenoid joint or involvement of the recurrent laryngeal nerve.
- The chest wall, extremities, and abdomen should be examined to note prior surgery or chemoport placement that might affect potential reconstructive options.

Imaging

- Cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) with contrast is used to determine the extent of the primary cancer and the presence of regional metastasis. Contrast-enhanced CT imaging is highly sensitive for evaluation of pre-epiglottic and paraglottic space involvement by laryngeal cancer. MRI is more sensitive for detecting pathologic involvement of cartilage.
- Imaging of the lungs is recommended to evaluate for metastasis. CT of the chest is preferable to chest radiographs, given its higher sensitivity

and specificity for detecting metastasis. Evidence of restrictive lung disease should be noted, as this may be a relative contraindication for pectoralis major flap reconstruction with a large skin paddle.

- Abdominal imaging may be indicated in patients with a history of prior abdominal surgery and in whom gastric pull-up or jejunal free flap is being considered as a reconstructive option.
- 18-fluorodeoxyglucose positron emission tomography (PET) allows for evaluation of whole-body distant metastatic disease.
- Barium swallow esophagram can evaluate esophageal involvement either from direct extension of a laryngeal or hypopharyngeal primary cancer or a second primary cancer of the esophagus. It may also be useful in evaluating possible invasion of the prevertebral fascia.

Indications (Table 17.1)

- Advanced stage cancers of the hypopharynx (T3-T4)
- Advanced stage laryngeal cancers with involvement of the postcricoid mucosa, posterior hypopharyngeal wall, or the pyriform sinus with extension across the midline posteriorly
- Salvage surgery following primary chemoradiation in patients who fail organ preservation protocols

Contraindications

- Significant comorbidities precluding primary surgery and reconstruction
- Irresectable cancer such as encasement of the carotid artery or invasion of the prevertebral fascia
- Distant metastases

Preoperative Preparation

- Preoperative evaluation should note whether the patient may be intubated in a standard fashion or whether fiberoptic intubation is

indicated. In patients with a large obstructive cancer, awake tracheostomy under local anesthesia may be the safest choice.

- Pan-endoscopy should be performed to map the cancer, obtain tissue for pathologic examination and diagnosis, and to evaluate for involvement of the cervical esophagus. Tumor mapping allows for better prediction of planned cancer resection and coordination with the reconstructive surgeon.

Operative Period

Anesthesia

- General anesthesia

Positioning

- Bed turned 180 degrees and both arms tucked in
- Additional arterial and venous lines may be placed by the anesthesia team, with care taken to ensure that radial and/or femoral vessels are protected if reconstruction with radial forearm or anterolateral thigh free flaps is planned.
- Chest wall should be prepped if a pectoralis major myocutaneous flap is planned.
- Abdomen should be included in the field if there is a need for a jejunal free flap or mobilization of the stomach is required for a gastric pull-up.

TABLE 17.1

Staging of Hypopharyngeal Cancer

T1	Cancer limited to one subsite of hypopharynx and/or 2 cm or less in greatest dimension
T2	Cancer invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest diameter without fixation of hemilarynx
T3	Cancer more than 4 cm in greatest dimension or with fixation of hemilarynx or extension to esophagus
T4a	Moderately advanced cancer Cancer invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment

	soft tissue (includes prelaryngeal strap muscles and subcutaneous adipose tissue)
T4b	Cancer advanced locally Cancer invades prevertebral fascia, encases carotid artery, or involves mediastinal structures

Used with permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original and primary source for this information is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science+Business Media.

Perioperative Antibiotic Prophylaxis

- Perioperative antibiotics are started prior to the surgical procedure and continued for 24 hours postoperatively.
- Organisms covered include gram-positive microbes as well as anaerobes.

Instruments and Equipment to Have Available

- Standard head and neck surgical set
- Microvascular equipment—Sterile tourniquet, microvascular forceps (Jeweler's forceps), micro needle holders, arterial and venous frame and single clamps, vascular bulldog clamps, 8-0 or 9-0 nylon suture, microvascular anastomosis couplers, microscope or loupe magnification, heparinized saline, implantable Doppler

Key Anatomic Landmarks

- The hypopharynx consists of the pyriform sinuses, the postcricoid mucosa, and the posterior pharyngeal wall.
- The carotid sheaths lie immediately lateral to the hypopharynx.
- Sensory innervation is provided by the glossopharyngeal nerve (CN IX) and internal branches of the superior laryngeal nerve (CN X).
- The hyoid bone is the superior boundary of the hypopharynx, and the inferior boundary is at the lower border of the cricoid cartilage. This

border is contiguous with and narrows at the upper end of the esophagus. The postcricoid region is from the arytenoid cartilages to the inferior border of the cricoid cartilage and forms a connection between the bilateral pyriform sinuses. Thus the postcricoid region is the anterior wall of the hypopharynx. The pyriform sinuses extend from the pharyngoepiglottic folds to the superior aspect of the cervical esophagus and are bound medially by aryepiglottic fold, the arytenoid cartilages, and the cricoid cartilage and bound laterally by the thyroid cartilage.

Prerequisite Skills

- Microvascular reconstructive surgeon for free tissue transfer
- General surgeon if gastric pull-up or a jejunal free flaps is indicated

Operative Risks

- Bleeding, infection, injury to accessory/hypoglossal nerves, pharyngocutaneous fistula, wound healing, and flap failure

Surgical Technique—Total Laryngopharyngectomy

1. An apron incision is planned with incorporation of the tracheostomy site with extension laterally to allow for bilateral neck dissection.

2. Subplatysmal flaps are elevated to the level of the hyoid bone superiorly and laterally, exposing both sternocleidomastoid muscles.

3. The cervical fascia is incised along the anterior border of the sternocleidomastoid muscles.

4. The fascia on the inferior border of the submandibular gland is incised to identify the posterior belly of the digastric muscle and connected to the fascial incision at the superior border of the sternocleidomastoid muscle.

5. Outer tunnels are developed between the strap musculature and the

sternocleidomastoid muscles.

6. Bilateral neck dissections are performed with removal of lymph node levels II-IV. Neck dissection may be performed separately or left in continuity with the main specimen.

7. Arterial stumps including lingual, facial, superior thyroid, and transverse cervical arteries are preserved to allow for microvascular anastomosis.

8. Venous stumps including external jugular, anterior jugular, and interior jugular branches such as common facial and transverse cervical veins should be maintained, unless oncologic resection requires sacrifice of the internal jugular vein.

9. Strap muscles are divided superior to the tracheostoma, if present, or above the manubrium.

10. Dissection is continued superiorly along the trachea to the thyroid isthmus. Selected cancers may allow for sparing one or both lobes of the thyroid gland. In these cases, the thyroid isthmus is divided and the lobes are freed from their attachment to the trachea. Certain cancers may require removal of one or both lobes of the thyroid gland with the main specimen. Dissection is continued superiorly to the first or second tracheal ring.

11. Inner tunnels are developed between the carotid sheath and larynx along the prevertebral fascia. The superior laryngeal neurovascular bundle is ligated. Parathyroid glands are preserved, if possible.

12. The hyoid bone is exposed and the suprahyoid musculature is incised and dissected off of the superior aspect of the hyoid bone. The central portion may be grasped with a towel clamp and retraced laterally in either direction to expose the lateral cornua. Each cornu is retracted medially to rotate the hyoid away from the hypoglossal nerve and lingual artery. Dissection is continued bilaterally along the hyoid until each cornu can be freed using the finger loops of a hemostat for retraction.

13. Depending on the location of the cancer, the larynx may or may not be skeletonized as in a total laryngectomy. If limited circumferential resection is indicated, the larynx may be rotated and the pharyngeal constrictor muscles incised along the lateral border of the thyroid

cartilage contralateral to the cancer. The pyriform sinus mucosa is reflected off the thyroid lamina using a Freer elevator. The mucosa is elevated on the side contralateral to the cancer. Alternatively, the deep cervical fascia may be divided medial to the carotid artery along the prevertebral fascia and the pharynx bluntly mobilized off the prevertebral fascia, assessing for tumor extension past the buccopharyngeal fascia. This allows for resection of a larger section of pharynx. Invasion of the prevertebral fascia indicates that the cancer is unresectable. If circumferential mobilization is performed, the pharynx may be entered above the hyoid contralateral to the site of most superior extent of the cancer.

14. Pharyngeal mucosal incisions are made horizontally along the posterior pharyngeal wall to free the upper pharynx and entire larynx. Typically a 2-cm margin superior to the highest extent of the lesion is required. Large cancers of the pyriform sinus may require resection of a portion of the base of the tongue as a superior margin.

15. Tracheal incisions are performed next, typically between the first and second tracheal rings. The anterior tracheal wall is sutured to the skin to prevent retraction of the distal trachea into the mediastinum. An endotracheal tube is placed and sutured to the skin. Scissors are used to extend the tracheostomy superiorly.

16. If cervical esophageal resection is indicated, incisions are made below the cancer. If total esophagectomy is performed, blunt dissection is performed superiorly along the esophagus, with dissection of the esophagus through an abdominal approach.

17. Surgical margins are sent for frozen specimen analysis. Wide margins should be taken, as hypopharyngeal cancers may have submucosal spread with diffuse local spread a common finding at surgery.[3] Fig. 17.1 illustrates intraoperative defect from total laryngopharynectomy.

18. Some cancers may necessitate mediastinal tracheotomy or manubrial resection for removal of superior mediastinal lymphadenopathy.

19. Tracheoesophageal puncture is typically delayed until healing is complete.

20. The medial heads of the sternocleidomastoid muscle are released from the sternum. The inferior aspect of the tracheal stoma may be

completed prior to reconstruction. Half-vertical mattress sutures are placed, taking care to drape the skin over exposed cartilaginous rings.

21. Circumferential pharyngeal reconstruction is then completed by the reconstructive team (Table 17.2). Nasogastric tubes are placed prior to pharyngeal reconstruction in the absence of gastrostomy or jejunostomy tubes. Figs. 17.2 to 17.4 illustrate reconstruction with a tubed anterolateral thigh free flap with a salivary bypass tube.

Common Errors in Technique

- Accurate preoperative assessment of the surgical defect is critical for planning the reconstruction.
- Staging endoscopy is an important adjunct to imaging and allows for localization of the cancer disease and evaluation of esophageal extent.
- Cancers with less than 15 cm of cervical esophageal extent can be reconstructed with a jejunal free flap. Cancers with greater than 15 cm of cervical esophageal extent or those for which distal esophageal extent is intrathoracic require total esophagectomy with gastric pull-up.

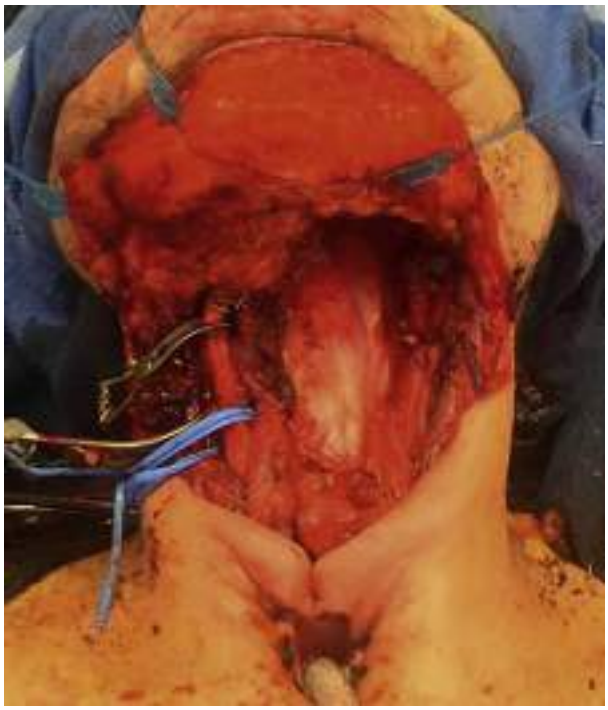

FIG. 17.1 Intraoperative photograph of total laryngopharyngectomy defect. Circumferential pharyngectomy defect is present. Courtesy of Dr. Steven Cannady.

TABLE 17.2

Reconstructive Options for Total Laryngopharyngectomy Defect

Reconstructive Technique	History/Physical Examination Points	Indications	Contraindications	Use/Key Points
Pectoralis major myocutaneous flap	1. Prior chest wall surgery or vascular graft 2. Restrictive lung disease may limit chest expansion following right sided closure	1. Failed previous reconstruction 2. Vessel-depleted neck 3. Lack of available donor sites 4. Medical comorbidities limiting lengthy surgery	1. Previous surgery involving pectoralis major muscle 2. Previous skin excision over pectoralis major muscle may result in loss of myocutaneous perforators 3. Previous surgery in subclavicular region may have affected vascular pedicle 4. Extension to nasopharynx may require free flap due to shorter pedicle length 5. Significant bulk of the pectoralis major muscle may hinder placement in neck (obese patients, women with large breasts)	1. Complete skin island tubed flap for excision of oropharynx 2. 270-degree paired tubed flap with suturing of flap to prevertebral fascia 3. Salivary bypass tube recommended
Anterolateral thigh free flap	1. Injury or prior surgery may limit anterolateral thigh donor site as an option 2. Patients with previous history of gastric disturbance may require alternative flap harvest sites 3. Presence of excessive subcutaneous adipose tissue in thigh may result in bulky flap, limiting reconstructive repair	1. Partial to circumferential defects 2. Cranial skin defects 3. Limited esophageal mucosal defect above thoracic inlet not requiring gastric pull-up 4. Reconstruction of combined mucosal and skin defects	1. Prior injury to donor site 2. Severe arthritic changes to profunda femoris or superficial femoral artery (being bypassed by descending branch of lateral femoral circumflex artery) may limit selection of this flap	1. Paired flap for hypopharyngeal defects with sufficient posterior pharyngeal wall mucosa 2. Tubed flap with sufficient cervical esophagus for anastomosis (see Fig. 17.2) with salivary bypass tube (see Figs. 17.3 and 17.4) 3. Combined mucosal and external skin defects
Radial forearm free flap	1. Injury or prior surgery to forearm may limit radial forearm as donor site 2. Prior cervical esophageal injury/surgery 3. Preoperative swallowing assessment to evaluate for cervical esophageal involvement/extent	1. Reconstruction of partial or circumferential defects where anterolateral thigh free flap is overly bulky 2. Cervical esophageal reconstruction	1. Inadequate ulnar arterial flow to the hand via Allen test or ultrasound	1. Defects in which thin, pliable tissue is indicated 2. Tubed pharyngeal reconstruction with salivary bypass tube 3. Limited cervical esophageal involvement
Jejunal free flap	1. History of abdominal surgeries (e.g., prior jejunostomy tube placement) 2. Length and location of esophageal defect	1. Short esophageal defects (<15 cm) with accessible distal esophagus through the neck	1. Defects greater than 15 cm 2. Distal esophagus inaccessible 3. Prior extensive abdominal or jejunal surgery	1. Short esophageal defects—jejunal segments are limited by segmental blood supply
Gastric pull-up	1. Pulmonary status 2. Prior abdominal surgery (e.g., prior percutaneous gastrostomy tube placement, prior laparotomy) 3. Pre-existing gastrointestinal disorders (e.g., peptic ulcer disease)	1. Complete defect of cervical and upper thoracic esophagus	1. Advanced pulmonary disease 2. Stomach involvement with previous abdominal or gastric surgery	1. Vascular supply is right gastroepiploic and right gastric arteries 2. Proximal portion of stomach is at high risk—abdominal blood supply from gastroepiploic artery

Postoperative Period

Postoperative Management

Patients are typically managed in the intensive care unit in the immediate postoperative period. Aggressive pulmonary management is advocated especially in high-risk patients, such as those undergoing gastric pull-up procedures. Routine stoma care is provided. Regular calcium monitoring is indicated with supplementation as required. Perioperative antibiotics are continued for 24 hours. Tube feedings may begin on postoperative day 1 with slow rates and close monitoring for reflux. Proton-pump inhibitors are recommended following total laryngopharyngectomy reconstruction. Drains are closely monitored for salivary leakage and removed typically when the output is less than 20 mL/day. Free flaps are monitored every hour while in the intensive care unit and may be supplemented by portable Doppler. Pricking the flap with a needle to

assess for blood flow may also be appropriate. Swallowing assessment varies per reconstructive technique and team. Salivary bypass tubes are removed prior to assessment for a leak. Barium swallow may be used as early as 7 to 10 days to assess the suture line, and patients may be advanced to a clear liquid diet if the suture lines are intact. Some reconstructive surgeons keep patients NPO for 1 month. Voice rehabilitation is via electrolarynx until tracheoesophageal perforation is performed.

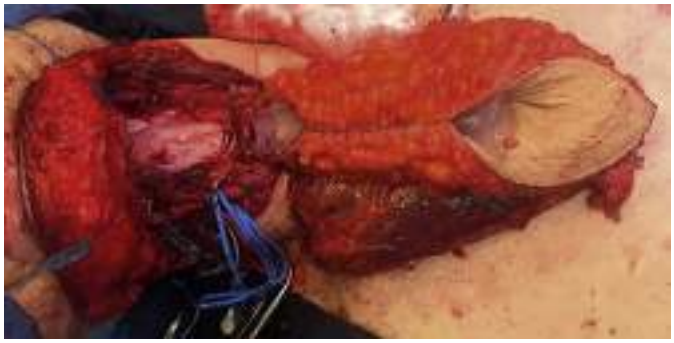

FIG. 17.3 Intraoperative photograph of a tubed anterolateral thigh free flap with salivary bypass tube prior to inset. Courtesy of Dr. Steven Cannady.

FIG. 17.4 Intraoperative photograph of inset of a tubed anterolateral thigh free flap with salivary bypass tube. Courtesy of Dr. Steven Cannady.

Complications

- Hypocalcemia is common following laryngopharyngectomy and has been reported to be as high as 45% in a large surgical series.[4]
- The same series reported a pharyngocutaneous fistula rate of 33% with wound complications in 25% of cases. Early fistulas may require opening the wound and packing, given the risk of mediastinitis. Packing is directed away from the carotid arteries or microvascular pedicles. Pharyngeal or esophageal anastomoses with leaking jejunal or gastric secretions may warrant return to the operating room to create a pharyngostome or repair with vascularized, nonirradiated tissue such as a pectoralis muscle flap.
- Strictures may occur at the inferior aspect of the reconstruction at the esophageal inlet and may occur weeks to months following surgery or after completion of radiotherapy. Repeat endoscopy to assess for recurrence followed by dilation may be performed on an outpatient basis.
- Jejunal free flaps may maintain enteric contractility and may result in functional dysphagia due to circumferential contractions during bolus

transport.

- Gastric pull-up may result in regurgitation due to the loss of normal gastric reservoir or pyloric narrowing.
- The same large surgical series reported a late complication rate of 26% and a stricture rate of 15%. Permanent gastrostomy tube requirement was 16% and tracheoesophageal puncture for voice restoration was performed in 44%.

Alternative Management Plan

- Prognosis for hypopharyngeal cancer is poor. Rates of regional metastasis at presentation are between 60% and 80%, with 40% occurring contralateral. Distant metastatic rates are up to 60% at presentation or at follow-up.[5] A large epidemiological study noted 50% recurrence rate within 12 months, with a 50% distant metastatic rate.[3]
- Radiotherapy alone has a worse prognosis when compared with surgery and radiotherapy combined.[6-8]
- Induction chemotherapy with definitive radiation therapy is an alternative treatment option for hypopharyngeal cancer to surgery with adjuvant radiotherapy with comparable disease-free survival rates.[9,10]

Evidence-Based Medicine Question: What Is the Most Common Staging of Hypopharyngeal Carcinoma at Presentation?

Patients with hypopharyngeal squamous cell carcinoma typically present with advanced stage disease. Hall et al. reported TNM staging of 595 patients presenting with hypopharyngeal squamous cell carcinoma.[3] The most common T stage was T2 (34%) and the most common nodal stage was N0 (35%). Advanced T stage disease was T3—29%, T4a—20%, and T4b—4%. Advanced N stage disease was N2c—8% and N3—5%. The most common overall combination was T3N2 (13%). Overall stage IV presentation was 57%, with 20% of patients presenting with irresectable disease. Buckley et al. reviewed nodal metastasis in laryngeal and

hypopharyngeal squamous cell carcinoma.[2] In the hypopharyngeal subset, 9/25 were N+ on clinical staging. Clinically staged N0 patients had 9/16 ipsilateral and 7/15 contralateral pathologic nodes. All 12 clinically staged N+ patients had bilateral nodal metastasis on pathologic examination. Patients with squamous cell carcinoma of the hypopharynx are at high risk of advanced tumor staging and bilateral nodal metastasis at presentation.

Editorial Comment

Because of the propensity of cancer of the hypopharynx to spread submucosally, wide surgical margins are required with frozen section control. Predicting the correct reconstructive option is important so that the correct surgical team is at hand. A critical step in the evaluation is to determine whether a cervical esophagectomy is required and that the lower anastomosis can be done in the neck or whether the distal resection margin is in the mediastinum and that a total esophagectomy is required with a gastric pull-up. A tubed pectoralis major or latissimus dorsi flap is a good alternative to a jejunal free flap.

Johan Fagan

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Approximately what percentage of patients with hypopharyngeal squamous cell carcinoma of the hypopharynx will have occult nodal metastasis at the time of presentation?

   a. 25%

   b. 50%

   c. **75%**

   d. 90%

2. A patient presents with postcricoid squamous cell carcinoma of the hypopharynx. On staging endoscopy, 17 cm of cervical esophageal extent is noted. What would be the best reconstructive option following total laryngopharygectomy for this patient?

a. Tubed pectoralis major myocutaneous flap

b. **Gastric pull-up**

c. Radial forearm free flap

d. Anterolateral thigh free flap

3. Which of the following syndromes is associated with increased risk of squamous cell carcinoma of the hypopharynx?

a. **Plummer-Vinson syndrome**

b. Familial adenomatous polyposis

c. Li-Fraumeni syndrome

d. Birt-Hogg-Dubé syndrome

Operative Otolaryngology: Bronchoscopy

Neil A. Christie

Introduction

Bronchoscopy is an important diagnostic tool that can also be used therapeutically. Both rigid (Fig. 18.1) and flexible bronchoscopes (Fig. 18.2) can be used, and both techniques have relative advantages and disadvantages. Although flexible bronchoscopy has largely replaced rigid bronchoscopy for diagnostic procedures, rigid bronchoscopy remains an important modality for therapeutic procedures.[1] The newer technologies of navigational bronchoscopy[2] and endobronchial ultrasound[3] have extended the diagnostic utility of bronchoscopy to include the assessment of peripheral lung nodules and peribronchial lymph nodes.

Bronchoscopy can allow for pathologic diagnosis of endobronchial lesions; peribronchial mediastinal and hilar lymphadenopathy; and now for peripheral lung lesions. It also is an effective tool for diagnosis and management of hemoptysis, airway obstruction, tracheobronchomalacia, and foreign bodies in the airway.[1]

Key Operative Learning Points

1. Flexible bronchoscopy can be done with local anesthetic and spontaneous respiration and allows evaluation down to the segmental and subsegmental airways. However, the diameter of the working channel for biopsy and suction is small.

2. Rigid bronchoscopy is stimulating and requires general anesthesia, and the scope can reach down only to the trachea and the main stem

bronchi. However, the diameter of the scope is large and allows for better suctioning and doing biopsies and other procedures.

3. Electromagnetic bronchoscopy allows virtual bronchoscopy and the passage of a directable catheter out in to the lung parenchyma to allow biopsies of peripheral lung lesions to be undertaken.

4. Endobronchial ultrasound allows visualization and real-time imaging for biopsy of mediastinal and hilar lymph nodes via bronchoscopy (Fig. 18.3).

Preoperative Period

History

1. Hemoptysis
   a. What is the volume of the blood expectorated?
   b. Is the blood bright red or dark in color?
   c. Is it associated with any pneumonic symptoms or excessive mucous production?
   d. Is the patient taking any anticoagulants?
   e. Where there any preceding episodes?
   f. Is the patient a past or present cigarette smoker?
   g. Does the patient have a history of lung cancer or any risk factors for lung cancer?
2. Airway obstruction
   a. The degree of dyspnea present; at rest or only with exertion?
   b. The onset and duration of dyspnea
   c. Is the dyspnea positional?
   d. Any history of airway intervention in the past, such as oral tracheal intubation and mechanical ventilation (and for how long) or tracheostomy
   e. Any history of Wegener disease?

f. Any history of foreign body aspiration?

Physical Examination

1. The patient's cardiorespiratory status should be evaluated, including cardiovascular stability and the degree of respiratory insufficiency.

2. Patient's body habitus should be evaluated, as well as the patient's degree of neck extension for oral tracheal intubation.

3. Evaluate for inspiratory or expiratory stridor, as well as the presence of distal airway wheezing (either unilateral or bilateral).

4. Evaluate for palpable cervical lymphadenopathy.

5. Evaluate the patient's dentition and oral cavity, checking for any loose teeth.

Imaging

1. Plain chest radiograph can be useful to evaluate tracheal narrowing, tracheal deviation, and lung parenchymal collapse or infiltrate. Gross mediastinal adenopathy and peripheral lung masses may also be apparent.

2. Computed tomography (CT) scan of the neck and chest can better evaluate the diameter of the airway, as well as the detection of lesions compressing the airway, either intrinsic airway lesions or lesions causing extrinsic compression. Will also demonstrate the presence and location of an aspirated foreign body. Any potentially pathologic lymph nodes or lesions of the lung parenchyma will be visualized. A CT scan may also show evidence of aspirated blood. If intravenous (IV) contrast is given, one can also evaluate for a potential pseudoaneurysm or the site of active bleeding.

3. Intraoperative fluoroscopy can be undertaken with bronchoscopic procedures, such as deployment of an airway stent and transbronchial biopsy of the lung.

Indications

1. Evaluation of patients with unexplained cough who do not have an obvious explanation, such as reactive airways disease or respiratory infection

2. Diagnosis of malignant disease. It could include biopsy of an endobronchial tumor, transbronchial aspiration of a mediastinal or hilar lymph node with the aid or endobronchial ultrasound, or biopsy of a more distal lesion in the lung parenchyma with electromagnetic navigational bronchoscopy.

FIG. 18.1 Rigid bronchoscope with light source attached.

FIG. 18.2 Flexible bronchoscopes from top to bottom: endobronchial ultrasound bronchoscope, therapeutic bronchoscope, regular adult bronchoscope, pediatric bronchoscope.

3. Bronchoscopy can be used in patients who have hemoptysis to evaluate for the source of bleeding (either identification of an endobronchial lesion or, if the bleeding source is more distal, evaluation for which lobe or segment the blood is emanating from). Therapy can also be accomplished for hemoptysis with removal of blood clots from the airway, laser ablation of bleeding endobronchial tumors, or placement of balloon catheters to isolate bleeding portions of the lung.

4. Bronchoscopy can identify the site and degree of airway obstruction (diameter of residual airway and length of obstructing lesion). Interventions include débridement of obstructing endobronchial tumor with forceps or laser ablation and/or placement of endobronchial airway stents.

5. Bronchoscopy can also be used to evaluate and retrieve foreign bodies from the airway.

6. Lung washings and random transbronchial biopsies can be performed using bronchoscopy in the evaluation of patients with interstitial lung disease and infiltrates of unclear etiology in immunocompromised patients or patients who have undergone lung transplantation.

7. For patients with pulmonary abscess, occasionally bronchoscopy can be useful in establishing internal drainage of the abscess cavity to the airway.

8. Bronchoscopy can be used for clearing secretions for pulmonary toilet in patients with hypoxia and/or lung collapse not responding to more conservative respiratory measures.

FIG. 18.3 Ultrasound probe on endobronchial ultrasound bronchoscope.

9. Mediastinal lymph nodes can be affected by a spectrum of pathologic conditions, both benign and malignant. Although the overall clinical situation in addition to imaging may be suggestive of a diagnosis, in most cases pathologic confirmation by tissue diagnosis of mediastinal or hilar lymph nodes is usually required for a definitive diagnosis. Real-time bronchoscopic endobronchial ultrasound-guided visualization of intrathoracic lymph nodes can be accompanied by transbronchial needle aspiration for diagnosis. This technique can be useful for diagnosing infectious diseases, sarcoidosis, and lymphoma and for staging lung cancers or other cancers metastatic to the mediastinal lymph nodes (see Fig. 18.3).

10. Peripheral lung nodules located distal to the segmental and subsegmental airways can now also be biopsied bronchoscopically using electromagnetic navigational bronchoscopy. The patient is on a table that emits electromagnetic waves that are detected by a miniature receptor located at the tip of a directable catheter, which is introduced via the bronchoscope. The system is linked to a computer where the patient's preloaded fine-cut CT scan serves as a virtual roadmap for the procedure. The probe on the end of the catheter can be directed to lesions that have been identified on the CT imaging. After the navigatable catheter has been moved into position the probe is removed, and biopsies can be obtained through the catheter.

11. Bronchoscopy can be used for placement of endobronchial catheters for brachytherapy.

12. Bronchoscopy can be used to facilitate placement of oral or nasal endotracheal tubes, particularly in patients with a difficult airway due to upper airway abnormalities or limited neck flexion or in patients who need to undergo an awake intubation. Bronchoscopy is also routinely used to confirm the correct positioning of double-lumen endotracheal tubes.

Contraindications

1. Patients undergoing rigid bronchoscopy need to be able to tolerate

general anesthesia.

2. Patients with limited neck flexion may not be able to be positioned adequately to allow safe passage of the rigid bronchoscope.

3. In patient with hypoxia requiring high concentrations of oxygen, laser ablation of endobronchial lesions is contraindicated due to the risk of airway fire.

4. In patients with massive hemoptysis, flexible bronchoscopy is contraindicated because the capacity for blood aspiration through the small-diameter suction channel of the scope will not allow effective management.

5. Flexible bronchoscopy is contraindicated in patients with high-grade obstruction due to tracheal lesions, bilateral main stem bronchial lesions, or large extrinsically compressing mediastinal masses for which the surgeon is not confident that one can safely bag ventilate the patient after the induction of anesthesia.

Preoperative Preparation

1. The patient needs to be fluid resuscitated and hemodynamically stable for anesthesia.

2. Any coagulopathy needs to be treated with vitamin K and blood factors, as appropriate, prior to intervention.

3. Appropriate imaging needs to be performed and immediately available for review in the operating room during the procedure.

4. Depending on the diagnosis, the patient and his or her family need to be aware of the gravity of the situation, potential morbidity or mortality associated with the procedure, and potential need for postoperative ventilation.

Operative Period

Anesthesia

Flexible bronchoscopy can be undertaken with local anesthesia and IV

sedation and spontaneous respiration or via an oral endotracheal tube under general anesthesia. Rigid bronchoscopy is very stimulating and requires general anesthesia.

1. Local anesthesia may include nebulized lidocaine, Cetacaine spray to the oropharynx, and direct installation of 1% lidocaine in the piriform sinus, on the vocal cords and into the trachea and main stem bronchi via the bronchoscope as it is advanced. A percutaneous intratracheal injection of lidocaine may also be useful. In addition to pharyngeal and airway topicalization, IV sedation with propofol, fentanyl, or Versed may also be administered. In patients undergoing bronchoscopy for retained secretions and respiratory insufficiency when one is attempting to avoid intubation, usually local treatment alone is undertaken. Similarly, in patients with high-grade airway obstruction in whom we are not confident that we could ventilate them on anesthetic induction, evaluation of the patients with local anesthesia alone and no sedation is indicated.

2. Rigid bronchoscopy requires general anesthesia, and several options of ventilation are available.

a. Spontaneous ventilation. In cases of obstruction caused by high-grade endobronchial obstruction or very significant extrinsic compression, it is much safer to keep the patient breathing spontaneously until the bronchoscope is passed safely and a secure airway is established. In such cases, anesthesia is kept light enough that the patient is spontaneously breathing until such time as the rigid scope is in place in the airway. The disadvantage is the lack of muscular relaxation, which may preclude safe atraumatic passage of the rigid scope.

b. Intermittent ventilation. With this technique the ventilatory circuit is intermittently attached to the scope to ventilate the patient. If a large air leak is present, one may need to occlude the mouth and nose with a hand or pack the oropharynx with moist gauze packing. While the patient is being ventilated, the surgeon cannot visualize the airway through the scope or perform any interventions (Fig. 18.4).

c. Continuous ventilation. The viewing end of the scope is covered with a glass lens, and the ventilatory circuit is attached to a side port

on the scope. Packing of the pharynx and/or nose and mouth occlusion may be required. It allows for uninterrupted viewing through the scope, but opening the port for interventions will interrupt the ventilation as it opens the ventilatory circuit.

FIG. 18.4 Connection of rigid scope to ventilator circuit with occluding window on the end of the bronchoscope.

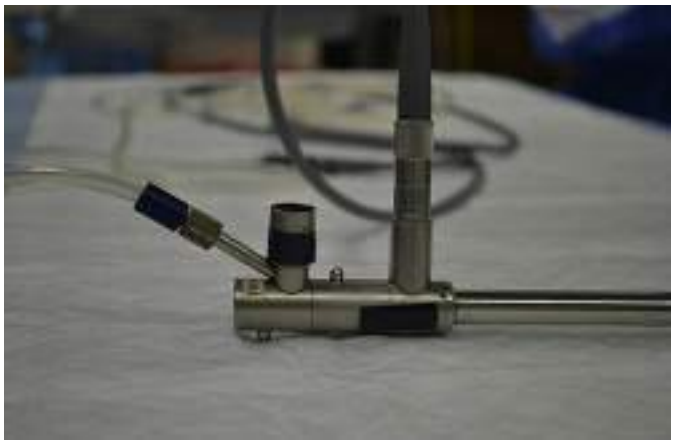

FIG. 18.5 Connection of High Frequency (JET) ventilator to rigid bronchoscope.

FIG. 18.6 High Frequency (JET) ventilator controls showing rate (usually 100 to 120 cpm), driving pressure (usually 15 to 25 psi), and inspiratory time (usually 40%).

d. High Frequency (JET) ventilation. This is the preferred and the most common mode of ventilation during the performance of rigid bronchoscopy. It allows for continuous intervention in the airway because a closed airway circuit is not required for High Frequency (JET) ventilation. The respiratory rate, inspiratory time, and driving pressure can be adjusted to maintain adequate oxygenation and ventilation during the procedure (Figs. 18.5 and 18.6).

In the case of airway obstruction in which the airway is still narrow at the end of the procedure and will not accommodate an endotracheal tube, or if a proximal endobronchial airway stent has been placed, or if one has concerns about obstruction at the level of the larynx, it may be necessary to maintain the patient with the rigid scope and JET ventilation until such time as the anesthetic has been reversed and the patient is breathing spontaneously.

For endobronchial ultrasound in which the scope is relatively large and stimulating and patient movement and coughing can challenge the ability to do safe transbronchial lymph node aspirates, it is generally preferable to do this procedure under general anesthesia. Likewise for electromagnetic navigational bronchoscopy where patient movement can disrupt the catheter, it is also preferable to perform this procedure under general anesthesia; however, both procedures have been also performed successfully with conscious sedation.

Positioning

- Patients are positioned supine.
- For electromagnetic navigational bronchoscopy, patients have to be placed and centered on a detector plate that lies underneath them.
- For patients in severe respiratory distress, flexible bronchoscopy can be undertaken with the patient sitting up.
- Initiation of rigid bronchoscopy can be undertaken with the patient sitting up and then gradually placed supine when the airway is secure.
- For rigid bronchoscopy the patient's head is placed on a donut pillow, and the neck is extended such that the chin points vertically to facilitate the introduction of the bronchoscope.

Preoperative Antibiotic Prophylaxis

Prophylactic antibiotics are generally not required.

Monitoring

1. Continuous oximetry

2. Continuous electrocardiogram

3. Bispectral Index (BIS) monitor and nerve stimulator if rigid bronchoscopy is being done under general anesthesia

Instruments and Equipment to Have Available

1. Suction

2. Mouth guard protector and eye protector

3. Rigid bronchoscopes of several sizes (Fig. 18.7)

4. Flexible bronchoscope, including pediatric bronchoscope, regular adult scope, and therapeutic flexible bronchoscope (see Fig. 18.2)

5. Laryngoscope with a variety of blades. Video laryngoscope may also be of benefit in assessing the airway.

6. An assortment of endotracheal tubes

7. Lidocaine and a slip tip syringe for airway topicalization and aerosolization of the pharynx

8. Suction catheters and biopsy forceps and graspers for the rigid bronchoscope. If appropriate for the procedure, olive tip tracheal dilators should also be available.

9. An assortment of graspers and retrieval baskets for removal of foreign bodies

10. Flexible biopsy forceps for the flexible bronchoscope

11. Adjustable height stool on wheels for rigid bronchoscopy

12. Laser and laser fiber for cases of hemoptysis

13. Fluoroscopy equipment for cases of endobronchial stent deployment or electromagnetic navigational bronchoscopy

FIG. 18.7 Small and large rigid bronchoscope.

Key Anatomic Landmarks

1. Epiglottis

2. Vocal cords

3. Glottic opening

Prerequisite Skills

1. For flexible bronchoscopy, one must be facile with operation of a flexible endoscope.

2. For endobronchial ultrasound, one must be familiar with the ultrasound appearance of mediastinal lymph nodes and adjacent vascular structures.

3. For rigid bronchoscopy, one should be facile with laryngoscopy and oral tracheal intubation.

Operative Risks

1. Flexible bronchoscopy
   a. Risk of hemorrhage with endobronchial biopsy that may overwhelm the limited suction capacity of the flexible bronchoscope. Possibly leading to oxygen desaturation
   b. With electromagnetic navigational bronchoscopic biopsy of a parenchymal lesion there is risk of a pneumothorax.
2. Rigid bronchoscopy
   a. Injury to the teeth
   b. Pharyngeal injury
   c. Laceration, contusion, or edema of the tongue
   d. Laryngeal injury
   e. Tracheal injury, particularly if dilating the airway, which could produce a pneumothorax or pneumomediastinum

Surgical Technique

1. Flexible bronchoscopy

   Simply need to be facile with the endoscopic controls

2. Endobronchial ultrasound

Need to be familiar with endoscopic ultrasound visualization of the mediastinal structures, as well as passing the needle sheath apparatus and aspirating

3. Electromagnetic navigational bronchoscopy

Need to be facile with driving the directable catheter to the site of interest with the aid of the program software. Also need to be competent in passing the various biopsy needles, brushes, and forceps through the directable catheter once locked in place

4. Rigid bronchoscopy

a. Apply eye protection and rubber tooth guard over upper teeth or gums (Fig. 18.8).

b. Place the patient's head on a donut pillow, and extend the chin such that it is pointing vertically (see Fig. 18.8).

FIG. 18.8 Passage of the rigid scope through the mouth with protection of the upper teeth with the thumb.

c. Using a Yankauer suction, the pharynx is cleansed of any saliva that may obscure visualization of the epiglottis and the vocal cords.

d. Place the examiner's thumb over the upper teeth or gums to guide the rigid bronchoscope and to protect those structures from injury.

e. With the bronchoscope oriented vertically, and while viewing through the end of the bronchoscope, advance it down posterior to

the tongue in the midline and elevate the tongue by dropping the proximal end of the scope down to visualize the epiglottis (see Fig. 18.8).

f. Advance the bronchoscope posterior to and distal to the epiglottis and then lift the bronchoscope anteriorly to visualize the arytenoids and the vocal cords and the glottic opening. At this juncture, the rigid bronchoscope will be horizontally orientated. External pressure can be placed on an anteriorly placed larynx to facilitate visualization of the vocal cords.

g. An alternative technique is to visualize the vocal cords with a handheld laryngoscope in the left hand and then pass the rigid bronchoscope with the laryngoscope in place with the right hand.

h. After the glottis is in view, the rigid bronchoscope is advanced toward the glottic opening.

i. Prior to passing the bronchoscope through the cords, it is rotated 90 degrees to align the vertically oriented glottic opening with the tip of the bronchoscope.

j. The bronchoscope is passed through the larynx into the trachea and rotated back to the proper orientation.

k. The operating table and the examiner's stool are adjusted so the examiner is comfortably situated.

l. Ventilation is then initiated through the bronchoscope by connecting either the ventilatory circuit to a side port of the scope or the High Frequency (JET) ventilator onto the Luer-Lok connector on the bronchoscope.

m. A rigid telescope may be passed through the rigid bronchoscope for better visualization, or alternatively the flexible bronchoscope may be passed through the rigid bronchoscope for better visualization of the distal airway.

n. It may be necessary to temporarily hold ventilation to avoid movement of foreign bodies while grasping them with forceps. Small foreign bodies less than the diameter of the rigid scope may be drawn out through the lumen of the scope. Larger foreign bodies require withdrawal of the rigid scope while holding the foreign body at the tip of the scope with grasping forceps.

o. On conclusion of the procedure, the patient can be ventilated using the rigid bronchoscope until such time as the anesthetic agent is cleared and the patient is breathing spontaneously, and then the bronchoscope can be safely removed.

p. While drawing back the rigid bronchoscope on termination of the procedure, the proximal trachea, larynx, and pharynx may be examined.

Common Errors in Technique

1. Levering the rigid scope off the upper teeth and in so doing causing injury to the teeth (see Fig. 18.8)

2. Not adequately topicalizing the pharynx and cords with peroral bronchoscopy prior to introduction of the bronchoscope

3. Inadequately sedating the patient prior to attempting to introduce the rigid bronchoscope

Postoperative Period

Postoperative Management

1. Patients should be monitored postoperatively in the recovery room or the intensive care unit, if indicated, for any signs of airway compromise due to laryngeal edema or pharyngeal or lingular injury secondary to introduction of a rigid bronchoscope.

2. A chest radiograph should be performed to rule out pneumothorax or pneumomediastinum following instrumentation with the rigid bronchoscope.

Complications

1. Injury to the teeth

2. Lacerations, contusions, or edema of the pharynx or tongue

3. Damage to the vocal cords or dislocation of the arytenoid

4. Massive hemorrhage that may overwhelm the ability to clear endobronchial blood, causing secondary hypoxemia. Particularly in the case of flexible bronchoscopy

5. Airway injury with secondary pneumothorax, pneumomediastinum, or subcutaneous emphysema

Alternative Management Plan

In patients with very severe and extensive airway compromise in significant respiratory distress, it may not be safe to administer any sedation to allow safe passage of the rigid scope. An alternative in such cases would be vascular cannulation for veno-venous extracorporeal membrane oxygenation or femoral arterial and venous cannulation for cardiopulmonary bypass. The patient could be thus supported until such time as a secure airway could be established either by stenting the airway or débriding endobronchial tumor.

Discussion

Evidence-Based Medicine Question

Is a patient with high-volume hemoptysis best evaluated with flexible or rigid bronchoscopy?

When managing a patient with massive hemoptysis, it is far safer to evaluate the airway with a rigid bronchoscope in place. It allows the operator a much greater capacity for suction to clear blood from the airways. It also allows the passage of occlusion balloon catheters to isolate a bleeding lung to allow ventilation via the contralateral lung until such time as definitive treatment of the source of the bleeding can be undertaken.

Editorial Comment

The first bronchoscopy is attributed to Professor Gustav Killian, in 1897, who used a rigid bronchoscope under local anesthesia to extract a foreign body from the tracheobronchial tree of an adult. Dr. Chevelier Jackson,

who was born, raised, educated, and trained in Pittsburgh, refined the rigid bronchoscope in the 1920s by placing the light at the distal tip of the bronchoscope, which provided enhanced illumination. He is regarded as the "Father of Endoscopy."

Rigid bronchoscopes were used exclusively until Professor Sigato Ikeda of Japan invented the flexible bronchoscope in 1966 using fiberoptic bundles as a light source. More recently fiberoptic scopes have been replaced by bronchoscopes with a video chip located at the distal extremity of the scope. Bronchoscopy has come a long way since Dr. Jackson's time, but technological innovations have not altogether eliminated rigid bronchoscopy. Flexible bronchoscopy has largely replaced rigid bronchoscopy for diagnostic purposes, which can now be done as an office procedure, whereas rigid bronchoscopy remains the technique of choice for therapeutic procedures, such as extraction of foreign bodies, diagnosis and management of hemoptysis, and lower airway obstruction. The newer technological advances, including endobronchial ultrasound and navigational bronchoscopy, have extended the diagnostic utility of rigid bronchoscopy to include the assessment of peribronchial lymph nodes and peripheral lung nodules.

The evolution of this instrumentation has made bronchoscopy an area of overlapping interests for thoracic surgeons, otolaryngologists, and pulmonologists carrying out diagnostic bronchoscopy. Thoracic surgeons and otolaryngologists use both rigid and flexible bronchoscopes, and pulmonologists use flexible bronchoscopes exclusively. As the old saying goes "It ain't the engine, it's the engineer." Hands-on training in the use of these techniques is of utmost importance to ensure the accuracy of the procedure and the safety of the patient.

Review Questions

1. Rigid bronchoscopy is the preferred approach over flexible bronchoscopy in all circumstances, except

   a. Massive hemoptysis

   b. **Low-volume intermittent hemoptysis**

c. Severe airway compromise with extrinsic compression of the trachea due to a large mediastinal mass

d. A large aspirated foreign body

2. Which technique would allow for best yield in diagnosing the cause of mediastinal adenopathy?

a. Flexible bronchoscopy with blind transbronchial biopsy

b. **Flexible bronchoscopy with endobronchial ultrasound-guided aspiration**

c. Electromagnetic navigational bronchoscopic biopsy

3. What is the preferred mode of patient ventilation during the conduct of rigid bronchoscopy?

a. Spontaneous ventilation

b. Intermittent positive pressure ventilation

c. Continuous positive pressure ventilation

d. **JET ventilation**

4. In a patient in severe respiratory distress secondary to high-grade extrinsic compression of the airway, which anesthetic technique should be used prior to introduction of the rigid bronchoscope?

a. **Topicalization of the throat and larynx with lidocaine only until such time as the scope is in position**

b. Rapid induction of general anesthesia with intravenous (IV) propofol

c. Rapid administration of general anesthesia with IV propofol and muscular relaxation with succinylcholine

d. Topicalization of the throat and larynx with lidocaine and IV conscious sedation with propofol

Open Tracheostomy

David M. Johnson, and David Eibling

Introduction

- Tracheostomy is essentially a "shortcut" into the airway that "bypasses" the upper airway.
- Most tracheostomies are performed for ventilator support in critically ill patients or as a temporary airway to accompany surgical procedures on the oral cavity, pharynx, or larynx (Fig. 19.1).
- Less common indications include sleep apnea, chronic lung disease, primary alveolar hypoventilation syndrome (Ondine curse), and conditions requiring prolonged mechanical ventilation.[1]

Key Operative Learning Points

- Performance of a tracheostomy is substantially easier than making the decision to perform the procedure and where, when, and how to perform it.
- Most adverse outcomes from tracheostomy occur in the postoperative period, not intraoperatively.
- Cricothyroidotomy is the preferred procedure in emergency airway settings where seconds count.

Preoperative Period

History

- Why does this patient need a tracheostomy?

- How soon will it be necessary?
- How long will it be required?
- Will the patient be on mechanical ventilation?
  - If so, for how long?
- Are there any alternatives?
- Where and by whom will the tracheostomy be managed?

Past Medical History

- Has the patient undergone prior tracheostomy or other neck surgery?
- Can the patient tolerate general anesthesia?
- Is the patient anticoagulated? If so, can it be stopped for the procedure?
- If on mechanical ventilation, what are the peak pressures?

Physical Examination

- Position of cricoid cartilage and trachea in the neck
- Presence of overlying masses or open wounds
- Evidence of blood dyscrasias (bleeding from puncture sites, gums)
- Ability of the patient to extend the neck

Imaging

Not required

Indications

1. Relief of upper airway obstruction (both acute and chronic)
2. Provide a means for assisted mechanical ventilation
3. Facilitate efficient tracheobronchial toilet

Contraindications

There are almost no absolute contraindications to tracheostomy. Those most commonly encountered are uncorrectable coagulopathies such as in patients with end-stage liver failure and extremely high ventilation pressures that may lead to flash pulmonary edema if the pressure is relieved suddenly for the time required for a tracheostomy.

Preoperative Preparation

- Decide whether a tracheotomy is indicated.
  - The decision to proceed with a tracheostomy is complex. Factors to consider include the following:
    - Relative advantages and risks of tracheostomy
    - Expected duration of endotracheal intubation
    - Capabilities of the institution and its personnel
    - Unique features of the patient's airway and respiratory physiology
    - Specific disorder or disease process and its likely course
- Every effort should be made to ensure that the patient's condition is optimized before the tracheostomy. Coagulopathies should be corrected and aspirin or other nonsteroidal anti-inflammatory medications stopped if possible.
- Patients presenting with stridor require that a safe airway be established as rapidly as possible.
  - Often, emergency control of the airway can be most rapidly accomplished with endotracheal intubation with or without endoscopic guidance.
  - Inability to intubate due to pharyngeal or laryngeal edema or tumor, or severe facial or laryngeal trauma, may mandate awake tracheostomy or cricothyroidotomy.
  - In an emergency, when seconds count, most surgeons would choose to perform cricothyroidotomy. Although it avoids the thyroid isthmus, cricothyroidotomy is not bloodless.

- Location: Tracheostomy in many institutions is routinely performed in the operating room (OR), whereas in others it is safely performed in the intensive care unit. Adequate instrumentation, lighting, suction, and assistance are required.
- Anesthesia or critical care teams should be present to manage the patient's cardiorespiratory function during tracheostomy. Patients with chronic respiratory insufficiency may require assisted ventilation and even cardiopulmonary resuscitation once obstruction is relieved.
- Preoperative planning should consider appropriate tracheostomy tube selection.
  - The tube must provide an adequate airway, facilitate artificial positive pressure ventilation if necessary, seal the trachea to reduce aspiration of material from above, and provide a means of suctioning the tracheobronchial tree.
  - Aspects of tube selection include the length, diameter, and shape of the tube and the neck plate. Typically, cuffed tubes are placed in adults to reduce aspiration of secretions. Tubes with an inner cannula provide an added safety dimension because the inner cannula can be quickly removed in case there is a mucous plug, leaving the outer cannula in situ and the airway protected.

FIG. 19.1 Large-volume papilloma obstructing the airway

in a young child.

- Obese patients with thick pretracheal soft tissues may require extended-length tubes to decrease the risk of accidental decannulation or tube displacement.
- Extended-length tracheostomy tubes with proximal or distal extensions are available, as are tubes with adjustable flanges and length.
- Surgeon protection: All personnel in the OR should wear masks with face shields because splattering of purulent tracheal secretions commonly occurs at the time the cannula is inserted into the trachea.

Operative Period

Anesthesia

- Tracheostomy may be performed under general, local, or awake sedation.
  - The choice of local or general anesthesia is dictated by the circumstances.
  - Patients with a marginal airway and respiratory distress must be managed with local anesthesia alone without sedation, which may suppress respiratory drive.
  - In children, the procedure is usually carried out under general anesthesia.
- When performing the procedure under local anesthesia, additional plain lidocaine is injected into the pretracheal tissues as the dissection deepens, because early airway injection may precipitate panic with subsequent obstruction.
- The surgeon should always stand by during intubation because adverse airway events can occur unexpectedly.
- Decisions and discussions regarding oxygen saturation should occur before starting the procedure. If the patient requires higher than 30% oxygen to maintain saturation, then electrocautery should not be used

when the trachea is opened. Many teams routinely switch to 100% oxygen at this point due to the risk of desaturation from loss of airway pressure.

Positioning

- Position the patient supine with the neck extended.
- Usually the patient is placed on the operating table with a rolled towel or sheet under the shoulders to extend the neck, unless the patient has documented or suspected cervical spine injuries.
- Adults with airway obstruction may not be able to lie flat, and the tracheostomy may need to be performed with the patient sitting up at 45 degrees.
- Patients with severe cervical osteoarthritis, kyphoscoliosis, or other conditions in which the neck cannot be hyperextended present a formidable surgical challenge.

Perioperative Antibiotic Prophylaxis

- Although considered a "clean contaminated" procedure, tracheostomy is often performed in the presence of purulent tracheal secretions.
- If the patient is not already on antibiotics, they must be administered during induction of anesthesia and continued for a minimum of 24 hours.
- Antibiotic choices are typically driven by prior cultures in ill patients.
  - Clindamycin
  - Amoxicillin-clavulanate
  - Cephalosporin and metronidazole

Monitoring

- Routine anesthesia monitoring is needed with careful attention to oxygen saturation.

Instruments and Equipment to Have Available

- Routine tracheostomy set
- Confirm the presence of a "trachea hook" in the set.
- Tube should be selected and the cuff tested and then deflated

Key Anatomic Landmarks

- Thyroid notch
- Cricoid cartilage
- Sternal notch

Prerequisite Skills

- Basic surgical skills
- Experience with anterior neck surgery
- Familiarity with the anatomy of the cricoid, thyroid, and trachea and the accompanying venous structures

Surgical Technique

- Lidocaine 1% with 1:100,000 epinephrine is injected into the skin and subcutaneous tissue where the incision will be made. The neck, face, and upper chest are prepared with a suitable solution, and a drape is placed to allow easy access to the neck and oral cavity.
- A transverse incision is made in a skin crease approximately 1 cm above the suprasternal notch or 2 cm below the cricoid cartilage.
- Sharp dissection is carried through the subcutaneous tissue. Small rake retractors are used to provide good exposure. The anterior jugular veins should be identified and retracted laterally (Fig. 19.2); they need not be ligated unless inadvertently cut.

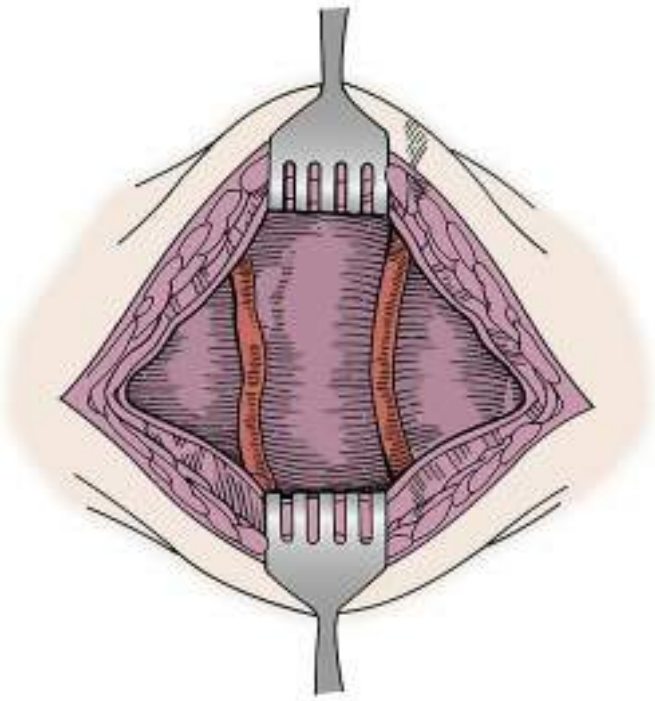

FIG. 19.2 The anterior jugular veins do not need to be sacrificed if uninjured.

- The strap muscles are split in the midline and retracted laterally (Fig. 19.3A).
- The thyroid isthmus is visualized and the anterior wall of the trachea identified (see Fig. 19.3B). Some surgeons routinely divide the thyroid isthmus, whereas others routinely retract it superiorly (see Fig. 19.3C). Ligation of the isthmus is facilitated by first incising the fascia inferiorly to the cricoid, exposing the trachea, then undermining the isthmus, which is then clamped, transected, and suture-ligated.
- Once the trachea is identified, a tracheal hook is placed under the cricoid or at the second tracheal ring and held by an assistant to immobilize the trachea.
- In infants and children, a vertical incision is made between the second and the third or the third and the fourth tracheal rings without removing any cartilage. Traction sutures are then placed just lateral to the incision (Fig. 19.4).
- In adults, the trachea is opened transversely between the second and third or third and fourth rings. Caution should be exercised when using electrocautery close to the trachea because of the risk of airway

fire.

- Resection of the anterior portion of a tracheal ring may facilitate insertion of the tracheostomy tube. In older patients, the tracheal ring is calcified, and heavy scissors or a Kerrison rongeur must be used to excise the anterior portion of the tracheal ring.
- Traction sutures are placed in the midline around the inferior and superior rings with a ligature carrier (Fig. 19.5) or curved needle. Traction is applied to both sutures to exteriorize the stoma and retract the wound edges.
- The endotracheal tube or bronchoscope can be withdrawn to a point above the stoma at this point.
- Once the traction sutures have been satisfactorily placed and the endotracheal tube withdrawn, the tracheal cannula, with the obturator inserted, may be introduced into the stoma (Fig. 19.6A). Introduction of the tube is facilitated by beginning with the cannula at right angles to the trachea; then, as the cannula is inserted, it is rotated so that its axis is parallel to that of the trachea. Once the cannula is properly placed in the trachea, the obturator is removed and the inner cannula inserted. When the tracheostomy tube is in place and adequate ventilation through the tracheostomy tube is assured, the endotracheal tube or bronchoscope used to stabilize the airway may be removed.
- The tracheostomy tube is secured by suturing the neck plate to the skin (see Fig. 19.6B) and by a Velcro strap or tracheostomy tapes tied securely with the neck flexed. In patients undergoing head and neck surgery, the tape is not used if it crosses the cervical flap incision or causes constriction of the blood supply of a flap brought up through the neck. The stay sutures are taped to the neck.
- It is important to secure all bleeding points with ligatures or electrocautery to prevent bleeding postoperatively. The incision should not be sutured or packed to prevent subcutaneous emphysema. The wound may be left open or a very light dressing applied.

Special Considerations for the Obese Patient

- Obstructive airway pathology is commonly comorbid with obesity and

can complicate both the initial procedure (flash pulmonary edema) and decannulation plans (poor tolerance of capping due to sleep apnea). Patients and family should be counseled accordingly.

- Removal of excessive subcutaneous tissue is advisable to create a shorter tract between skin and trachea, and it assists in creating skin flaps to mature the stoma.
- Maturation of the stoma with half-mattress sutures between skin and trachea is a valuable adjunct in obese patients and will reduce the chances of a false passage should the tube become dislodged in the early postoperative period. However, eventual closure will require a secondary surgical procedure.
- Extended-length tracheostomy tubes (e.g., Shiley XLT) are available to better match the patient's anatomy (Fig. 19.7).

Special Considerations for Pediatric Tracheostomy

Airway misadventures are potentially catastrophic consequences in children. Pediatric tracheostomy tubes (Shiley #3 or smaller) do not have inner cannulas. As a result, the following technical modifications should be considered:

- Naso- and orogastric tubes are removed prior to tracheostomy so that they are not mistaken for the trachea during palpation.
- A vertical skin incision may be preferred (despite its cosmetically less desirable nature) for ease of extending the incision if necessary and because transverse skin flaps may obscure tract visualization.
- Repeated palpation to ensure midline dissection is paramount.
- The thyroid isthmus is always divided so it does not obstruct the tract in case of accidental decannulation.
- Nondissolvable monofilament traction sutures are placed lateral to the proposed tracheal incision to facilitate exposure; they are labeled LEFT and RIGHT, taped securely to the chest, and removed following successful first tube change.
- The stoma can be matured by tacking the skin and tracheal incisions together in half-mattress fashion using dissolvable suture.

- Flanges are securely tied around the neck using shoestring-style ties. In children, the flange is not sutured to the skin, which would hinder replacement in case of accidental decannulation or plugging, particularly when the tracheostomy tube does not have an inner cannula.

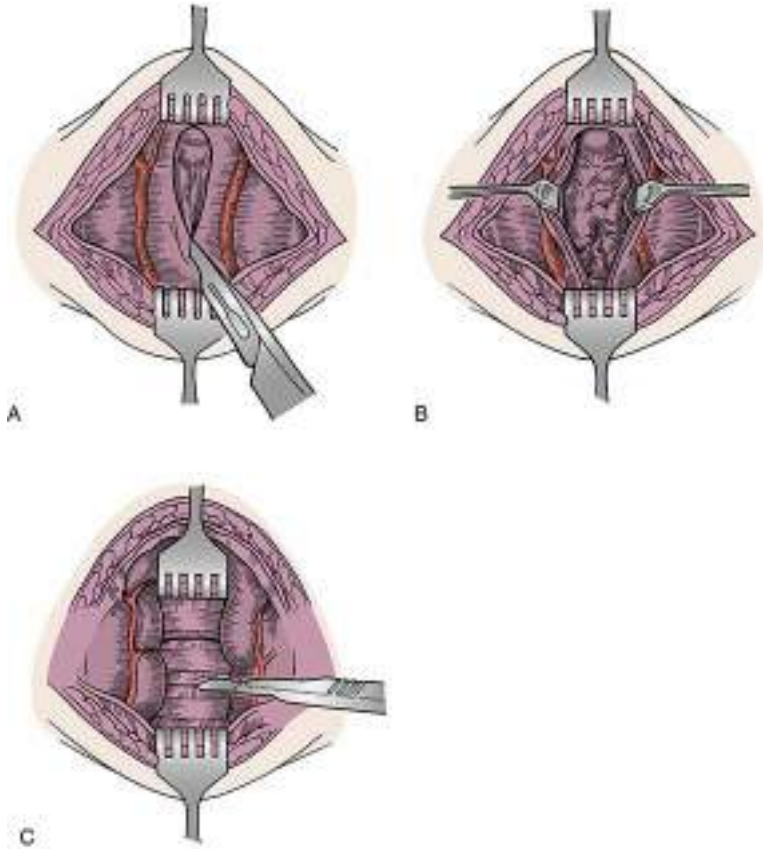

FIG. 19.3 **A,** The strap muscles are split in the midline and retracted laterally. **B,** The trachea and thyroid isthmus are identified. **C,** The trachea is entered through an incision between the second and third tracheal rings as the thyroid isthmus is retracted superiorly, or divided, as required.

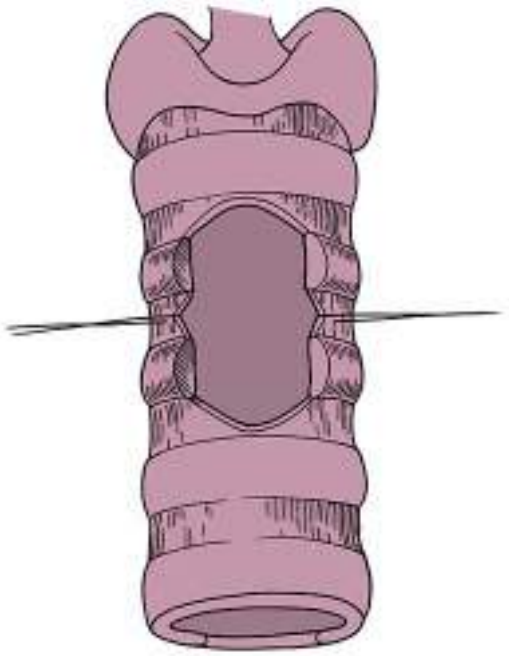

FIG. 19.4 Traction sutures are placed lateral to the stoma in children. No cartilage is removed.

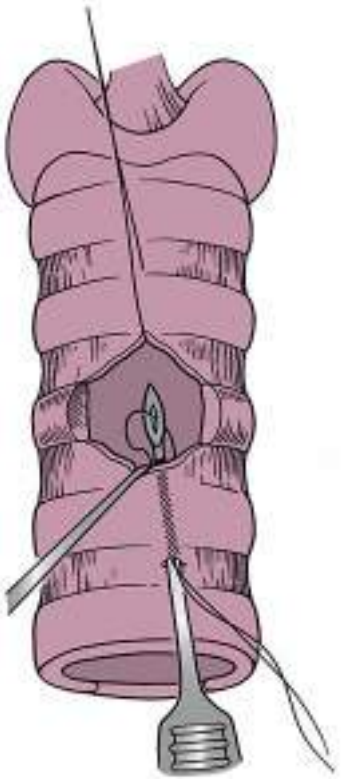

FIG. 19.5 Traction sutures are placed superior and inferior to the stoma in adults.

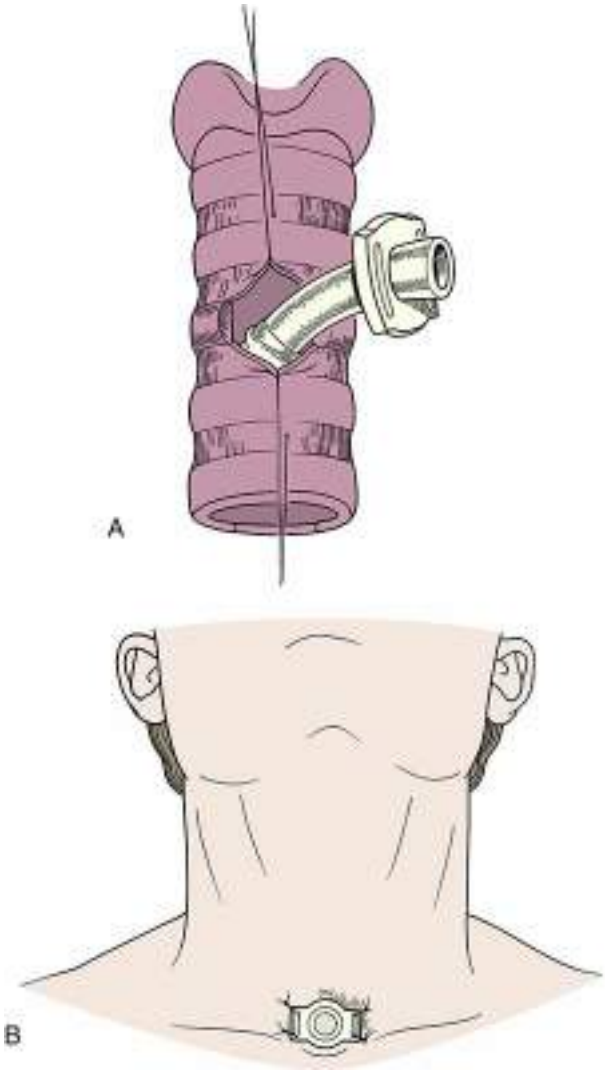

FIG. 19.6 **A,** The tracheostomy tube is inserted into the trachea. **B,** The neck plate of the tracheostomy tube is sutured to the skin. The use of tapes is optional.

Common Errors in Technique

Intraoperative Complications

Hemorrhage

- Bleeding during tracheostomy may be minimized by careful attention to the details of the procedure. Bleeding is usually minimized by staying in the midline with the dissection, being cautious to dissect layer by layer, and maintaining adequate light and assistance with

retraction of the soft tissues for adequate exposure.

- Bleeding from transection of the anterior jugular vein, the thyroid isthmus, or a high innominate artery are all possible and should be dealt with appropriately by identifying, ligating, or cauterizing the injured vessel.

Intraoperative Tracheoesophageal Fistula

- Intraoperative tracheoesophageal fistula may occur when the tracheal wall has been injured inadvertently, usually during an "urgent" tracheostomy with overpenetration of the trachea itself.
- An open neck exploration and repair may be necessary once the airway has been established. The wounds in the trachea and the esophagus must be closed separately.

Pneumothorax and Pneumomediastinum

- Entrainment of air into neck tissues is most likely to occur in a patient suffering from air hunger when the patient is struggling to breathe against an obstructed airway. Entrained air is then "pulled" into the mediastinum.
- Pneumothorax may occur due to direct puncturing of the pleura by the surgeon; this is most common in children, in whom the apex of the lung protrudes into the lower neck.
- Pneumothorax may also occur if the tracheostomy tube is inadvertently inserted into a "false passage" (Fig. 19.8).
- Pneumomediastinum is most common in children and is usually noted on routine chest radiographs.
  - Air can be forced from the open tracheostomy into the deeper planes of the neck by excessive coughing or positive pressure ventilation.
  - Patients with pneumomediastinum are generally asymptomatic, and no therapy is required.

Cardiopulmonary Complications

- Cardiopulmonary arrest may occur after an obstruction is resolved in patients who have had chronic air hunger and elevated CO_2 levels. The anesthesia team should be alerted to this possibility in the event that cardiopulmonary resuscitation is necessary.
- Sudden release of endobronchial pressure may also result in flash pulmonary edema or congestive heart failure due to extravasation of fluid into alveoli in response to reduction of obstruction-induced positive end-expiratory pressure.

Fire

- Fire during tracheostomy is a rare but catastrophic event. Fire requires fuel, oxidizer (enriched oxygen/nitrous), and a source of ignition.
- Fire risk should be discussed prior to any surgical procedure as part of the preprocedure briefing, especially tracheostomy, and plans regarding oxygen delivery reviewed with the team.
- External burns may result from the use of electrocautery shortly after prepping the skin with alcohol-containing solutions (fuel).
  - This is of particular concern in hirsute patients, in whom body hair interferes with the drying of the solution.
  - Every effort should be made to ensure that the operative field is completely dry before electrocautery is used. Alcohol-based solutions should be avoided.
- Fire may occur any time electrocautery is used in the presence of high concentrations of oxygen, whether delivered by mask (as in local procedures) or via the endotracheal tube under general anesthesia. In the latter case, the endotracheal tube is the fuel. Oxygen concentrations should be kept at a minimum safe concentration for the patient, and cautery should never be used to enter the airway, especially in unstable patients in whom reducing the oxygen concentration represents unacceptable risk.
- In the unfortunate instance of an airway fire, the immediate response includes the following:
  - Disconnect the oxygen supply.

- Remove and replace the endotracheal tube.
- Flood the field with water.
- Perform bronchoscopy to assess the extent of injury.
- Treat medically with antibiotics and steroids, and observe in the ICU.

FIG. 19.7 **A,** Three common tracheostomy tubes. *Top to bottom*: #4 uncuffed Shiley, #6 cuffed Shiley, #8 cuffed percutaneous tracheostomy tube (note the tapered distal end). The smaller-diameter tubes are also shorter. **B,** Two specialized tubes. *Top*: uncuffed #7 Shiley XLT (extra length). This tube is termed "proximal" because the extra length is the proximal portion of the tube before the bend to accommodate a deeper neck incision. *Bottom*: Bivona Fome-Cuf tube, typically used for patients requiring chronic ventilator support.

Postoperative Period

Postoperative Management

Most adverse events occur in the first postoperative week, so care of the tracheostomy is critical in assuring a safe outcome for the patient.

- Nursing staff must be aware of the unique needs of the patient with a fresh tracheostomy. Family counseling and highly skilled nursing care are extremely important to support the patient during this time.
- Postoperative care is greatly facilitated through preoperative teaching. This helps allow both children and adults undergoing tracheostomy to adjust to this new way of breathing. Evidence indicates that patients undergoing tracheostomy experience reductions in their quality of life.[2]
- Patients are placed in a semi-Fowler position in the initial postoperative period to maximize the ease of coughing and deep breathing, to facilitate suctioning, and to minimize discomfort.
- Vital signs must be monitored carefully because changes in blood pressure, respiratory rate, or pulse rate may indicate that there is a new or ongoing respiratory problem or that the tube may be plugged or has been displaced out of the trachea. Agitation, anxiety, and restlessness may all indicate hypoxia.
- Tracheal suctioning is performed as necessary to clear pulmonary secretions and aspirated oral secretions and to verify patency of the tracheostomy tube.
- Humidification is required to facilitate mucociliary transport of secretions and to prevent crusting, accumulation of secretions, and eventual obstruction of the airway. Humidification is usually delivered through a tracheal mask. The use of a T-piece is avoided because the torque exerted on the tracheostomy tube traumatizes the tissue with movement.
- The inner cannula is removed frequently and cleaned or replaced to assure that obstruction with insipated mucus does not occur.
- The tracheostomy site should be cleaned as often as necessary with normal saline or hydrogen peroxide but at least 3 or 4 times daily. The skin under the tracheostomy neck plate should be kept dry with a thin

nonadherent dressing such as Telfa to prevent maceration.

- In the absence of complications, the tube should not be changed until adhesions form between the overlying soft tissues and the trachea, typically 5 to 7 days postoperatively.
- Changing the tracheostomy tube requires some finesse and should not be required unless the patient is to be changed from a cuffed to an uncuffed tube or if the cuff fails. Tube replacement in the first 48 hours requires the following:
  - Optimal patient positioning

FIG. 19.8 Mechanism of false passage between the sternum (S) and the trachea (T). From Myers EN, Stool SE, Johnson JT: Complications in tracheostomy. In Myers EN, Stool SE, Johnson JT [eds]: Tracheostomy. New York: Churchill Livingstone; 1985, p 150.

  - Assistance
  - Adequate light
  - Tracheal hook

- Suction

- The use of a tube exchanger, a long semiflexible tube with a central lumen through which ventilation is possible, may be useful in difficult tracheostomy tube changes.

Decannulation

- Decannulation in adults can be safely accomplished by following a few simple steps.
  - Indirect or flexible endoscopy should be used to ensure that the upper airway is adequate and the larynx is competent.
  - The tracheostomy tube is then downsized and plugged during waking hours. The patient must be instructed to remove the plug in the event of dyspnea or shortness of breath.
  - If the patient tolerates the plug for 24 hours, the cannula can be removed and the stoma covered with a light dressing and occlusive tape. The period of plugging allows for adequate evaluation of airway adequacy. If the plug is not tolerated, the nature of the obstruction must be investigated.
- Children should undergo endoscopy before decannulation. Often a granuloma in the stomal site is found; removing the granulomas enhances successful decannulation.

Postoperative Complications

Unfortunately, complications following tracheotomy are not rare. Most occur hours, days, or weeks following the procedure, rather than intraoperatively.[3,4] A recent collaborative study has been established to maintain a database on post-tracheotomy events (www.globaltrach.org), and instructional videos and teaching materials are available on a website (www.tracheostomy.org.uk).

Immediate Postoperative Complications

Tube Obstruction

- The tube may be obstructed by thick or dried mucus or blood clots.
- Prevention includes attentive nursing care, proper humidification, and frequent suctioning.
- When possible, a tracheostomy tube with an inner cannula should be selected to facilitate regular inspection, cleansing, and suctioning.
- If an obstructed tube cannot be cleared, it should be removed and replaced.

Displaced Tracheostomy Tube

- Displacement of the tracheostomy tube may occur at any time and is potentially fatal.
- Accidental decannulation in the early postoperative period can be catastrophic because the tract has not formed. After the tube is removed, the tissues collapse, sealing off the airway and making tube replacement difficult or impossible.
- Attempts to replace the tube blindly can lead to a false passageway, leading to death (see Fig 19.8).
- Patient factors that may predispose to displacement of the tube include the following:
  - Obesity
  - Excessive coughing
  - Agitation
  - Physical factors include the following:
    - Incorrect tube selection (usually too short)
    - Incorrect location of the opening into the trachea (usually too low)
    - Creation of a false passage (see Fig. 19.8)
    - Loosened or inadequately tied tracheostomy tapes
    - Use of bulky dressings under the neck flange: Such situations are largely preventable by selection of the correct tube and suturing the neck plate to the skin.

- Displacement of the tracheostomy tube should be suspected when a patient with a recent tracheostomy develops respiratory distress or is suddenly unable to speak.
- It is important to avoid positive pressure ventilation through a displaced tube because pneumomediastinum and tension pneumothoraces may lead to patient demise within minutes.
- Replacement of the tube is facilitated in the early postoperative period by using the traction sutures.
- If tube reinsertion fails, or in a patient with known difficult insertion, it may be best to reintubate the patient from above and identify the tracheostomy tract once the airway is secured.
- Identifying the tracheal opening with a flexible endoscope or a suction catheter and inserting the tracheostomy tube using the Seldinger technique is an alternative method of restoring the airway.

Postoperative Hemorrhage

- Postoperative bleeding may occur as in any surgical procedure.
- Treatment requires identification and ligation of the offending vessels.
- For "oozing," use of a hemostatic packing such as Surgicel may be helpful.
- Coagulopathies should be identified and corrected.
- If bleeding is significant, the patient should be returned to the OR, the wound explored, and hemostasis achieved.
- Packing an actively bleeding tracheostomy site should be avoided because the packing can divert air into the subcutaneous tissues and blood into the tracheal lumen.

Wound Infection

- The tracheal wound is colonized within 24 to 48 hours by many species of organisms, including *Pseudomonas* and *Escherichia coli,* as well as gram-positive cocci such as *Staphylococcus epidermidis.*

- Antibiotics do not prevent colonization of the wound and the biofilm on the tube itself.
- The longer the tube is in place, the heavier the load of biofilm. Regular tracheostomy tube changes every 2 weeks have been shown to decrease the incidence of granulation tissue and biofilm formation.[5]
- Tracheobronchitis may be due to underlying disease, aspiration, or both. Treatment is suctioning, vigorous pulmonary exercise (blow bottles, cupping and clapping, ambulation), and judicious administration of antibiotics.
- Rarely, necrotizing stomal infections may occur with substantial loss of soft tissue down to and including the tracheal wall. Rarely, local flaps may be necessary to provide soft tissue coverage of vital structures.

Subcutaneous Emphysema

- Air may be forced into the subcutaneous tissues during or shortly after tracheostomy. Factors predisposing to this complication include the following:
  - Excessive coughing
  - Use of an uncuffed tracheostomy tube
  - Tight suturing of the wound around the tracheostomy tube
  - Packing of the wound
- If the subcutaneous emphysema is severe, the wound should be opened and any packing removed.
- If mild and not progressing, no treatment is necessary because the air will eventually be absorbed from the tissues.

Late Postoperative Complications

Granulation Tissue

- Considered to be a late complication or sequela of tracheostomy, variably reported as occurring in 3% to 80% of cases
- Commonly seen in children, especially those in whom a fenestrated

tube has been used

- May lead to bleeding, difficult tube changes, delayed decannulation, and even completely obstruct the tracheostomy tube
- Factors believed to favor formation of granulation tissue include the following:
  - Bacterial infection
  - Gastroesophageal reflux
  - Suture material
  - Powder from surgical gloves
- Treatment
  - Topical treatments such as steroid creams, antibiotic ointments, and silver nitrate may be beneficial.
  - Larger amounts of granulation tissue, particularly when obstructive, may require surgical excision, with or without the use of the laser.
- The prolonged presence of the same indwelling tracheostomy tube elicits an inflammatory tissue response favoring the growth of granulation tissue, increased secretions, and bacterial colonization with biofilm production.[5] Regular tube changes, on a schedule of every 2 to 3 weeks, have been shown reduce the incidence of granulation tissue.

Late Tracheoesophageal Fistula

- Rare complication
- May result from an overinflated or improperly fitted cuff or malpositioned tracheostomy cannula pushed to the posterior wall of the trachea against an indwelling nasogastric tube
- Often a misdiagnosis because appearance of food through the tracheostomy is more likely to represent aspiration rather than a tracheoesophageal fistula
- Modified barium swallow will distinguish between these diagnoses.

Innominate Artery Rupture

- Rare
- Usually occurs within the first 3 weeks after tracheostomy
- May occur in patients of any age
- Predisposing factors include the following:
  - Placing the tracheostomy low in the neck below the third tracheal ring where the inferior concave surface of the cannula may erode the artery
  - Aberrant course of the innominate artery such that it crosses the trachea at an abnormally high level
  - Selection of an excessively long or curved tube, the tip of which may erode the trachea and the vessel wall deep to it
  - Overextending the neck during the tracheostomy procedure
  - Prolonged excessive pressure on the tracheal wall by an inflated cuff
  - Tracheal infection
- Recognition and treatment
  - Rupture of the innominate artery is usually heralded by a "sentinel bleed," which may stop and be followed a few days later by a catastrophic hemorrhage. The patient coughs up bright red blood from the tracheostomy tube.
  - If recognized, the cuff of the tracheostomy tube should immediately be overinflated and suprasternal pressure applied in an attempt to control the hemorrhage long enough to transport the patient to the OR for emergency thoracotomy.

Tracheal Stenosis and Tracheomalacia

- Late complications due to overinflation of the tracheostomy tube cuff with resultant necrosis of mucosal and ultimately the underlying cartilage rings
- Prevention requires careful monitoring of tracheostomy cuff pressures by nursing staff.

Tracheocutaneous fistula, depressed scar, and *laryngotracheal stenosis* are

discussed elsewhere.

Alternative Management Plan

Decision making typically includes tracheostomy versus intubation versus observation. In selected terminal cases, decisions to forego airway intervention may be appropriate.

Discussion

Evidence-Based Medicine Question

Which patients with tracheostomy are at the highest risk?

It is usually assumed that the riskiest period for patients undergoing tracheostomy is during the procedure. However, several recent studies refute this and point out that adverse outcomes, including death, are much more common in the postoperative period. Halum et al.[4] in a large series of 1175 tracheostomy procedures performed in multiple institutions in a 2-year period observed that only 1.4% of the patients in the series suffered an intraoperative complication, whereas 5.6% suffered a complication in the first week and 7.1% suffered some sort of late complication. Of their series, 22% died during their hospital stay; however, only a small minority died of complications due to the tracheostomy. See also Das.[3]

Editorial Comment

Although the earliest reference to tracheostomy dates back to Egyptian tablets from about 3600 BC,[6] the most dramatic was attributed to Alexander the Great (356–323 BC), who is said to have performed a tracheostomy with the tip of his sword on one of his soldiers who was choking.[7]

The use of tracheostomy has increased during the last 2 centuries, and the indications have broadened. The most common indications have changed in more recent years from urgent airway establishment as a result of obstruction due to inflammation, foreign body, trauma, sleep

apnea, and neoplasm to the use of mechanical artificial respiration in patients in intensive care units.

Endolaryngeal endotracheal intubation dates back to Avicenna (AD 980–1037), who bent tubes of gold and silver and used them to cannulate the larynx and trachea in patients with airway distress. This means of establishing and maintaining an airway has certain limitations in long-term usage such as damage to the vocal cords, subglottis, and trachea. The use of a tracheostomy in the near term for patients who will require long-term ventilatory assistance will prevent such problems.

A tracheostomy can be the simplest or the most difficult operation that the surgeon may need to perform. Because the procedure is done frequently and may be considered rather simple, its performance may be delegated to entry level residents who, especially if they are unsupervised or do not have proper lighting, suction, and assistance—all prerequisites for a successful tracheostomy—may lose a patient or have complications that may be deadly or at least quite problematic. Therefore the tracheostomy should be given a lot of respect for the great benefits of its use and for the complexity of the indications and the proper surgical techniques.

Review Questions

1. A patient presents to the emergency department with airway obstruction. Fiberoptic examination reveals a massive supraglottic tumor, and the patient is assessed as impossible to intubate. During evaluation, his CO_2 rises over 100, and he becomes somnolent and is observed not to be moving air. Which option describes the most effective intervention?

   a. Take him to the OR when the next room becomes available, and perform a tracheostomy below the third tracheal ring.

   b. Call a team meeting with the family, palliative care, social work, and the hospital care manager to map out an appropriate treatment course.

c. **Do an immediate cricothyroidotomy and revise after the airway is stabilized.**

d. Make a vertical incision from chin to sternum, and try to find an airway somewhere.

2. A woman with a massive, rapidly enlarging thyroid tumor presents with stridor. Fiberoptic examination reveals normal vocal cords and an urgent computed tomography (CT) demonstrates marked tracheal compression. Which option is the safest treatment?

a. **Intubate her in the OR and then establish an airway by resecting the tumor if possible or performing a tracheostomy.**

b. Perform a tracheostomy at the bedside under local anesthesia.

c. Perform a percutaneous dilatational tracheostomy.

d. Place her on extracorporeal membrane oxygenation (ECMO) and arrange for transfer.

3. An obese patient on high-dose steroids for idiopathic thrombocytopenic purpura (ITP) undergoes a tracheostomy for respiratory failure following splenectomy. One week later she is off the ventilator, her tracheostomy tube is downsized, and the stay sutures are removed. An hour later, the code team responds to a Condition A and after a brief attempt to resuscitate her, she is pronounced dead. Which option describes the most likely cause of death?

a. **Dislodged tracheostomy tube in a false passage, forcibly ventilated with an Ambu bag with resultant pneumomediastinum and bilateral pneumothoraces**

b. Bleeding from her splenectomy bed

c. Pulmonary embolus

d. Hypoxia due to obesity

e. Diabetic coma

4. Open surgical tracheostomy, compared to percutaneous tracheostomy, is:

a. A much less morbid procedure

b. Associated with much less bleeding and infection

c. **The most appropriate choice in a patient with an unprotected airway**

d. The most appropriate choice in a patient with a history of previous tracheostomy

e. Associated with easier postoperative nursing care

Percutaneous Tracheostomy

Karen M. Kost

Introduction[1]

Endoscopic percutaneous dilatational tracheostomy (PDT) is a safe and simple bedside procedure that is particularly well suited to patients in the intensive care unit (ICU). Almost two-thirds of tracheostomies are performed in ICU patients. These critically ill patients, usually with multisystem disease are at high risk for complications. Moving these patients with their monitors and endotracheal tubes (ETTs) to the operating room (OR) for an open surgical tracheostomy (ST) carries several risks during transport. These risks include accidental extubation and vital sign changes requiring pharmacologic intervention.

Standard ST at the bedside in the ICU requires transporting instrument trays, adequate suction, extra lighting, and electrocautery from the OR. The procedure may be compromised by the lack of trained OR nurses and assistants. Risks include inadequate or difficult exposure and spontaneous ignition with the use of electrocautery in the presence of oxygen concentrations exceeding 30%.

Interest in a bedside percutaneous tracheostomy procedure led to the early development of several techniques, most of which were quickly abandoned. The development of a reliable bedside percutaneous dilatational technique in 1985 generated ongoing interest. The "blind" aspect of the procedure was later addressed by the addition of continuous endoscopic guidance. Endoscopic PDT requires no special lighting, no special equipment, and no electrocautery, and there is no need to move patients. My experience with more than 1500 of these procedures has demonstrated that, with bronchoscopic visualization and attention to technical detail, endoscopic PDT is a safe, cost-effective alternative to ST in the OR with comparable or lower complication rates.

1. Technique based on progressive dilatation of a tracheal puncture

2. Always performed with endoscopic guidance

3. Only performed in adult, intubated patients in the ICU

4. At least as safe as open ST

Key Operative Learning Points

1. Always performed with endoscopic guidance

2. Instruments should be held like a pen.

3. Forceful dilatation is never indicated and usually means that there is a problem.

4. Bleeding during the procedure is usually tamponaded by the tracheostomy tube.

Preoperative Period

History

1. What is the nature of the current illness?
   a. Why is the patient intubated?
   b. What organ systems are involved?
   c. Is there trauma to the neck?
   d. Is the cervical spine stable?
   e. Has the patient had a recent thoracotomy?
   f. What is the patient's physical status classification as per the American Society of Anesthesiology (ASA)?
   g. Is the patient currently on anticoagulants (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], antiplatelet agents, Coumadin)?
2. Is tracheostomy indicated?
   a. Expected intubation for greater than 10 days

b. Upper airway obstruction (e.g., trauma, neoplasms, subglottic stenosis)

c. Prolonged mechanical ventilation (e.g., stroke, central nervous system [CNS] disorders, respiratory failure)

d. Tracheobronchial toilet (e.g., chronic obstructive pulmonary disease, adult respiratory distress syndrome)

3. Past medical history

a. Previous tracheostomy

b. Previous surgery, radiotherapy, or trauma to the neck/cervical spine, all of which may make the procedure more difficult

c. Difficult or abnormal neck anatomy (e.g., kyphoscoliosis, cricoid cartilage at the sternal notch)

d. History of midline neck masses, high innominate artery, large thyroid gland, or goiter

e. Other comorbidities

f. Medications, in particular anticoagulants, and herbal products that affect coagulation

Physical Examination

1. Is the patient intubated?

2. Body habitus: Obesity with a body mass index (BMI) greater than 30 is more technically challenging and associated with a higher complication rate.

3. Neck extension: Are there limitations from anatomic abnormalities (e.g., kyphoscoliosis) or an unstable cervical spine? If so, an open ST should be performed in the OR.

4. Anatomic landmarks: The thyroid and cricoid cartilages as well as the sternal notch must be palpable.

5. Are the anatomic landmarks midline? If not, why?

6. A low-lying cricoid cartilage makes the procedure more technically challenging.

7. Are there any masses in the neck, neoplastic or otherwise, in the operative field? If so, an open ST should be performed in the OR.

8. A high innominate artery in or very close to the operative field is an indication for an open ST in the OR.

Imaging

1. A recent chest radiograph is useful in indicating a tracheal shift, lung abnormalities, or other anatomic aberrations that may affect the procedure.

Indications

1. Adult intubated patients in a monitored setting: ICU, coronary care unit (CCU), or postoperative recovery room

2. Percutaneous tracheostomy can be safely performed:

   a. In obese patients

   b. In patients with a prior history of tracheostomy, whether it was performed percutaneously or open

Absolute Contraindications

1. Inability to palpate the cricoid cartilage above the sternal notch

2. The presence of a midline mass in the neck (e.g., large thyroid) or goiter

3. A high innominate artery

4. Positive end-expiratory pressure requirement of greater than 15 cm H_2O

5. Children

6. Airway emergency, unsecured airway

Relative Contraindications

1. Inability to correct the International Normalized Ratio (INR) to ≤1.5

Many ICU patients are on anticoagulants and for medical reasons cannot have their anticoagulation completely corrected preoperatively. Others have liver failure with associated coagulation defects. Percutaneous tracheostomy is the preferred procedure in these situations because of the small incision, blunt dissection, and tamponade effect of the tube.

2. Inability to correct the platelet count to ≥50,000

Preoperative Preparation

1. Comorbidities should be optimized.

2. Preoperative testing is minimal and includes hemoglobin levels, INR, prothrombin time, partial thromboplastin time, and platelets. INR should be corrected to ≤1.5, and platelets should be corrected to ≥50,000 functioning platelets, whenever possible. Because blood loss tends to be minimal, a preoperative crossmatch is unnecessary, unless hemoglobin levels are extremely low (≤7). Similarly, preoperative transfusions are also unnecessary, even in the presence of low hemoglobin levels.

3. Required personnel: surgeon, endoscopist (resident, ICU physician), nurse to administer medications, and a respiratory therapist to regulate ventilator settings

4. Prepare the instruments on a Mayo stand in the order in which they are to be used.

5. Consider the type/size of the tracheostomy tube:

   a. For most patients a size 6 internal diameter (I.D.) tracheostomy tube with an inner cannula works well.

   b. A size 8 I.D. tube may be necessary in patients with copious secretions.

   c. In obese patients or those with a "deep" trachea, a proximally extended tube will prevent accidental decannulation.

Operative Period

Anesthesia

1. Intravenous sedation with or without muscle relaxants. Frequently used combinations include midazolam, fentanyl, and propofol.

2. Topical anesthesia: One or two milliliters of 2% to 4% lidocaine can be injected into the ETT or through the bronchoscope to suppress the cough reflex.

3. Local anesthesia: 1% or 2% lidocaine with 1:100,000 epinephrine is used to infiltrate the incision site to decrease cutaneous bleeding.

Positioning

1. Supine: The patient is positioned as for conventional tracheostomy with the neck extended.

Perioperative Antibiotic Prophylaxis

1. None: Within 24 to 48 hours, tracheostomy sites are colonized with a variety of organisms, including *Pseudomonas, Escherichia coli,* and gram-positive cocci. Tracheostomy tubes are frequently colonized by bacteria, such as *Staphylococcus epidermidis,* which are imbedded in a biofilm. Antibiotics do not prevent colonization and simply select out resistant organisms. Meticulous local hygiene and frequent tracheostomy tube changes control bacterial loads and provide the best defense against true infection.

Monitoring

1. Continuous monitoring of vital signs: particularly important in this very ill ICU patient population. Vital signs may be volatile and require pharmacologic intervention.

   a. Heart rate

   b. Blood pressure

   c. Oxygen saturation

d. Ventilator settings are set to deliver 100% oxygen.

Instruments and Equipment to Have Available

1. Percutaneous tracheostomy kit: Currently, there are several kits available based on the principle of dilatation of an initial tracheal puncture. The most thoroughly evaluated kit is the Ciaglia Blue Rhino Percutaneous Introducer Kit (Cook Critical Care Inc., Bloomington, Indiana). This kit includes:

a. Scalpel

b. Introducer needle

c. Curved J-wire

d. Introducer dilator

e. Guiding catheter

f. Loading dilators

g. Sharply tapered single dilator

2. Other instruments: scalpel (if not in the kit), curved hemostat or mosquito, straight scissors, needle driver, nonresorbable sutures, water-based lubricant, a small bowl of sterile saline to activate the hydrophilic tip of the single dilator, and three 10-mL syringes.

3. All instruments should be placed on a Mayo stand in the order in which they are to be used.

4. Appropriately sized tracheostomy tube with an inner cannula. An inner cannula facilitates care and hygiene and adds an element of safety. In the event of obstruction by secretions, the inner cannula can be removed and replaced.

5. A proximally extended tracheostomy tube should be planned for patients with an obese neck.

6. Bronchoscope: preferably with a tower and screen, allowing the surgeon to visualize the intratracheal portion of the procedure. A smaller diameter or pediatric bronchoscope should be used when the ETT is ≤7.5

I.D. to allow for adequate ventilation.

7. Crash cart nearby with necessary equipment for intubation

Key Anatomic Landmarks

1. Lower border of the cricoid cartilage

2. Suprasternal notch

3. Estimate of pretracheal soft tissue thickness, especially in obese patients

Prerequisite Skills

1. Surgical skills

2. Thorough knowledge of the procedure

3. Having attended a training workshop

4. Ability to use a bronchoscope

5. Ability to establish an emergency airway

6. Ability to manage complications, such as bleeding

Operative Risks

1. Accidental extubation

2. Volatile vital signs

3. Bleeding

4. Injury to posterior esophageal wall

5. Creation of a false passage

Surgical Technique

The Incision

- Prepare the instruments on a Mayo stand in the order they will be used (Fig. 20.1).

FIG. 20.1 Instruments are laid out on a Mayo stand in the order in which they are to be used. From left to right: (1) hemostat with sponge for prepping the skin, (2) syringe with local anesthesia, (3) scalpel, (4) curved hemostat, (5) syringe with introducer needle, (6) J-wire, (7) 14F introducer dilator, (8) guiding catheter positioned within single dilator, and (9) tracheostomy tube with loading dilator, inner cannula, and syringe attached to pilot balloon. Top left to right: (1) prep solution, (2) gauze, (3) silk suture, needle driver, and scissors, and (4) saline to activate the hydrophilic coating of the single dilator.

- Prefit the tracheostomy tube with the appropriate loading dilator.
- Prep and drape the surgical site as for a conventional tracheostomy.
- Plan the incision site one to two fingerbreadths below the cricoid cartilage.
- A skin incision is made, 1.5 to 2 cm, just long enough to accommodate the tracheostomy tube.
- Spread the subcutaneous tissue and strap muscles laterally with a curved mosquito clamp or a hemostat.
- The thyroid isthmus is not manipulated.

- Palpate the cricoid and the first and second tracheal rings.

Inserting the Bronchoscope

- The endoscopist (ICU physician, or resident, or anesthetist) prepares for insertion of the bronchoscope: The ETT is suctioned, 1 ml of 4% lidocaine is instilled into the ETT, and tapes holding the ETT are loosened.
- Insert the lubricated bronchoscope through the adapter and into the ETT, advancing until the tip of the bronchoscope lies flush with the ETT. The light will be seen through the incision as the bronchoscope is advanced.
- Hold the ETT securely during all manipulations to avoid accidental extubation.
- Partially deflate the ETT cuff.
- Slowly withdraw the ETT and bronchoscope as a unit until the incision is transilluminated/and or digital compression of the trachea is visualized.
- The remaining surgical steps are visualized by the endoscopist and surgeon on the screen with the endoscopic view.

Creating a Tracheal Aperture

- Place the 16-gauge introducer needle between the first and second or second and third tracheal rings. An intertracheal position is verified endoscopically.
- Advance the J-tipped guidewire through the needle until resistance is encountered (Fig. 20.2).
- Remove the needle, and thread the 14F introducer dilator over the J-wire into the trachea (Fig. 20.3).
- Dip the tip of the guiding catheter/single dilator assembly in saline.
- Remove the introducer dilator, and dilate the tracheal aperture by advancing the guiding catheter/single dilator assembly over the guidewire into the trachea until the 36F marking on the dilator is seen

endoscopically (Fig. 20.4).

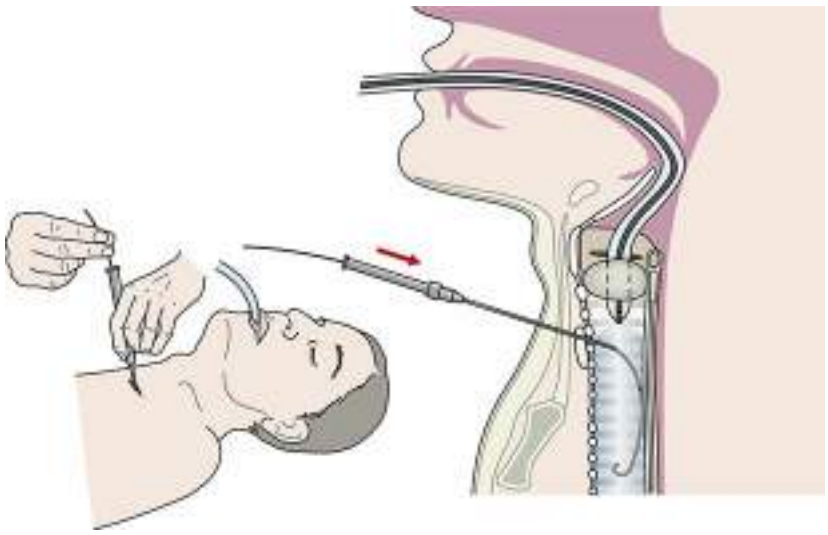

FIG. 20.2 The guidewire is advanced through the introducer needle.

- Overdilatation facilitates insertion of the tracheostomy tube.
- Expect some collapse of the anterior tracheal wall during this maneuver.
- In patients with calcification of the tracheal rings, fracture of a ring may occur. It is not a cause for concern.
- Remove the single dilator, leaving the guidewire and guiding catheter in place.

Inserting the Tracheostomy Tube

- Thread the tracheostomy tube with the loading dilator over the guidewire/guiding catheter and into the trachea (Fig. 20.5).
- Expect two points of resistance: the interface between the loading dilator and the tracheostomy tube and upon insertion of the balloon.
- Remove the dilator, guiding catheter, and guidewire, and position the inner cannula.
- Inflate the cuff and ventilate through the tracheostomy tube.

- Secure the tracheostomy tube with four corner sutures and tape ties.
- Remove the ETT only when adequate ventilation is ensured.

Common Errors in Technique

1. Failure to securely hold the ETT, resulting in accidental extubation

2. Puncturing the posterior wall of the trachea on insertion of the needle. Withdraw the needle into the lumen, and proceed.

3. If the puncture site is lost by accidentally removing the guidewire, restart the procedure.

4. Excessive force should never be used and is likely to lead to complications. Resistance to any step always indicates a problem. Stop and evaluate the situation, find the source of resistance, and resolve the problem. Possible causes include the following:

   a. The size of the incision and soft tissue "tunnel" should be verified. As a general rule, the surgeon's index finger should fit comfortably in the incision and soft tissue tunnel, without "pulling" on the skin when it is removed. Extending the incision and/or additional spreading in the soft tissue tunnel will correct the problem.

   b. If the needle is inserted through a tracheal ring rather than between rings, dilatation will be difficult. The needle should be repositioned between two rings.

   c. Resistance to dilatation occurs in some cases because of calcified rings. Repeated "short" dilatations with *gentle pressure* will lead to adequate dilatation.

5. The tracheostomy tube should never be forced. Repeat the dilatation, overdilate, and try again. This may be necessary when using tubes with a rounded distal edge because of the large step at the interface between the loading dilator and the tracheostomy tube.

6. Failure to place a proximally extended tracheostomy tube in an obese patient

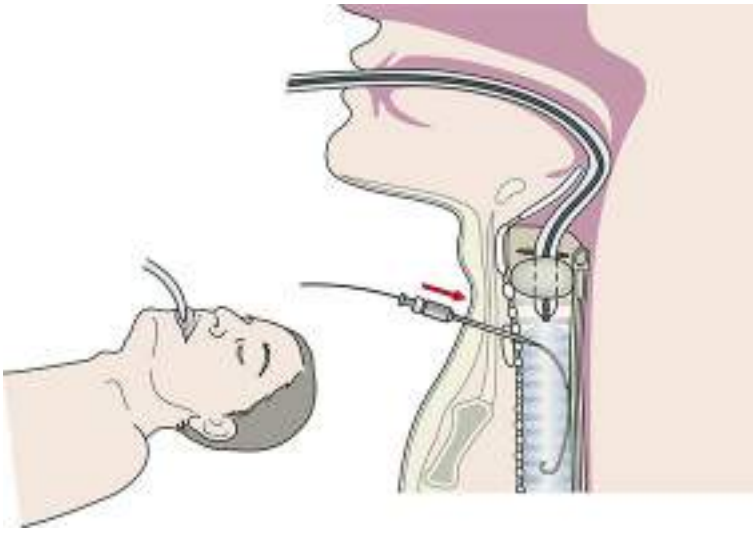

FIG. 20.3 The introducer needle is replaced by the 14F introducer dilator. This facilitates further dilatation of the trachea.

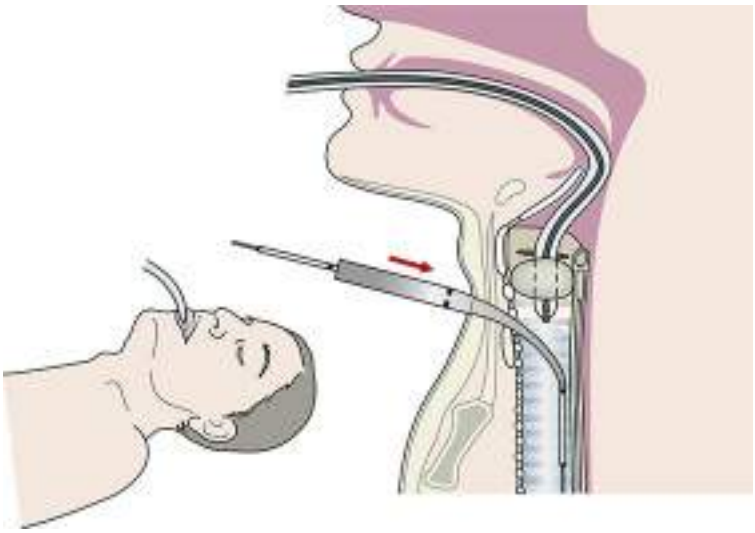

FIG. 20.4 The single dilator/guiding catheter unit is dipped in saline to activate the hydrophilic coating of the dilator. The dilator is held like a pen and introduced over the J-wire into the trachea. Overdilatation facilitates insertion of the tracheostomy tube.

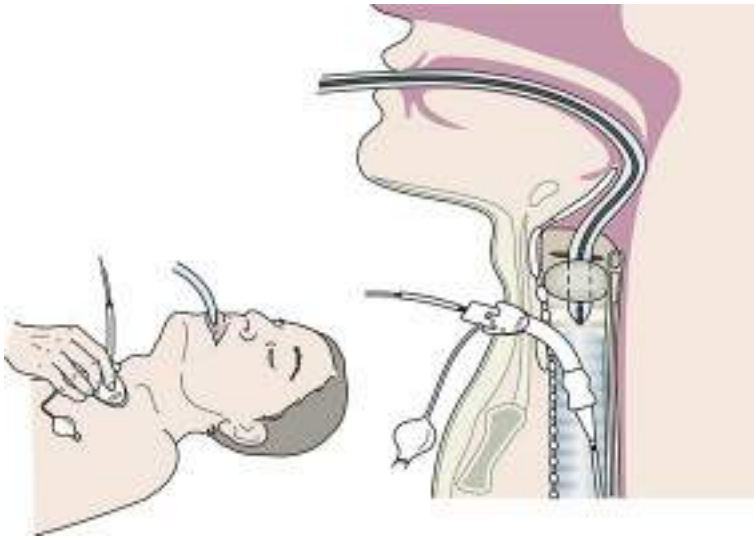

FIG. 20.5 The single dilator is removed, leaving the J-wire/guiding catheter in situ. The tracheostomy tube, prefitted with the loading dilator, is advanced over the J-wire/guiding catheter into the trachea.

Postoperative Period

Postoperative Management

1. In the minutes following the end of the procedure, be alert for changes in vital signs, such as hypotension and tachycardia, which may occur when the intense stimulation of the procedure is over. Pharmacologic correction may be required.

2. Suction the trachea free of any blood or secretions.

3. A postoperative chest radiograph is ordered to rule out pneumothorax and pneumomediastinum, although it is probably necessary only in more difficult cases or where the anatomy is unusual.

4. This technique is dilatational, resulting in a small tract with a tight-fitting tracheostomy tube. Traction sutures cannot be placed. In the event of accidental decannulation within the first 7 days, the patient should be reintubated orally. Attempting to re-insert the tracheostomy tube could result in bleeding, creation of a false passage, pneumomediastinum, subcutaneous emphysema, hypoxia, and even death.

5. Elevate the head of the bed to 30 degrees to facilitate coughing, deep breathing, and suctioning.

6. High humidity delivered via a collar is extremely important to:

   a. Facilitate mucociliary transport

   b. Prevent crusting, accumulation of secretions, and tube obstruction

7. Changes in vital signs later in the postoperative period may indicate a new respiratory problem, exacerbation of an existing problem, tube obstruction, or displacement.

8. Agitation, anxiety, and restlessness almost always indicate a problem and are frequently signs of hypoxia. Tube obstruction or displacement are frequent causes.

9. Tracheal suctioning must be performed as often as required to maintain:

   a. Pulmonary toilet

   b. Tube patency

10. Suctioning should be performed as follows:

   a. Aseptically

   b. For patients on mechanical ventilation, give at least five breaths of 100% oxygen before and after suctioning to prevent hypoxia and cardiac arrhythmias.

   c. Apply suction a maximum of 12 seconds at a time.

   d. Alternatively, a closed, multiple-use suction catheter within a sheath may be used.

11. Meticulous wound care is essential in preventing complications, such as:

   a. Skin breakdown

   b. Progression from bacterial colonization to infection

   c. Tube obstruction

12. Major principles of wound care include:

   a. Clean the wound as often as needed. Initially, this may be 3 to 4

times daily.

b. Use normal saline or peroxide.

c. Change the tracheostomy tube ties when wet or soiled.

d. Keep the skin under the neckplate clean and dry—use a dry, thin, nonadherent dressing.

13. The inner cannula should be cleaned or changed frequently to prevent accumulation of secretions.

14. Tracheostomy tube replacement within the first 7 to 10 days requires special precautions because of the tight tract. Guidelines include:

a. Optimal patient positioning

b. Assistance

c. Adequate light

d. Tracheal hook

e. Suction

f. Tracheostomy tube exchanger: essential because it has a central lumen through which ventilation is possible, and it fits within the tracheostomy tube, serving as a "guide," over which the tube may be changed

Complications

1. Potential intraoperative and postoperative complications are similar to those reported for open tracheostomy (see Chapter 19), except for fire, which does not occur with PDT, because no cautery is used. Notable differences are discussed next.

a. Desaturation: inconsistently reported for both PDT and ST. In PDT, it may occur briefly at the time of tracheostomy tube insertion, particularly in patients with compromised pulmonary function.

b. Bleeding: occurs less frequently than with ST and tends to be less severe with PDT because of the small tight tract and tamponade effect of the tube. Bleeding can almost always be controlled by local measures. Surgicel can be very useful for localized bleeding.

c. Infection: occurs less frequently than with ST because of the smaller surface area available for colonization

d. Accidental extubation: true incidence unknown because it is inconsistently reported for both ST and PDT. The risk can be reduced by loosening ETT ties only upon insertion of the bronchoscope and having only the physician (with help from the respiratory therapist, if needed) manipulate the ETT.

e. Injury to the posterior wall: usually limited to overzealous needle insertion and easily corrected by withdrawing the needle. Serious injury to the posterior wall should not occur with continuous endoscopic visualization and attention to technical detail. Proper positioning or layering of the guidewire, guiding catheter, and single dilator is very important in this regard.

f. Accidental decannulation: occurs infrequently because of the tight tract. Obese patients and those with a short, thick neck are at highest risk because the increased thickness of the pretracheal tissue effectively shortens the intratracheal portion of the tube. Anticipating this problem and using a proximally extended tracheostomy tube at the outset largely obviates the issue.

g. False passage, pneumothorax, and pneumomediastinum: These potentially fatal complications can be almost completely avoided by continuous endoscopic visualization from beginning to end.

Alternative Management Plan

1. Open ST should be used when:

   a. PDT is contraindicated.

   b. The surgeon does not have the necessary skills/training for PDT.

   c. The required instruments are not available.

   d. The required personnel are not available.

   e. The surgeon is uncomfortable because of the patient's anatomy (thick neck) or personal factors (inexperience).

Discussion

Evidence-Based Medicine Question

Is percutaneous tracheostomy as safe as open tracheostomy in the OR?

ICU patients account for almost two-thirds of currently performed tracheostomies. It is recognized that the risk of surgical complications is higher in this patient population because of multisystem disease and multiple comorbidities. The overall complication rate for endoscopic PDT is approximately 9%. This compares favorably with complication rates of 14% to 66% in ICU patients undergoing open ST in the OR and to complication rates of 4% to 41% in ICU patients undergoing open ST at the bedside.

There has been much debate in the literature over the need for continuous endoscopic guidance during PDT. Opponents argue that it lengthens the procedure and complicates adequate ventilation during the procedure. These suggestions are largely unsupported by evidence. However, there is a highly statistically significant relationship between the risk of complications and the use of bronchoscopic guidance. Indeed, the risk of serious complications, which includes pneumothorax, pneumomediastinum, and false passage, doubles when bronchoscopic guidance is not used. I have not had a single case of pneumothorax, pneumomediastinum, or false passage in more than 1500 PDTs.

Obese patients in the ICU with a BMI ≥30 are at higher risk for complications. This is true whether they undergo PDT or standard open tracheostomy. For those obese patients undergoing PDT, the most common complication is accidental decannulation due to the thickness of the subcutaneous tissues. Use of a proximally extended tracheostomy tube prevents this problem.

As with most other minimally invasive techniques, there is a learning curve with PDT, which is often evident in the first 30 to 40 cases. Reducing complications or mishaps associated with the learning curve is possible by obtaining adequate "hands-on" training, careful selection of patients with anatomically favorable necks, and attention to technical detail.

Comparative data indicate that endoscopic PDT is at least as safe as standard open tracheostomy. The overall incidence of bleeding and infection is likely lower in PDT because of the small tract, the tamponade

effect of the tube, and the smaller surface area for bacterial colonization.

Editorial Comment

Endoscopic PDT provides an attractive alternative to open ST in adult, intubated ICU patients. With appropriate training and attention to detail, it is a safe and simple procedure. PDT is significantly faster to perform compared with ST, and, from a training perspective, residents consider endoscopic PDT to be easier than open ST.

David Eibling

Review Questions

1. Percutaneous tracheotomy is absolutely contraindicated in which of the following situations?

   a. Unpalpable cricoid cartilage

   b. Airway emergency

   c. Children

   d. Nonintubated patient

   e. **All of the above**

2. Which of the following statements is true?

   a. Bleeding is a more frequent complication of percutaneous tracheotomy compared with open tracheotomy.

   b. **The use of bronchoscopy significantly decreases the risk of serious complications.**

   c. Obese ICU patients have fewer complications if they undergo an open ST.

   d. Accidental decannulation within the first 7 days following percutaneous tracheostomy should be treated by simply reinserting the tracheostomy tube.

   e. Perioperative antibiotics prevent wound infection.

3. Which of the following statements is false?

a. Postoperative high humidity is important to prevent tube obstruction.

b. Tracheostomy tubes with an inner cannula confer an element of safety.

c. **Sudden anxiety and agitation postoperatively indicate the need for an anxiolytic.**

d. 100% oxygen should be administered before suctioning mechanically ventilated patients.

e. Extended-length tracheostomy tubes should be used on obese patients to prevent accidental decannulation.

Operative Otolaryngology

Laryngotracheal Separation

David Eibling

Introduction

1. Airway protection is the most fundamental role of the mammalian larynx. (See Additional Sources for in-depth discussion.)

2. For some patients, laryngeal function is compromised by disease processes to the extent that its airway protection role becomes inadequate in preventing aspiration.

3. Chronic aspiration can be managed in most patients with alternative feeding, tracheostomy for pulmonary toilet, and oral care (Box 21.1).

4. Occasionally patients cannot be managed satisfactorily by conservative measures. A variety of surgical strategies can be used (see Box 21.1).

5. Among the surgical strategies, the most definitive, straightforward, and acceptable procedure is laryngotracheal separation (LTS) (Fig. 21.1).[1]

Key Operative Learning Points

1. Decision making regarding surgical intervention with LTS is more difficult than the procedure itself.

2. The anatomy of the tracheoesophageal party wall facilitates the safe performance of LTS in that a layer of loose areolar tissue separates the membranous posterior wall of the trachea from the esophagus.

3. The posterior wall of the trachea is a fibrous layer contiguous with the perichondrium of the tracheal rings and the inter-ring connective tissue

that permits circumferential dissection of the trachea.

4. Removing and weakening tracheal rings permits closure of the proximal stump of the trachea.

Preoperative Period

History

1. History of present illness
   a. Etiology of aspiration (See Falestiny in Additional Sources for more in-depth discussion.)

      Temporary or long-term?

      Treatable primary disease process?

      Local (laryngopharyngeal) or neuromuscular?

   b. Episodes of pneumonia?

      Minimal (mild pneumonitis) or severe

      Number of episodes?

      Courses of antibiotics? Colonized with resistant organisms?

   c. Prior or current tracheostomy?

   d. Feeding strategies?

   e. Weight loss/inanition?

2. Past medical history
   a. Onset and progression of primary illness

   b. Comorbidities

   c. Anticipated progression of primary illness and comorbidities

   d. Current admission status (hospital, long-term care, nursing home)

   e. Expected survival duration?

   f. Patient and family goals of care for remaining life

Physical Examination

1. General—degree of frailty, nutritional and cognitive status, communication skills, open wounds in head and neck region

2. Laryngopharyngeal endoscopic examination

Vocal cord mobility—is there any motion?

Glottic closure—Can the glottis close to protect the airway? Is there an alternative strategy based on enhancing closure?

Pooling of secretions. Often extent of secretions precludes examination

3. Oral cavity

Is the patient able to handle his or her secretions?

Tongue and palate mobility. Even if aspiration is controlled inability to move tongue or absence of the tongue may prevent swallowing.

4. Neck

Prior tracheostomy?

Position of tracheostomy?

Is there adequate trachea available above stoma for closure?

Imaging

Not required for this procedure

Indications

1. Morbid aspiration with recurrent episodes of pneumonia not adequately managed by conservative measures

2. No acceptable alternative

3. Patient and family desire the procedure

Patient, family, and other stakeholders need to recognize that most patients lose their ability to speak, if able to speak preoperatively, and less than ½ of patients who undergo LTS are able to swallow postoperatively. Some, but not all, patients are able to be discharged after aspiration has been controlled.

Contraindications

1. Absolute:
   a. Family and patient refuse the procedure
   b. Technically impossible due to very high tracheotomy—particularly if future reanastamosis is considered a possibility. Consider narrow-field laryngectomy as an alternative.
2. Relative:
   a. Duration of anticipated survival
   b. Aspiration managed successfully with conservative strategies
   c. High tracheotomy (will require removal of portion of cricoid ring to gain sufficient mucosa for closure)

BOX 21.1 Treatment of Morbid Aspiration

Nonsurgical Strategies

Nasoenteric tube feeding (or gastrostomy)

Nothing by mouth

Postural feeding technique

Swallowing therapy

Adjunctive Surgical Procedures

Cricopharyngeal myotomy

Gastrostomy/feeding jejunostomy

Tracheostomy

Vocal cord injection or thyroplasty for vocal cord medialization

Definitive Surgical Procedures

Glottic closure

Laryngotracheal separation
Laryngeal stenting
Narrow-field laryngectomy
Supraglottic closure
Tracheal flap closure
Tracheoesophageal diversion

FIG. 21.1 Laryngotracheal separation.

The proximal trachea is closed as a blind pouch. From Eibling DE, Bacon GW, Snyderman CH: Surgical management of chronic aspiration. *Adv Otolaryngol Head Neck Surg* 6:108, 1992.

Preoperative Preparation

1. Extensive discussion with patient (if able to understand), family, and other stakeholders. Assessment of goals, recognition of the futility of additional treatment and likely progression of primary disease, likelihood that the patient may not be able to swallow or be discharged

even if the procedure is performed successfully

2. Optimize medical status to ensure safe surgical performance and healing. In addition to assessing the current status of anticoagulation and cardiac systems, some assessment of healing ability is necessary, especially because most patients have suffered considerable weight loss with a drop in standard measures of nutritional status. Typically this is not feasible, and surgery must be performed in less than ideal circumstances.

3. Determine whether the patient is a candidate for general anesthesia.

Operative Period

Anesthesia

General: Although this procedure can be performed under local with awake sedation, general anesthesia is preferred for patient comfort, particularly when transecting the trachea, removing rings, and closing the proximal stump.

Positioning

Supine: The patient is positioned as for tracheotomy, with the neck extended over a shoulder roll. Anesthesiologist may remain at the head of the table to facilitate airway management.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin if not allergic to penicillin. Choice depends on the current status of the patient's bacterial load and virulence. Patients undergoing LTS are often in an intensive care unit and colonized with multiple resistant organisms, so antibiotic choices must be made accordingly.

Second-generation cephalosporin—may be required if cultures indicate necessity

Clindamycin is an ideal choice if allergic to penicillin.

Monitoring

None required except routine EKG, pulse-oximetry, and capnography

Instruments and Equipment to Have Available

1. Basic tracheostomy set

2. Woodson elevator

3. Extra endotracheal tube as well as cuffed tracheostomy tube

4. Sutures to close the proximal stump and create a permanent stoma (2-0 and 3-0 Vicryl or similar)

Key Anatomic Landmarks

1. Cricoid cartilage

2. Sternal notch

Prerequisite Skills

1. Ability to discuss "bad news" and options for palliation with patient and family

2. Standard tracheotomy skill set

Operative Risks

1. Intraoperative fire—similar to any tracheostomy (see Chapter 19). If fuel (tracheostomy or endotracheal tube) and ignition source (electrocautery) are adjacent in the presence of high levels of oxygen, fire is a distinct possibility.

2. Inability to close the proximal stump due to short remaining trachea. In these situations the anterior arch of the cricoid can be removed to free sufficient mucosa for closure. If the mucosa is still insufficient,

consideration must be given to performing a narrow-field laryngectomy.

Surgical Technique

- If a tracheotomy has previously been performed, the incision is widened laterally, and the previous tracheotomy scar and granulation tissue are excised from the skin down to the level of the trachea.
- Patients who have not undergone tracheotomy previously are approached as they would be for a routine tracheotomy—via a horizontal incision with dissection through subcutaneous tissue and splitting of the strap muscles to expose the trachea.
- Division of the thyroid isthmus (if not performed previously) is necessary to gain adequate exposure for closure of the proximal stump of the trachea.
- The location for the separation is identified at the site of the previous tracheotomy or at the interspace of the third or fourth tracheal ring.
  - In older patients with an increased anteroposterior dimension of the chest, the larynx may be located more inferiorly and be resistant to retraction superiorly. In these patients the trachea may need to be divided more superiorly, at the second interspace.
  - The higher levels of tracheal division may make the procedure easier; however, the short stump dramatically increases the difficulty of reanastomosis if attempted later.
  - In most patients who have previously undergone tracheotomy, the proximal trachea will usually consist of only one or two rings above the level of the stoma.
- Dissection is carried laterally around the trachea at the site of the stoma.
- The trachea is opened if the patient does not have an indwelling tracheostomy.
- An endotracheal tube is passed into the distal trachea for ventilation throughout the remainder of the procedure.
- The trachea is then transected, with care taken to maintain the dissection next to the wall of the trachea to avoid injury to the

recurrent laryngeal nerves.

- The posterior wall is then transected, exposing the loose areolar tissue within the party wall, with care taken to not enter the esophagus. This is usually performed by continuing the tracheal incisions through the lateral walls bilaterally and across the posterior wall until they meet. Care should be taken to maintain this line of transection in a straight transverse plane to avoid tapering superiorly such that closure of the proximal stump becomes problematic.

- After the trachea has been divided, it is dissected free with blunt dissection in both a superior and an inferior direction.
  - Care should be taken to avoid extending the dissection too far into the soft tissues laterally to prevent injury to the recurrent laryngeal nerve.

- An incision is made in the tracheal perichondrium to expose the inferior-most ring(s) in the superior stump.
  - The ring is then dissected free using a small periosteal elevator. Care should be taken to avoid injury to the underlying perichondrium and mucosa. Removing this ring frees the internal mucoperichondrium and permits closure of the mucosa (Fig. 21.2).

- Collapse of the superior stump is facilitated by dividing the ring(s) superiorly to allow the ring to collapse on itself and reduce tension on the mucosal closure Fig. 21. 3).
  - In cases of a prior high tracheotomy with insufficient remaining trachea, the anterior arch of the cricoid itself may be resected. Unfortunately this effectively eliminates the possibility of future reanastomosis.

- The mucosa is then closed with a running inverting suture similar to a pharyngeal closure in a laryngectomy.

- The mucosal closure is reinforced by additional interrupted sutures placed through the remaining but divided tracheal ring. This effectively reinforces the closure and helps to prevent postoperative leaks (Fig. 21.4).

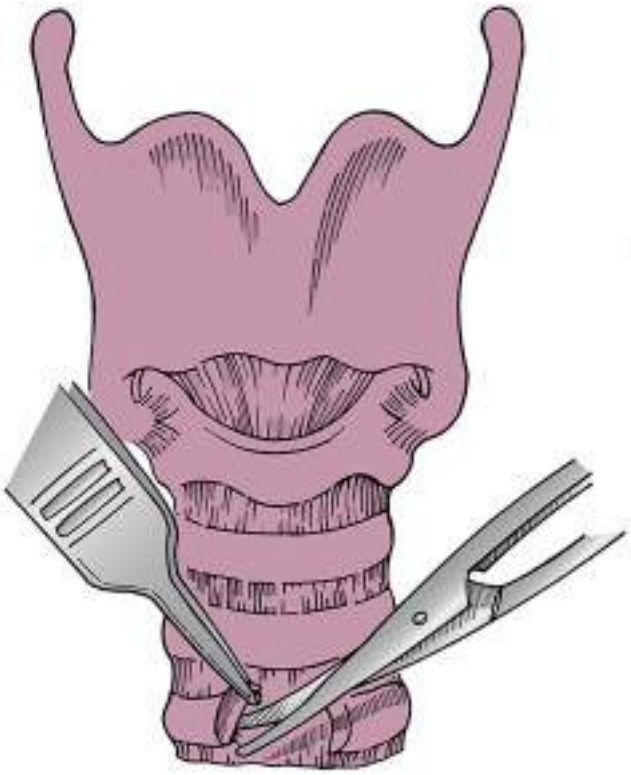

FIG. 21.2 After the trachea is divided, a ring is removed by dissecting the cartilage away from the mucosa. This provides mucosa for closure.

- Some surgeons routinely reinforce the closure with a flap of strap muscle sewn below the proximal tracheal closure. Unfortunately, this maneuver does not always prevent a fistula. An adequate inverting mucosal closure performed without tension appears to be the most critical step in this part of the procedure.
- The distal trachea is then brought to the skin, and a stoma is formed in a manner identical to that for a laryngectomy stoma. Half-mattress sutures are used to advance skin from the lateral to the medial aspect as would be done in a total laryngectomy (Fig. 21.5).
- A small Penrose drain is brought out from one corner of the wound, and any remaining skin lateral to the tracheostoma is then closed.
- A cuffed tracheostomy tube is inserted to help prevent aspiration of any wound drainage that seeps from the skin edges.

Common Errors in Technique

- Selecting the procedure for an aspirating patient unlikely to benefit is the most common error of novice surgeons.
- Attempting to close a stump that is too short dooms the procedure to failure. This is best rectified by removing the anterior arch of the cricoid or converting to a narrow field laryngectomy.
- Tearing the tracheal mucosa makes it impossible to close the mucosa in an inverted manner.
- Failure to collapse the superior ring will place excessive tension on the stump mucosal closure.
- Failure to drain the space below the stump will lead to a collection of fluid and inevitable wound infection.

Postoperative Period

Postoperative Management

- Expect some leakage from the drain.
- Continue perioperative antibiotics for 24 hours.

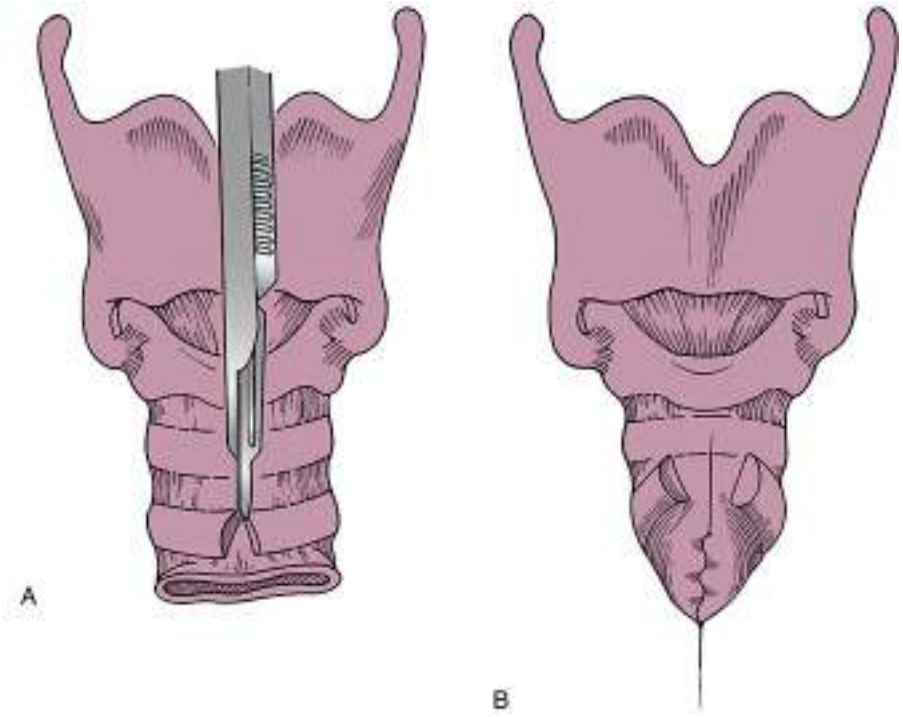

FIG. 21.3 Stump closure. **A**, The next ring above is then divided. **B**, The mucosa is closed in a watertight fashion with inverting continuous suture.

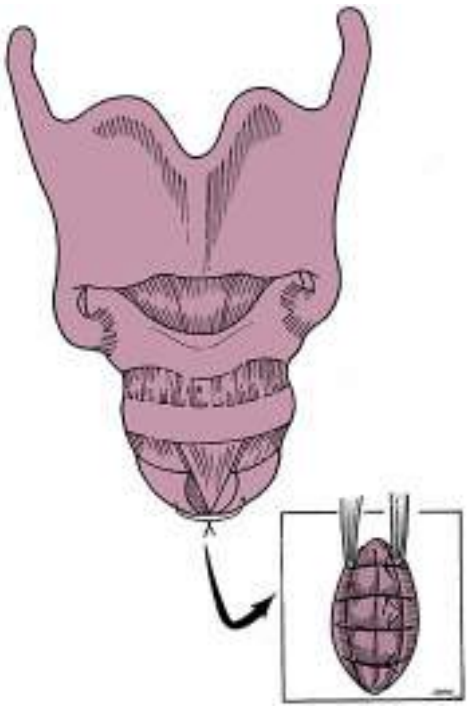

FIG. 21.4 The divided ring is then collapsed with a clamp, and an additional layer of reinforcing sutures is placed to

reinforce the closure.

- Leave tube in place until the risk of fistula formation has passed and peristomal edema has resolved.
- Instruct the patient and the family in stomal care.
- Wait several days before initiating swallowing trials.

FIG. 21.5 Stoma created similar to that of a laryngectomy. Note the Penrose drain left in place for 24 hours to avoid subcutaneous collection of fluid.

Complications

1. Wound infection—associated with collection of fluid adjacent to the stump. Risk can be minimized by drainage of secretions.

2. Fistula: A temporary fistula can be expected to occur in approximately 1⁄3 of patients.[1] Usually does not impact pulmonary status and usually will resolve spontaneously in several weeks if nutrition is adequate

Alternative Management Plan

1. Tracheostomy and gastrostomy. This is the most common strategy for the aspirating patient. It is preferred over LTS for patients in whom the process is expected to resolve in several weeks to months. However, the

requirement for frequent tracheal suctioning, even with an inflated tracheostomy tube cuff, mandates that the patient stay in a special care unit.

2. Laryngeal stenting. In conjunction with tracheostomy and gastrostomy a laryngeal stent can dramatically reduce aspiration and reduce the requirement for intensive nursing care. Unfortunately, stenting is only effective for several weeks to months.

3. Laryngeal closure. Several procedures have been described; none are as simply performed or as reliable as LTS.

4. Laryngotracheal diversion. The first procedure reported by Lindeman, it is now seldom used because retention of food in the closed proximal pouch has been shown not to result in infection or other difficulties.

5. Narrow-field laryngectomy. An effective solution, although technically more demanding than LTS. May also be more prone to wound complications in the setting of poor nutritional status. Also more likely to be rejected by patients and family due to the finality of the procedure, even though reanastamosis is exceptionally uncommon

Discussion

Evidence-Based Medicine Question

Does LTS achieve its intended goal of preventing pneumonia?

- Control of aspiration. Numerous surgeons have reported their experience with LTS, with uniform control of aspiration.[1-5] The largest series, 56 patients over an 18-year period, was that of Cook published as a Triological Thesis in 2009.[5] All of the patients in all of the series had either elimination or dramatic reduction in episodes of aspiration pneumonia and, for those who monitored tracheostomy care, reductions in the need for suctioning.
- Intensity of nursing care. In a series of 11 children with severe neurologic disorders undergoing LTS reported by Takamizawa et al., the frequency of performing suction fell from an average of once every 30 minutes to once every 4.5 hours.[4]

- Health care costs. Cook reported substantial reductions in cost of care following the procedure due to reduced admissions for aspiration pneumonia.[5]
- Loss of voicing. Although the procedure entails giving up voice, the majority of patients with advanced neuromuscular disease leading to intractable aspiration are unaffected due to the fact they did not have usable speech preoperatively due to their primary disease process. A few surgeons (see list of Additional Sources) have reported successful speech rehabilitation in selected patients using tracheoesophageal puncture following LTS.

Editorial Comment

Laryngotracheal separation is the most satisfactory way of definitively managing intractable aspiration with recurrent episodes of pneumonia. Most patients with intractable aspiration will have already had a tracheostomy and conservative measures, such as dietary modification and postural changes, without relief.

An astonishing statistic was pointed out by Broniatowski et al.[6] that approximately 500,000 patients per year in the United States are affected by stroke-related dysphagia. Approximately 50% of these patients experience pneumonia and death. However, stroke patients are not the only ones who benefit from LTS. Patients with central nervous system disease and advanced cancer of the tongue or larynx are another potential group of candidates for this procedure. In these patients there is usually no chance that the underlying cause of the aspiration will improve.

There is another group of patients in which the aspiration may be temporary, such as those patients with multiple sclerosis. I have personally used this as a lifesaving procedure in several such patients and have been able, when their aspiration dissipated as they went into remission, to take down the laryngotracheal separation and reestablish normal voice and swallowing.

In patients who have not had radiation therapy to the inferior aspect of the neck, voice can be reestablished using the tracheoesophageal puncture technique. In those who have had radiation therapy, the risk of

poor healing following the puncture makes this additional procedure too risky.

I performed a total glossectomy and bilateral modified neck dissection in a relatively young healthy man who had been a heavy smoker and had been exposed to Agent Orange during service in the Vietnam War. Although he was, in my judgment, a good candidate for this procedure, he immediately experienced severe aspiration that was not controlled with conservative measures and the tracheostomy that I had carried out during the surgical procedure. The patient had pneumonia that could not be controlled by antibiotics because the tracheobronchial tree was constantly soiled by the aspiration. After serious discussion with the patient and his family, I carried out a laryngotracheal separation using the technique described in our department by Snyderman and Johnson[3] (see section on "Surgical Technique"). Although the aspiration was completely controlled, he did not regain his ability to swallow. A gastrostomy was performed to restore a means of delivering nourishment. The patient had more than 40 cervical lymph nodes positive for metastatic cancer, many with extracapsular spread, so he was treated with chemoradiation. Unfortunately the radiation to the lower neck was a contraindication for tracheoesophageal puncture and insertion of a speaking valve. The patient is now 20 years postoperative without evidence of recurrent cancer despite his heavy tumor burden and has supported his family, including five children, working as a landscaper.

Eugene N. Myers

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Which of the following is the most critical point in the performance of LTS?

   a. Patient indications for procedure

   b. **Patient and family goals and expectations**

   c. Health care costs

   d. Presence of a prior tracheotomy

e. Comorbidities

2. Performance of LTS results in:

   a. Restoration of swallowing function in nearly all patients

   b. Elimination of voicing for all patients

   c. **Dramatic reduction in number of episodes of pneumonia**

   d. Minimal change in care requirements

3. A temporary pouch fistula following LTS

   a. **Is not uncommon and will usually resolve**

   b. Is rare and indicates poor technique

   c. Should not be discussed with patient and family preoperatively

Tracheal Resection

Neil A. Christie

Introduction

Tracheal resection may be undertaken for tracheal strictures and tracheal tumors. Most commonly the trachea is exposed through a cervical incision, but for distal tracheal or carinal access either a sternotomy or a right thoracotomy may be required. Up to half the trachea may be resected with construction of a primary tracheal anastomosis. For the extensive resections, release techniques will be required. Preoperative planning is important to precisely define the tracheal lesion and always includes imaging and bronchoscopy.

Key Operative Points

1. Preoperatively one must accurately assess the length and location of the lesion that is being resected.

2. The tracheal resection must include all of the diseased airway so that the anastomosis can be done with healthy trachea.

3. Neck flexion and release procedures should be done as required in order to minimize tension on the anastomosis.

4. Circumferential mobilization of the airway should be minimized to maintain the circulation of the trachea.

5. The recurrent laryngeal nerves are located in the trachea-esophageal groove and should be preserved to prevent vocal cord palsy.

Perioperative Period

History

1. History of diabetes, previous external beam radiation, or steroid use, which can impair the healing of the trachea

2. Previous tracheostomy or oral tracheal intubation and, if so, the duration of intubation

3. History of Wegener disease or sarcoidosis, which can lead to tracheal stenosis

4. A history of cigarette smoking

5. Dyspnea and, if so, the duration and severity

6. Cough

Physical Examination

1. Overall body habitus

2. Examination of the neck, including length, ability to extend the neck, and presence of kyphosis

3. Cervical lymph adenopathy

4. Audible stridor or wheezing

Imaging

Imaging is important to fully define the nature of the tracheal lesion for preoperative planning of the operation, with regard to location of the incision and the need for any tracheal release procedures.

1. Chest and neck radiograph may show evidence of airway obstruction in the proximal trachea and would also detect gross mediastinal adenopathy or lesions in the lungs.

2. Computed tomography (CT) scan is the most informative imaging study.

   a. It provides information regarding both the intraluminal and extraluminal extent of tracheal lesions.

b. Evaluation of spread of tracheal cancers to the regional lymph nodes or the pulmonary parenchyma

c. Allow for assessment of any other underlying pathology in the lung parenchyma.

Indications

1. Airway intubation injury is the most common cause of tracheal strictures. It can occur from placement of oral endotracheal tubes or from previous tracheostomy. Most intubation injuries are relatively proximal and short and best managed with tracheal resection.[1]

a. Strictures that occur after tracheostomy may be located either at the site of the tracheal stoma or at the site of the cuff on the tracheostomy tube.

b. Stenosis resulting from oral tracheal intubation usually follows a period of prolonged intubation for ventilator support. The level of injury can be the glottis, the subglottic segment, or the trachea.

2. Idiopathic tracheal stenosis is a circumferential fibrotic lesion that involves the subglottic area as well as the proximal trachea.[2]

3. Tracheal tumors may be benign or malignant. In children, the majority of tumors are benign, whereas in adults, most are malignant.[3]

a. The most common benign tumors are carcinoid tumors and chondromas.

b. The most common malignant tumors are squamous cell carcinoma and adenoid cystic carcinoma. Many malignant tracheal tumors are either locally advanced at presentation or have metastasized and as such are not treated with tracheal resection.

Contraindications

1. The maximum length of trachea that can be resected with a primary anastomosis is 5 to 6 cm or roughly half the length of the trachea. Unless the surgeon is planning on a prosthetic tracheal replacement, longer lesions are not amenable to tracheal resection.

2. Tracheal resection is generally not indicated in patients whose tracheal tumors have metastasized, although occasionally adenoid cystic metastases can progress extremely slowly and resection of an obstructing primary tracheal tumor may be appropriate.

3. Patients need to be physiologically fit for surgery, although most patients can tolerate a transcervical operation well.

4. Relative contraindications include:

   a. Diabetes

   b. Previous high-dose radiation to the trachea

   c. Current high-dose steroid use

   d. Active ongoing inflammation in the tracheal stricture

Preoperative Preparation

1. An acutely inflamed tracheal stricture should not be operated on; the surgeon should wait until the inflammatory phase has resolved with treatment and the stricture has matured.

2. Wean off of high-dose steroids prior to surgery.

3. Pulmonary function tests can give an objective measure of the degree of airflow obstruction. Flow volume loops will demonstrate the degree of airflow obstruction during both the inspiratory and expiratory phase of respiration. Typically intrathoracic lesions cause obstruction of airflow during expiration, whereas lesions that are more proximal (or extrathoracic) will cause airflow obstruction during inspiration. With severe advanced, both inspiratory and expiratory airflow obstruction may be present.

4. Bronchoscopy is used to accurately characterize the tracheal lesion prior to resection. That includes biopsy for histologic diagnosis of tracheal tumors. It also allows the surgeon to measure the longitudinal extent of tracheal lesions, document their precise location relative to the vocal cords and the carina, and evaluate the degree of obstruction of the airway. All of these factors are very important in establishing a patient treatment plan. In patients with severe airway obstruction and respiratory distress, endobronchial therapy via the bronchoscope can be

used to relieve the obstruction and stabilize the patient until such time as definitive resection can be undertaken. That could include laser débridement or mechanical débridement of an endobronchial tumor or dilation of a benign stricture. Bronchoscopy is also useful to document vocal cord function prior to surgery.

Operative Period

Anesthesia

Anesthetic management for tracheal resection is complex and requires close cooperation and communication between the surgeon and the anesthesiologist. The surgeon should always be present at the time of induction of anesthesia.

A rigid bronchoscope may be required to initially secure the airway, and dilation of a narrowed trachea may be required in order for an oral endotracheal tube to be passed at the beginning of the procedure.

Once the trachea has been exposed and the lesion identified, the trachea is divided distal to the lesion, and the distal trachea thus exposed is intubated with a cuffed endotracheal tube, which is then connected to a sterile ventilatory circuit that has been passed onto the operative field.

Performance of the tracheal anastomosis may require intermittent interruption of ventilation with removal of the endotracheal tube. Alternatively, jet ventilation may be used, which does not require a closed circuit and will not interrupt the conduct of the anastomosis in order to remove and replace the endotracheal tube.

Ideally at the end of the procedure the patient will no longer require positive pressure ventilation and be breathing spontaneously so that they can be extubated in the operating room.

Positioning

The patient is placed in the supine position. An inflatable bag is placed under the upper back, which is inflated to provide extension of the neck and then deflated during the operation to facilitate neck flexion for the conduct of the anastomosis.

For carinal resections, where one chooses to approach the operation transthoracically, the patient will be positioned in the left lateral position for a right fourth interspace thoracotomy.

Perioperative Antibiotics

One or two grams of Ancef are given intravenously preoperatively, and two doses are given postoperatively. Alternatively, 600 mg of clindamycin can be substituted in the patient who is allergic to penicillin.

Monitoring

1. Continuous electrocardiogram

2. Oxygen saturation monitor

3. Bispectral index (BIS) monitor for depth of anesthesia

4. Intraoperative monitoring of the recurrent laryngeal nerve

5. Blood pressure monitoring with an arm cuff should be adequate (unless the patient requires a thoracotomy).

Instruments and Equipment to Have Available

1. Rigid bronchoscopes of various sizes

2. Gum-tipped tracheal dilators for rigid bronchoscope

3. High Frequency (JET) ventilator and catheters for High Frequency (JET) ventilation

4. Nerve conduction monitoring apparatus and special endotracheal tube for nerve conduction monitoring of the recurrent laryngeal nerves

5. Sterile ventilatory circuit for cross table ventilation of distal trachea in the operative field

6. Several sizes of endotracheal tubes on the sterile field

7. Bipolar cautery

8. Inflatable bag for positioning behind the patient's back to facilitate neck extension and flexion during the procedure

Key Anatomic Landmarks

1. Cricoid cartilage

2. Anatomic location of the recurrent laryngeal nerves (Fig. 22.1)

Prerequisite skills

1. One must be facile with rigid (and flexible) bronchoscopy and oral tracheal intubation.

2. Familiarity with the setup and function of the High Frequency (JET) ventilator

Operative Risks

1. Failure to secure the airway at the time of anesthetic induction in a patient with significant tracheal obstruction due to tumor or stricture

2. Failure to accurately localize the upper and lower extent of the tracheal lesion on external examination of the trachea at the time of tracheal resection

3. Damaging one or both recurrent laryngeal nerves with attendant vocal cord palsy

4. Failure to protect the innominate artery from a tracheal anastomosis

5. Producing a tracheal anastomosis that is under tension by not using tracheal mobilization procedures or by resecting too much trachea

6. Excessive circumferential mobilization of the trachea, resulting in devascularization of the trachea and ischemic breakdown of the anastomosis (Fig. 22.1)

7. Damage to the esophagus during dissection of the posterior tracheal wall

8. Inadequate ventilation of the patient during the conduct of the

procedure, with secondary hypoxemia and/or hypercarbia

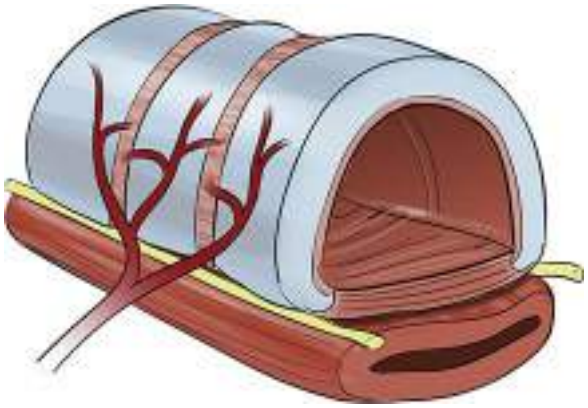

FIG. 22.1 Segmental arterial blood supply of trachea coming in laterally. Course of recurrent laryngeal nerves in tracheoesophageal groove.

FIG. 22.2 Location of collar incision on the neck for proximal and mid-tracheal resections.

Surgical Procedure

Tracheal Resection and Tracheal

Anastomosis

1. A cervical collar incision is made transversely, in a natural skin fold approximately 2 cm above the suprasternal notch (Fig. 22.2, Fig. 22.3). This incision should allow for exposure of the upper two-thirds of the trachea. The incision can be extended inferiorly into a partial or a complete sternotomy as required. Alternatively, lesions in the distal third of the trachea may be approached via a right posterolateral thoracotomy through the fourth interspace.

2. Wide sterile prep of the patient from above the chin to the upper abdomen to allow for laryngeal release procedures above or extension, if necessary, to median sternotomy below

3. The dissection is taken down through the platysma muscle, and then subplatysmal skin flaps are raised to the level of the inferior aspect of the thyroid cartilage superiorly and the suprasternal notch inferiorly.

4. The thyroid isthmus is divided if necessary, to expose the underlying trachea.

5. If the lesion is not obvious on external examination of the trachea, the location may be determined based on bronchoscope measurements of the distance of the lesion from certain anatomic landmarks such as the thyroid cartilage or the cricoid cartilage. Alternatively, a needle may be placed through the trachea externally and viewed internally with intraoperative bronchoscopy to determine the appropriate level for tracheal transection.

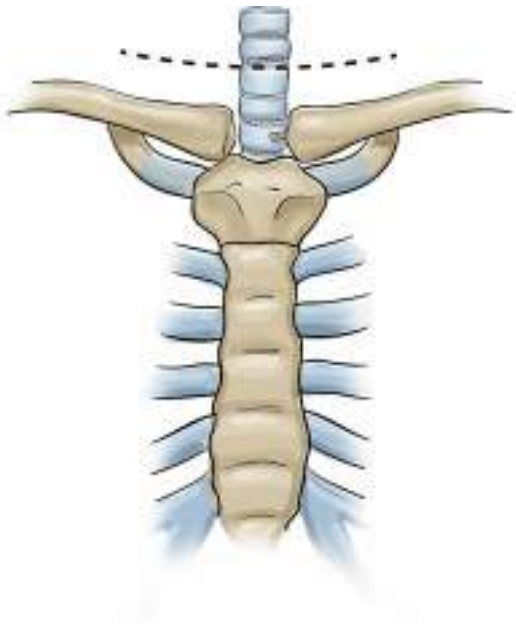

FIG. 22.3 Relationship of cervical incision to clavicles and sternum.

6. When resecting a tracheal stricture, the circumferential dissection of the trachea should be close to the trachea to avoid damage to the recurrent laryngeal nerves that run in the tracheoesophageal grooves. In the case of neoplastic lesions, the recurrent laryngeal nerves should be identified both above and below the tumor. They can then be safely mobilized off of the tumor or even resected if that is what is required for complete resection of the tumor. Intraoperative nerve conduction monitoring is also helpful in preserving the recurrent nerves (Fig. 22.1).

7. Excessive circumferential mobilization greater than 1 cm above and below the tracheal lesion should be avoided, as it will lead to devascularization of the trachea at the level of the tracheal anastomosis, with subsequent poor healing.

8. The initial division of the trachea is distal to the lesion (Fig. 22.4). The initial incision should be carefully placed to avoid resecting normal trachea. If abnormal tissue has been cut through, additional trachea should be resected until such time as there is normal tracheal tissue at the margin of resection. It is important to obtain histologic confirmation of negative margins with intraoperative frozen sections in cases of tracheal tumors.

9. Traction sutures should be placed in the distal trachea laterally at the

junction between the cartilaginous and membranous portion of the trachea, as well as anteriorly. These sutures facilitate stabilization of the distal trachea for placement and replacement of the endotracheal tube, as well as for exposure of the airway for performance of the airway anastomosis.

10. Once the trachea has been divided distal to the lesion, the peroral endotracheal tube is pulled back proximally and a second sterile armored cuffed endotracheal tube is passed across the sterile field into the distal segment of the trachea for cross table ventilation (Fig. 22.4).

11. The trachea is then divided proximal to the lesion, and the specimen is removed. Traction sutures are then placed in the upper end of the transected trachea.

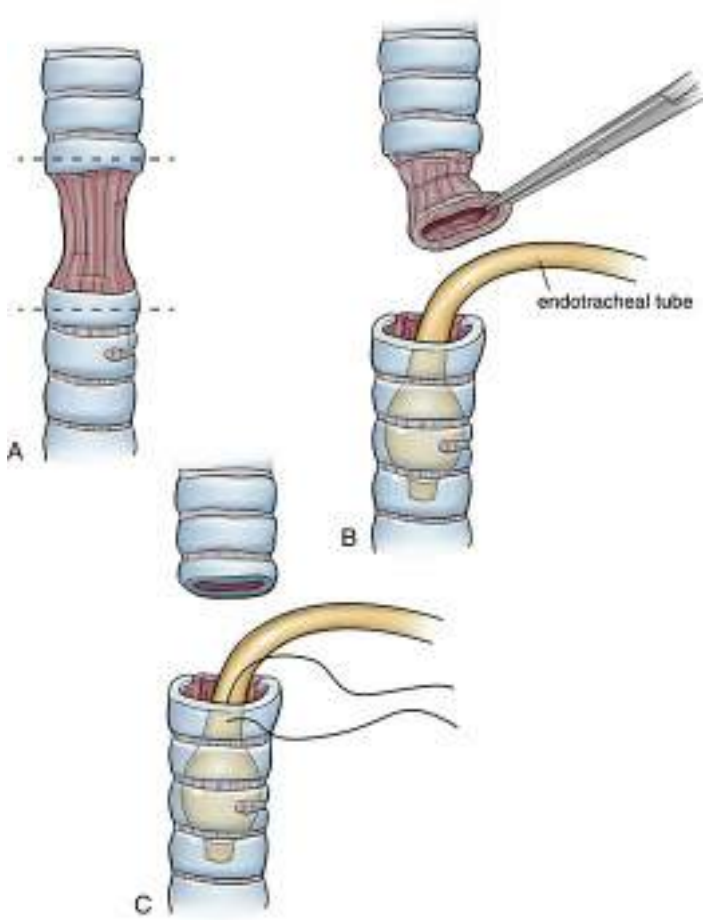

FIG. 22.4 **A,** Sites of division of trachea above and below the stricture to ensure complete resection of all abnormal tissue. **B,** Intubation of distal tracheal segment for cross

table ventilation after initial division of the tracheal. **C,** Complete excision of all the tissue from the stricture in the trachea.

12. Prior to beginning the anastomosis, the patient's neck should be flexed, by deflating the inflatable bag beneath the patient's shoulder blades.

13. The anastomosis is started with the membranous trachea (Fig. 22.5). The cartilaginous traction sutures are used to approximate the cut ends of the trachea and keep tension off of the suture line. The endotracheal tube in the distal trachea is removed as necessary to visualize the membranous trachea for placement of the sutures. Alternatively, High Frequency (JET) ventilation can be used to allow for continuous visualization of the membranous trachea during performance of the membranous tracheal anastomosis. The membranous trachea is sutured with running 3-0 maxon or polydioxanone (PDS) suture (Fig. 22.5).

14. Once the membranous tracheal anastomosis is complete, the endotracheal tube is removed and the peroral tube is advanced distally across the anastomosis, and ventilation is now continued with the oral endotracheal tube.

15. The anterior tracheal anastomosis is completed with interrupted sutures, with the knots tied on the outside of the trachea. Interrupted 3-0 Vicryl suture is used to perform the anterior tracheal anastomosis.

16. When the tracheal anastomosis is completed, the cuff to the endotracheal tube is deflated and the lungs hyperinflated. One can thus check for air leak by placing the airway under saline. If necessary the oropharynx may be temporarily packed with saline-soaked gauze while ventilating the lung with the cuff deflated.

17. If the innominate artery is in apposition to the tracheal anastomosis, a strap muscle should be interposed between them.

18. After placing a drain adjacent to the trachea, the thyroid and strap muscles are reapproximated in the midline.

19. At the conclusion of the operation, a heavy silk suture is placed from the skin of the chin to the skin of the anterior chest to encourage the patient to keep the neck flexed during the immediate postoperative

period (Fig. 22.6).

Median Sternotomy and Transpericardial Approach to Distal Trachea

In order to reach the distal third of the trachea or the carina anteriorly, this approach may be taken.

1. Full median sternotomy is performed.

2. An anterior division of the pericardium from the innominate artery above down to the right main pulmonary artery inferiorly

3. The ascending aorta and the superior vena cava are then mobilized and reflected laterally (superior vena cava to the right and aorta to the left).

4. The posterior pericardium is then divided, thus exposing the distal trachea and carina.

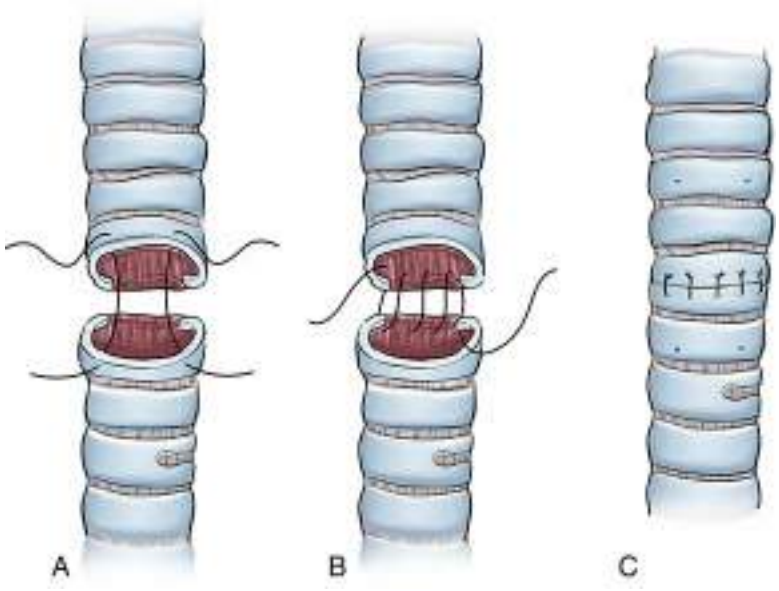

FIG. 22.5 **A,** Lateral stay sutures for positioning of trachea for airway anastomosis. **B,** Running posterior membranous tracheal anastomosis. **C,** Interrupted anterior cartilaginous tracheal anastomosis.

FIG. 22.6 Suture chin to presternal area to keep neck in flexion in order to keep tension off the tracheal anastomosis postoperatively.

Procedures Used to Lessen Tension on the Tracheal Anastomosis

If an extended tracheal resection (up to half the length of the trachea) is anticipated, or if at the time of the conduct of the tracheal anastomosis, the proximal and distal ends cannot be re-approximated, there are several options to try to relieve the tension:

1. Flexion of the neck

2. Blunt dissection anterior to the trachea as far as to the carina. This is the same plane that is routinely dissected bluntly during the performance of a mediastinoscopy.

3. Intrapericardial hilar release

4. Laryngeal release procedures. These can allow for an additional 2 or 3 cm of tracheal mobilization by allowing the larynx to descend inferiorly. It is associated with some degree of postoperative swallowing difficulty, which is usually transient.

   a. Suprathyroid laryngeal release. Requires division of the soft tissue attachments between the inferior border of the hyoid bone above

and the superior border of the thyroid cartilage below

1) The upper skin flap of the transverse cervical incision is dissected up to the level of the hyoid bone.

2) The sternohyoid muscles are retracted laterally from the midline.

3) The underlying thyrohyoid muscles are dissected out and divided transversely.

4) The underlying thyrohyoid membrane and thyrohyoid ligament thus exposed are transversely divided between the superior cornua of the thyroid cartilage. Care is taken not to damage the underlying submucosa of the anterior pharyngeal wall.

5) The tips of the superior cornua are amputated, avoiding the paired superior laryngeal nerve and artery, which lie laterally.

6) Having separated the thyroid cartilage from the hyoid bone above, the larynx can now drop down 2 to 3 cm, relieving tension on the tracheal anastomosis.

b. Suprahyoid release. Is purported to cause a lower incidence of uncoordinated swallowing postoperatively.

1) The skin flap is dissected to the suprahyoid region. (An alternate approach is to use a second transverse incision directly over the hyoid bone.)

2) The muscular attachments of the superior aspect of the hyoid bone, the mylohyoid, geniohyoid, and genioglossus muscles are detached from the hyoid bone over its central portion, thus exposing the pre-epiglottic space.

3) The lesser cornua and the hyoid bone itself are divided anterior to the tendinous attachments of the digastric muscles bilaterally.

4) Having thus separated the hyoid bone from the thyroid cartilage, the larynx can descend down 2 to 3 cm, relieving tension on the tracheal anastomosis.

5. Tracheal replacement with the use of prosthetic material

Common Errors in Technique

1. Failure to correctly identify the proximal and distal margins of the tracheal lesion to be resected

2. Failure to preserve the recurrent laryngeal nerves, resulting in vocal cord palsy or airway obstruction if bilateral

3. Inadequate tracheal mobilization, resulting in a tracheal anastomosis under tension

4. Excessive circumferential mobilization of the trachea proximally and/or distally, resulting in an ischemic tracheal anastomosis

5. Failure to leave the patient's neck flexed adequately at the end of the procedure with resultant tracheal anastomotic tension

6. Failure to confirm histologically negative margins with intraoperative frozen section when resecting tracheal tumors

Postoperative Period

Postoperative Management

1. The patient's head must be kept flexed, with the use of positioning and the heavy suture from the chin to the anterior chest.

2. If possible, the patient should be extubated at the end of the procedure. This is important to:

   a. Prevent pressure on the anastomosis with a cuffed endotracheal tube, which may impair mucosal circulation at the anastomosis.

   b. Avoid subjecting a distal tracheal anastomosis to positive ventilator pressure.

   c. Prevent pooling of the secretions adjacent to the anastomosis above a cuffed endotracheal tube.

3. Patients should be given humidified oxygen to inhale. If there is edema and stridor (most likely due to laryngeal edema), patients may receive heliox (80% helium, 20% oxygen), nebulized racemic epinephrine or

steroids, or systemic steroids.

4. Patients should receive a daily chest radiograph.

5. Patients are started on a clear liquid diet on the first postoperative day, and the diet is advanced as tolerated. If there is a question of intraoperative recurrent nerve injury, or if the patient has undergone a laryngeal release procedure, a bedside swallowing assessment by a speech language pathologist should be undertaken, with initiation of diet under their supervision. Swallowing difficulties, which are almost universally transient, are typically worse with liquids than with solids.

6. The head of the bed should be elevated 30 degrees to prevent edema in the upper airway.

7. A flexible bronchoscopic examination to directly evaluate the tracheal anastomosis should be performed under conscious sedation prior to discharging the patient or earlier if there are clinical signs of tracheal anastomotic narrowing or disruption.

Complications

1. Airway obstruction or edema:

   a. Can be treated by elevation of the head of bed, heliox, inhaled steroids, racemic epinephrine, or systemic steroids

   b. Reintubation or even tracheostomy may be required in severe cases.

2. Anastomotic leak with anastomotic breakdown and cervical abscess. If there is any question of anastomotic breakdown, evaluation using a flexible bronchoscopy, under copious sedation, should be undertaken immediately.

   a. Small areas of disruption will generally heal spontaneously and not result in tracheal anastomotic stricture.

   b. If there is an abscess adjacent to a tracheal anastomotic disruption the wound should be widely opened for drainage and packed with gauze.

   c. If more than a third of the circumference of the airway anastomosis is disrupted, the anastomosis should be stented open with the placement of a Montgomery T-tube.

3. Tracheal re-stenosis is usually a delayed complication occurring 4 to 6 weeks after surgery.

a. Initially treat with tracheal dilation, which can be repeated multiple times if necessary.

b. If the tracheal stricture recurs despite multiple dilations, tracheal re-resection is undertaken, if technically feasible.

c. If the stricture recurs and the patient cannot undergo re-resection, then a permanent tracheal stent will be required.

4. Granulation tissue at the anastomosis, which may bleed or cause obstruction, can be treated using a bronchoscope with mechanical débridement +/− YAG laser ablation (being careful to use the minimal amount of energy possible).

5. Bleeding in the neck. Neck re-exploration if required

6. Air leak and subcutaneous emphysema

a. At the conclusion of the surgical procedure and prior to extubation, the tracheal anastomosis should be examined under water by hyperinflating the lungs with the endotracheal cuff down (20 to 30 cm H_2O). Leaks thus identified should be surgically repaired by placing more sutures and/or buttressing with some vascularized tissue (usually strap muscle).

b. Small postoperative air leaks will usually heal spontaneously, particularly if the patient is not on postoperative positive pressure ventilation.

c. If the subcutaneous emphysema is severe, it can be decompressed by opening the wound.

d. If a pneumothorax is seen on a postoperative chest radiograph, then a chest tube is placed in the appropriate hemithorax.

7. Uncoordinated swallowing and aspiration. This is usually seen following laryngeal release procedures (the suprathyroid procedure more so than the suprahyoid procedure). It is usually transient but can be prolonged and is more often an issue in elderly patients. Can also be associated with intraoperative recurrent nerve injury and vocal cord paralysis

a. Speech therapy, bedside evaluation, and monitored advancement of diet

b. In severe and prolonged cases, a temporary nasal duodenal feeding tube may be required.

8. Recurrent nerve injury and vocal cord palsy

a. With careful surgery, permanent inadvertent recurrent nerve injury should be an uncommon occurrence.

b. Temporary palsy may result from intraoperative mobilization of the nerve.

c. Intraoperative recurrent laryngeal nerve monitoring with electromyography should be undertaken to minimize the risk of injury to the recurrent nerve.

d. If vocal cord palsy does not resolve with time, then peroral medialization of the vocal cord can be undertaken.

e. In a patient with poor postoperative pulmonary toilet and a documented vocal cord paralysis, then it may be appropriate to medialize the vocal cord in the immediate postoperative period.

9. Tracheoinomminate fistula. If the artery lies near the completed tracheal anastomosis, it should be protected with a muscular or omental pedicle interposed between the artery and the airway anastomosis.

10. Tracheoesophageal fistula. If an esophageal repair is part of the procedure, some vascularized tissue should be placed between the esophagus and the airway anastomosis.

11. Pneumonia. Patient should undergo aggressive postoperative pulmonary toileting and attention to pain control to facilitate good expectoration of secretions. If the vocal cord is paralyzed and there is a problem clearing sections, early vocal card medialization may be undertaken.

12. Deep venous thrombosis and pulmonary embolus. Risks minimized by early mobilization of the patient and prophylactic subcutaneous heparin 5000 units tid

Alternative Management Plan

1. Tracheal dilation may be effective to relieve airway obstruction, particularly in the case of a benign stricture. While it may be useful as a temporizing measure to relieve airway obstruction in order to allow for surgical planning or to allow time for resolution of inflammation in a tracheal lesion, it is generally not of durable benefit. For very short airway strictures or webs less than one-half centimeter, dilation alone may be successful as definitive therapy.

2. Tracheal stents may be placed to maintain an airway in patients with malignancy. They are particularly effective in the cases of extrinsic compression, often due to malignant mediastinal adenopathy. They may also be used for obstructing endobronchial tumors, typically after some endobronchial débridement. Tracheobronchial stents can also be used to maintain an airway in a patient with a benign stricture who cannot undergo tracheal resection.[4,5]

   a. Wire metal stents may be covered or uncovered. They are relatively easy to deploy with flexible bronchoscopy and fluoroscopy and have a wide diameter. Once deployed, however, they may become incorporated into the airway and are thus difficult to remove. They also may cause an excessive amount of granulation tissue.

   b. Silicone stents are more difficult to deploy than metal stents and require rigid bronchoscopy. Passing large tracheal stents across a narrow glottis may be difficult. They are also more prone to migration than metal stents. They are relatively nonreactive, however, and more easily removed than metal stents. They are more suitable for benign strictures than metal stents.

   c. Montgomery T-tube. These are silicone stents that have an external limb that projects through the trachea and neck. They can be placed through a pre-existing tracheostomy stoma, or a tracheostomy can be performed at the time of placement. Custom-made Y shaped T tubes can be made, which have limbs that extend into the main stem bronchi. They are introduced through a tracheal stoma and as such are good alternatives for patients with a small glottic opening that will a not allow atraumatic passage of a rigid scope loaded with a silastic tracheal stent. The side arm secures the stent, eliminating the risk of migration.

3. Tracheostomy. A tracheostomy tube may be inserted with the distal

opening placed beyond the tracheal stricture. If the tracheal stricture is located distally, extended-length tracheostomy tubes should be used. This allow for mechanical ventilation, which cannot be easily done in patients with silastic stents (usually a metals stent will allow passage of an oral endotracheal tube under bronchoscopic guidance, if necessary, for mechanical ventilation). As opposed to tracheal stents, the uncapped tracheostomy tube does not allow for airflow through the nasopharynx and across the larynx, so phonation is not possible, and the patient also does not get filtration and humidification of inspired air. Uncuffed tracheostomy tubes, or cuffed tubes with the cuff deflated, may allow for translaryngeal airflow; however, the resistance to breathing around the tracheostomy tube may be significant (fenestrated tracheostomy tubes may be used to decrease this resistance to flow by allowing flow through the lumen of the tracheostomy tube).

4. Endobronchial mechanical removal or YAG laser therapy of tracheal tumors. While these therapies offer good palliation of endotracheal tumors, typically they are extending into the trachea, or may even be extending full thickness through the trachea, and will not be cured with such endobronchial therapy, so it is not recommended in patients with technically resectable tumors.

5. Radiation or chemoradiation

   a. Malignant tumors have often metastasized at time of presentation and as such are not appropriate for resection.

   b. Alternatively they may be locally advanced and not technically resectable for a cure.

Discussion

Evidence-Based Medicine Question

Is endobronchial ablative or resective therapy a comparable but less invasive method of managing resectable tracheal tumors?

Endobronchial therapy for tracheal tumors, while potentially effective for palliation, offers essentially no chance of long-term cure, as it will not address tumors invading through the full thickness of the tracheal wall.

It should therefore not be offered to patients with resectable tracheal tumors who are physiologically fit for surgery.

Editorial Comment

Head and neck surgery is the ultimate expression of teamwork. Thoracic surgeons play an important role as members of our team, helping us provide the best care for our patients. However, head and neck and thoracic surgery are, in fact, areas of overlapping interest, since surgeons of both specialties carry out bronchoscopies, retrieve foreign bodies, and do tracheal resections for tracheal stenosis or tumors of the upper trachea.

Tracheal stenosis, caused by endotracheal tubes (especially in the pediatric population), and stenosis secondary to improperly done tracheostomies, as well as from endotracheal tubes in ventilator patients in the adult population, require the resection of a relatively short segment of the trachea. Head and Neck Surgeons have been trained to carry out these procedures in adults, and Pediatric Otolaryngologists have designed a number of rather sophisticated procedures to manage the vexing problem of the stenotic airway in children.

We are grateful to our colleagues in thoracic surgery who are a great help to our patients in the management of extensive tracheal stenosis and neoplasms of the lower tracheal bronchial tree and the many patients who have synchronous or metacronous secondary primary squamous cell carcinoma of the lungs. This chapter, by one of my dear colleagues, Dr. Neil Christie, takes us step-by-step through the details of the surgical technique necessary to overcome the challenging airway problems that are a result of tracheal strictures. His description of the techniques of the resection of the stricture segment and primary anastomosis, as well as the laryngeal release technique necessary for more extensive resections, is clear and concise. While Head and Neck Surgeons will not be doing these more extensive procedures, it is important for us to have a clear understanding of what is available and appropriate for our patients and the knowledge and skill sets involved.

Eugene N. Myers

Review Questions

1. How much of the trachea can be resected and still allow for a tracheal anastomosis?

   a. 1 cm

   b. One-fourth of tracheal length

   c. **One-half of tracheal length**

   d. Two-thirds of tracheal length

2. All of the following decrease tracheal anastomotic complications, except

   a. Keeping tension off the tracheal anastomosis

   b. **Perioperative systemic steroids**

   c. Resecting all of the diseased trachea before performing the airway anastomosis

   d. Avoiding excessive circumferential tracheal mobilization above and below the airway anastomosis

3. All of the following techniques may be used to avoid tracheal anastomotic tension, except

   a. Suprahyoid release

   b. Suprathyroid release

   c. Dissection in the pretracheal plane

   d. **Postoperative neck extension**

   e. Perihilar pericardial release

4. Resection and reconstruction of lesions in the distal trachea can be best accomplished by which of the following approaches?

   a. A generous collar incision

   b. A collar incision with a partial upper sternotomy

   c. **A right fourth interspace thoracotomy**

   d. A left fourth interspace thoracotomy

Management of a Tracheocutaneous Fistula and Depressed Scar

William G. Albergotti, and Eugene N. Myers

Introduction

A tracheocutaneous fistula (TCF) is a sequela of a tracheostomy and is usually associated with an unsightly depressed tracheostomy scar (Fig. 23.1). Formation of this fistula is predicated on squamous epithelium migrating from the skin into the trachea, forming an epithelial interface with the mucosa of the trachea, and thereby creating a true fistula that cannot close spontaneously. Marked separation of the strap muscles associated with a prolonged indwelling cannula, infection, and wasting of subcutaneous tissue due to poor nutrition and weight loss are important factors predisposing to the development of a depressed scar and fistula. These features facilitate epithelial migration toward the tracheal mucosa along the tract formed by the tracheostomy cannula. White and Smitheringale suggest that epithelial migration of skin into the trachea and extensive cicatricial resolution of chronic granulation tissue result in the formation of a dense connective tissue sleeve based around the entire opening of the tracheal stoma.[1]

During the performance of a tracheostomy, the strap muscles are retracted laterally, and the cannula is inserted. In a patient who has had a cannula in place for a prolonged period, infection and fibrosis occur and the strap muscles are scarred into a position lateral to the tracheostomy. When the patient is eventually decannulated and the stoma heals by secondary intention, the skin heals directly to the trachea, thus forming a depressed scar due to the separation of the strap muscle with or without a TCF. The relationship between the duration of tracheostomy and the development of a persistent fistulous tract has been well established, with a fistula rate of 50% identified in patients with a cannulation time of

longer than 1 year.[2,3] Other risk factors proposed include previous neck radiation or tracheostomy. Interestingly, stomal maturation has not been found to be a risk factor for formation of a TCF.[4]

FIG. 23.1 A tracheocutaneous fistula and depressed scar as a result of long-term placement of a tracheostomy cannula.

Persistence of a TCF may lead to increased morbidity, particularly in patients with limited pulmonary reserve, which is of particular concern in children.[1,5] Eaton and colleagues[6] stated that a persistent TCF may be a source of considerable morbidity because of problems with poor hygiene, aspiration, respiratory infection, and associated difficulty with voicing. In addition to functional problems with the TCF, unsightly scars often follow tracheostomy decannulation. With the skin directly adherent to the trachea at the site of the TCF, every time the patient swallows the skin moves up and down, which attracts unwanted attention. Many emergency tracheostomies are still carried out through a vertical incision, which itself may result in an unsightly scar or a keloid.

Several methods for closure of a TCF have been described, including primary closure, fistulectomy with primary closure in layers, and fistulectomy with healing by secondary intention. When a fistula is too large to close by secondary intention, a surgical procedure is necessary. Closure of a TCF was reported as early as 1934 by Jackson and Babcock.[7] They used a lined bipedicled flap reinforced with conchal cartilage.

Pressman described the repair of a depressed tracheostomy scar by detaching and transposing the origins of the sternocleidomastoid muscle into the defect.[8] Others have suggested the use of sternohyoid muscle rotational flaps, subcutaneous Z-plasty, turnover flaps, and V-Y advancement flaps.[9,10] For very small fistulas without concern for cosmesis, chemical or electrocautery has been described.[6]

Our technique for correction of the depressed scar emphasizes restoring the natural anatomic position of the strap muscles in the midline. This key feature has eliminated the need for the aforementioned procedures. Kulber and Passy have described a similar technique that prevents reattachment of the skin to the trachea by reapproximation of the strap muscles in the midline.

Key Operative Learning Points

- Patients should be evaluated endoscopically to ensure that the airway is patent before closure of a TCF.
- The key feature of the operation is dissecting the strap muscles free of scar tissue and the trachea and restoring the normal anatomy by reapproximating the strap muscles in the midline. This reinforces the closure in patients with a TCF and eliminates the depressed scar in all patients.
- Failure to thoroughly free the strap muscles from scar tissue and the trachea and to reapproximate the muscles in the midline will result in persistence of the depressed scar.
- Failure to provide airtight closure of the fistulous tract and provision of an inner epithelial lining will result in recurrence of the fistula.
- TCFs are colonized by bacteria, so perioperative antibiotics should be given to prevent infection.
- Patients, particularly those in the pediatric age group, may experience respiratory distress after closure of a TCF.
- Children undergoing closure of a TCF should be monitored in the intensive care unit after the procedure, because airway distress may be a complication of this procedure.

- Adult patients should be observed in the hospital overnight to ensure that the airway is stable.

Preoperative Period

History of Present Illness

- Indication for and duration of the tracheostomy
  - With particular attention to whether it was emergent or planned
- Amount of time since decannulation
- Previous attempts at repair
  - Previous attempts may decrease the likelihood of success with the currently planned repair. The surgeon will also need to be mindful of the likely presence of increased scar tissue.
- Associated symptoms
  - Shortness of breath
  - Difficulty with voicing
  - Productive cough
  - Saliva coming through the fistula
  - Dysphagia and/or pneumonia
  - Fistula site infections
  - Cosmetic concerns
- Past medical history
  - With particular attention to associated cardiopulmonary dysfunction, the need for positive pressure ventilation at baseline for obstructive sleep apnea or other cardiopulmonary disease
  - History of radiation of the neck, diabetes mellitus, and vascular disease may place patients at risk for poor wound healing or persistent fistula
- Past surgical history

- Particularly including history of tracheostomy, previous attempts at repair and other surgeries within the neck

- Social history
  - Tobacco use will impair wound healing and could contribute to the incidence of postoperative subcutaneous or mediastinal emphysema if there is coughing on emergence from inhaled anesthesia

Physical Examination

- Complete examination of the head and neck
  - Attention to TCF or depressed scar site (vertical or horizontal tracheostomy)
    - Presence and size of TCF
    - Presence of associated keloid or granulation tissue
  - Examination of the neck
    - Other scars within the neck
    - Thyromental distance
  - Examination of the oral cavity and oropharynx may suggest risk factors for obstructive sleep apnea or difficult airway perioperatively.
    - High, arched palate
    - Glossoptosis
    - Mallampati score
- Flexible laryngoscopy and tracheoscopy should be performed to assess the entirety of the upper airway to the level of the carina to ensure that there are no sources of obstruction.
  - Complications may occur after closure of a TCF, particularly in children, so it is of utmost importance to ensure that the caliber of the trachea is satisfactory before closure. One reason for persistence of the fistula may be that the patient does not have an adequate airway, and the fistula serves as an auxiliary airway. The concern is that once the fistula is closed in such patients, the airway might not

be patent enough to permit adequate air exchange.

- During airway endoscopy, particular attention should be paid to the suprastomal trachea and subglottis, as this is the most common site of granulation formation and stenosis in children.
- Awake transnasal bronchoscopy can also be performed in-office using a combination of nebulized and topical 4% lidocaine to assess the complete airway dynamically.
- In children who will not tolerate in-office endoscopy, formal airway endoscopy should be performed at the time of repair.

- Patients should be able to tolerate occlusion of the TCF for at least 24 hours.

Imaging

- Computed tomography of the neck (noncontrast) can be considered to evaluate the adequacy of the tracheal lumen, particularly if endoscopy is inadequate.

Indications

- Patients selected for this procedure have symptoms associated with the fistuous tract or scar, including difficulty with voicing, productive cough, saliva coming out of the fistula, dysphagia and/or pneumonia, fistula site infections, ineffective cough, or cosmetic concerns.
- The fistula should have been present at least 3 months after decannulation to allow for an adequate opportunity to heal secondarily.

Contraindications

- Inability to tolerate occlusion of the TCF or airway obstruction noted on endoscopy
- Active infection at the fistula site
- Chronic cough

- Need for positive pressure ventilation (relative contraindication)
  - Polysomnogram should be obtained preoperatively with occluded stoma for patients with known or suspected obstructive sleep apnea (OSA) to assess the degree of OSA. Patients with OSA should be counseled regarding the need for long-term positive pressure ventilation if TCF is closed.

Operative Period

Anesthesia

- May be performed under general or local anesthesia with intravenous sedation
  - Our preference in adults is local anesthesia with intravenous sedation in order to avoid the need for positive pressure ventilation during closure or coughing during emergence. In a patient with a difficult airway, general anesthesia is preferred.
  - General anesthesia is essential for children.
  - Given the potential use of electrocautery near the airway, an airway fire is a risk. The anesthesiologist should be made aware, and the fraction of inspired oxygen should be kept at a minimum.

Positioning

- The patient is placed in the supine position with the head extended. We use a shoulder roll to establish maximal extension of the head.

Perioperative Antibiotic Prophylaxis

- Perioperative antibiotics are administered to prevent infection, because the fistula is potentially colonized by pathogenic organisms. First-generation cephalosporin is administered prior to the skin incision.

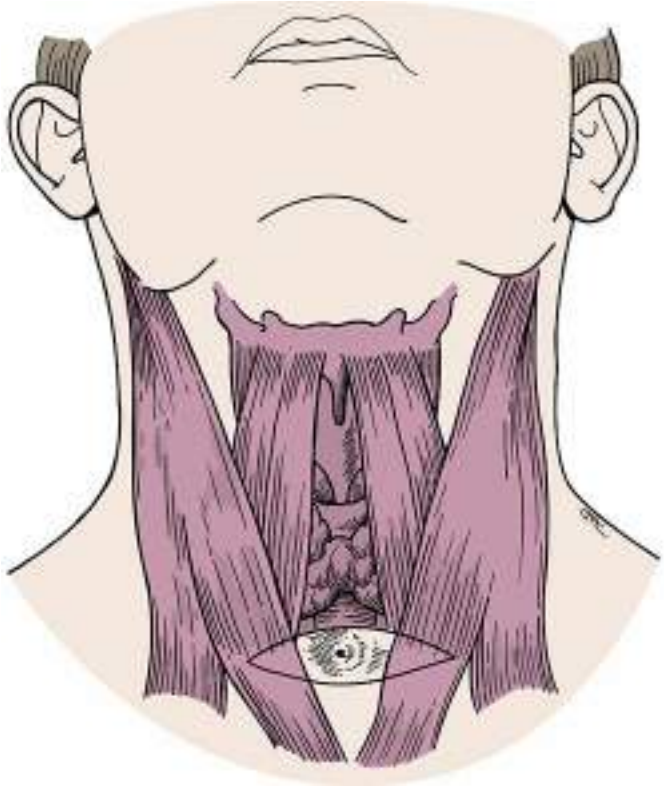

FIG. 23.2 The scar from the tracheostomy is excised almost down to the fistulous tract.

Instruments and Equipment to Have Available

- Standard neck dissection or tracheotomy instrument set
- Bovie electrocautery
- Suction
- Cuffed endotracheal tube or tracheostomy tube in case of need for urgent positive pressure ventilation

Key Anatomic Landmarks

- Thyroid notch of thyroid cartilage
- Cricoid cartilage
- Sternum

Prerequisite Skills

- Ability to perform a tracheostomy

Surgical Technique

- A transverse elliptical incision is made at the level of and extending somewhat lateral to the TCF (Fig. 23.2).
- The skin flaps are widely undermined. The scar between the skin and the fistula should then be released.
- Dissection is carried down along the fistula to the level of the trachea. The tract should then be excised, with just enough skin left to close the fistula by inverting the squamous epithelium as a "trapdoor" flap to form the inner epithelial surface of the anterior wall of the trachea (Fig. 23.3).
- The strap muscles will be found incorporated in dense scar tissue and adherent to the lateral aspect of the trachea. The strap muscles are then dissected free from the scar tissue and repositioned over the trachea to restore them to their normal anatomic position.
- The muscles are sutured together in the midline with absorbable suture (Fig. 23.4). This maneuver effectively separates the trachea from the skin, eliminates the depression, and prevents reformation of the depressed scar.

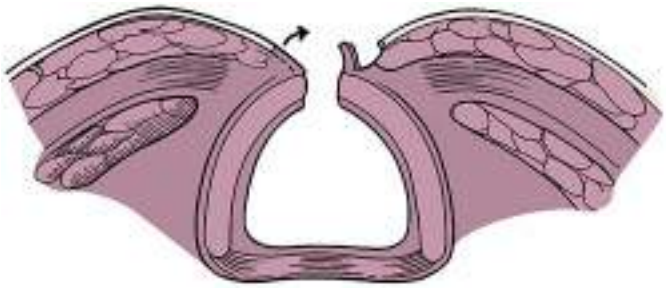

FIG. 23.3 Dissection is carried down to the surface of the fistula, and the skin of the fistulous tract is used as a skin flap. It is turned in to restore the anterior epithelial lining of the trachea.

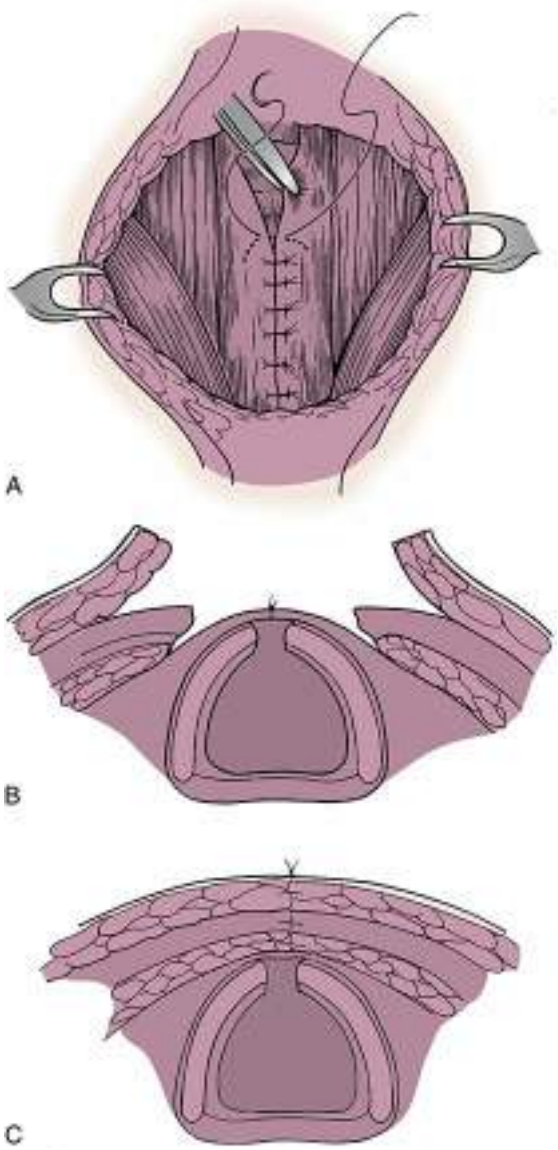

FIG. 23.4 **A** to **C,** The strap muscles are repositioned in the midline and sutured together. The subcutaneous tissue and skin are then closed.

- A small rubberband or Penrose drain is left just deep to the strap muscles to allow for air egress through the lateral aspect of skin closure. The drain is removed on postoperative day 1.
- The subcutaneous tissue is closed without tension. The skin incision is then closed with 6-0 chromic suture. A Z-plasty or a geometric broken-line skin closure may be used if necessary to produce a small, smooth scar. Steri-Strips are applied to the wound to minimize tension.
- A modification of this technique is also used for patients who have a

depressed tracheotomy scar without a TCF. The mechanism of the depressed scar with adherence to the trachea is similar; the only step that is unnecessary is excision of a fistula. The procedure results in an acceptable scar (Fig. 23.5). Returning the strap muscles to their anatomic position eliminates the depression and prevents its recurrence.

- Potential complications of repair include pneumomediastinum, pneumothorax, and respiratory insufficiency requiring tracheotomy. Complications typically occur in patients who undergo single-stage excision and closure of the TCF associated with large defects of the anterior tracheal wall. Therefore, for larger defects, the authors modified their technique as follows:
  - The TCF and scar are dissected out through a horizontal elliptical incision.
  - The fistulous tract is dissected down to the anterior tracheal wall and excised. If the defect in the anterior wall is greater than 4 mm, a no. 3 or 4 metal Pilling tracheotomy tube is inserted into the previous tracheotomy site.
  - The strap muscles are elevated and closed in the midline around the tracheotomy tube with 4-0 polyglactin. This eliminates the depressed scar.
  - The skin edges are widely undermined and then closed around the tracheostomy tube with a 5-0 nylon suture.
  - The tracheostomy tube is capped in the recovery room or on the first postoperative day, and the patient is decannulated on day 2. The small central area is allowed to heal by secondary intention.
- In children, this procedure is performed under general anesthesia by using the least complex method of closing a TCF, which consists of excising the epithelium of the fistulous tract and allowing the tract to close by secondary intention.
  - Such closure occurs rapidly and results in a watertight seal that will allow the patient to swim and bathe.
  - This method is recommended for young children, in particular because more extensive procedures may require lengthy anesthesia, and manipulation of the trachea may lead to edema and airway

obstruction.

- If the scar is not satisfactory, it may be revised later.
- Several studies have shown no difference in outcomes or complications between primary and secondary closure in children. Thus secondary closure is the preferred choice of closure in children.

Common Errors in Technique

- Failure to free the strap muscles thoroughly from scar tissue and the trachea and to reapproximate the muscles in the midline will result in the persistence of the depressed scar.
- Failure to provide airtight closure of the fistulous tract and provision of an inner epithelial lining will result in recurrence of the fistula.

Postoperative Management

- Adult patients are hospitalized overnight for observation of the airway and discharged the next day.

FIG. 23.5 **A,** Markings for planned excision of tracheocutaneous scar and **B,** postoperative appearance at one week after excision of tracheocutaneous scar.

- Infants or children who undergo this procedure are best monitored in an intensive care unit overnight to ensure adequacy of the airway.
- If a drain is kept in place, it is removed on postoperative day 1. If a tracheostomy tube is left in place, it is removed after an adequate trial of capping, usually by postoperative day 2.
- Care of the wound is minimal because the skin is closed with absorbable 6-0 catgut skin sutures and Steri-Strips, which are removed in 7 to 10 days.
- A tracheotomy set should be kept at the bedside in the unlikely event of airway obstruction.

- If positive pressure ventilation is required, it is started 2 weeks after surgery, unless severe obstructive sleep apnea (OSA) in which positive pressure is restarted the evening of surgery, knowing there is an increased risk of airway complications.

Complications

- The primary concern postoperatively is the development of subcutaneous emphysema, pneumothorax, or pneumomediastinum due to air escape from tracheal closure. This complication occurs in up to 3% of cases and may be exacerbated by the use of positive pressure, coughing, or other increases in intrathoracic pressure. Admission and observation in a monitored patient unit are mandatory for adult patients and intensive care for pediatric patients.
  - If this occurs, the wound should be opened at the bedside and a cuffed tracheostomy tube placed through the tracheostoma, with positive pressure provided through this route if needed. Positive pressure should not be applied via a face mask, as this can exacerbate the problem.
  - In patients with chronic cough or pulmonary disease who may be at risk for this complication, it is advantageous to perform excision of the tract with allowance of closure by secondary intention.
- Wound infection or dehiscence

Alternative Management Plan

- Observation
- Excision of tract with healing by secondary intention (see previous sections)

Discussion

Evidence-Based Medicine Question

Is there a difference in the success rate between primary closure of TCF

and healing by secondary intention?

- Among pediatric patients, a systematic review has found no difference in closure rates between primary and secondary closure (95.7% vs. 92.3%, respectively). Airway complications occur in 3.8% and 3.6%, respectively. Similarly, there was no difference found on meta-analysis in infection, fistula, and revision surgery. Excision of the tract alone has been shown to require less surgical time, however.
- Among adults, there is little evidence to support one technique above another; however, primary closure is preferred for cosmesis.

Editorial Comment

Many years ago, when Elizabeth Taylor and her then lover, Richard Burton, were in London, she became seriously ill with pneumonia. A life-saving tracheostomy was performed at her bedside by Sir Terrance Cawthorne, a distinguished otolaryngologist whose specialty was problems of the vestibular system. Fortunately, she survived but at the cost of an unsightly scar. Since no surgeon was ever brave enough to revise the scar, the beautiful actress hid the scar behind a series of especially designed diamond necklaces.

The depressed tracheotomy scar is a purely cosmetic issue. However, when combined with a tracheocutaneous fistula, the cosmetic defect is magnified by the leakage of saliva expelled through the fistula when coughing and the movement of the skin of the neck up and down during swallowing.

The solution to the problem is a simple one: Restore the anatomy to its normal state. This requires the following steps: Excise the scar and the fistulous tract saving enough skin to create a trap door flap closure of the stoma, providing the necessary inner epithelial lining; undermine the surrounding skin to release it from the trachea and the strap muscles; reapproximate the strap muscles in the midline; and perform a multiple layer closure of the wound.

In the pediatric age group, however, the solution to this problem is not so simple, primarily due to the size of the patient, the size of the structures, and the often tenuous state of the airway. Although a recent meta-analysis revealed that there was no difference in closure rates

between the primary closure and secondary closure, the overall condition of the patient and circumstances leading up to the tracheotomy and the request for closure of the fistula should be considered when deciding which path to take in solving this vexing cosmetic problem.

Stenosis of the Tracheostoma Following Total Laryngectomy

Eugene N. Myers, and Mark Mims

Introduction

Stenosis of the tracheostoma following laryngectomy is an infrequent but distressing complication that may occur despite meticulous attention to the construction of the tracheostoma. Stenosis can result from a variety of factors and usually occurs in the early months following laryngectomy.[1] However, stenosis may also occur years later despite the type of closure performed at initial surgery.[2] Wax et al. defined tracheal stenosis as a narrowing of the stoma that requires the patient to wear a stent (usually a laryngectomy cannula) for longer than 3 months after surgery or requires revision of the tracheal stoma.[3] Giacomarra et al. defined tracheostomal stenosis as respiratory insufficiency at rest or during exercise or if there is difficulty in clearing tracheal secretions because of nonlaminar flow, or both.[4] Although the patient with relatively good pulmonary function may maintain adequate exercise tolerance, many patients with emphysema or chronic obstructive lung disease may encounter respiratory insufficiency when stenosis of the tracheostoma occurs.[5] Adequate mucociliary transport may be impeded by stomal stenosis and may result in stagnation of mucus and the potential for recurrent pulmonary infection. Severe stenosis is potentially dangerous because complete obstruction may occur in the presence of crusting or a mucous plug, particularly during an episode of tracheitis or tracheobronchitis.[3] Stomal stenosis may also interfere with the proper insertion and use of a tracheoesophageal puncture speech prosthesis. Stenosis can occur regardless of the type of closure or reconstruction. A wide variety of techniques have been described to address stenosis ranging from noninvasive techniques, such as serial dilation or excision of peristomal

adipose tissue, to more invasive techniques, such as Z-plasties, local or advancement flaps, and even free flaps for recalcitrant stenosis. The common features for all techniques are (1) to eliminate circular forces of contraction and (2) to provide for healing by primary intention (e.g., skin to mucosa) (Fig. 24.1).

Key Operative Learning Points

1. Stenosis of the tracheostoma is a potential complication of total laryngectomy despite the type of closure performed at the initial creation of the stoma.

2. The goals of surgery are to eliminate circular forces of contracture and allow for healing by primary intention.

3. Care must be exercised if patient has received, or is planning on receiving, radiation therapy to the stoma site; however, previous radiation therapy does not preclude revision of the tracheostoma, provided the stoma was not included in the radiation portal.

Preoperative Period

History

1. The patient may present with any or all of the following symptoms:
   a. Increasing shortness of breath at rest or with exercise
   b. Inability to clear tracheal secretions
   c. Recurrent pulmonary infections
   d. Inability to properly use a tracheoesophageal puncture speech prosthesis
2. Patient history
   a. Timing of laryngectomy to onset of symptoms
      1) Stenosis typically occurs in the first several months after surgery, although it may present years later.
   b. Extent of primary surgery

1) Extensive resection of tracheal rings may lead to excessive tension on the stoma if not carefully designed.

c. Type of primary closure

d. Local wound care at home

e. History of radiation therapy

1) Radiation involving the stoma increases the risk of stenosis as is seen in patients with subglottic extension of the tumor.

f. Trial of serial dilation by increasing laryngectomy tube size

3. Risk factors for tracheostomal stenosis

a. Peristomal recurrence of cancer

b. Radiation therapy

c. Wound dehiscence with healing by secondary intention

d. Inadequate excision of peristomal skin and adipose tissue at the time of initial stomal construction

e. Devascularization of the trachea

f. Infection after surgery

g. Hypertrophic scarring

h. Diabetes mellitus

i. Poor nutritional status

Physical Examination

1. Recurrence of cancer must be excluded first as a cause for the above-mentioned symptoms.

a. This may include careful inspection, imaging, and/or biopsy.

2. Careful note of the diameter of the stoma must be made.

a. Markedly obese patients may have bulging of tissues into the stoma, resulting in a form of pseudostenosis.

3. Examine surrounding soft tissue for breakdown of skin edges.

4. Palpate for the presence of a high-riding innominate artery.

5. Ensure that the trachea inferior to the concentric scar band is of adequate caliber.

Imaging

1. Imaging is not typically required prior to correction of stenosis of the laryngostoma.

Indications

1. Symptomatic dyspnea at rest or with activity
2. Inability to clear secretions
3. Inability to provide adequate pulmonary toilet
4. Inability to use tracheoesophageal puncture speech prosthesis

FIG. 24.1 Tracheostomal stenosis.

Contraindications

1. No absolute contraindications other than severe comorbidities

2. Radiation is a relative contraindication.

   a. Patients who have had radiation therapy in which the radiation portals include the stoma should be treated by nonsurgical means.

   b. Operative repair can still be performed if meticulous technique is used in patients in whom the radiation portals did not include the stoma.

Preoperative Preparation

1. Patients who had a tracheostomy prior to their laryngectomy often develop local inflammatory response and colonization with bacteria in the peristomal skin.

   a. The peristomal skin and a tracheal ring below the stoma should be excised in these patients to prevent postoperative infection.

2. A review of the radiation portals must be undertaken to be sure that the stoma has not been radiated.

3. Careful planning must be undertaken to not damage a preexisting tracheo esophageal puncture (TEP).

4. Imaging is not typically required prior to correction of tracheostomal stenosis.

Operative Period

Anesthesia

1. Procedure may be undertaken either under local or general anesthesia

2. General anesthesia involves intubation through the tracheostoma, which requires that the surgical and anesthesia teams share the airway.

   a. Communication with the anesthesia team is important as revision of the stoma will require repositioning the endotracheal tube throughout the case.

3. We prefer to carry out this procedure under local anesthesia and intravenous sedation, which provides the surgeon with constant

exposure of the field in the absence of the endotracheal tube.

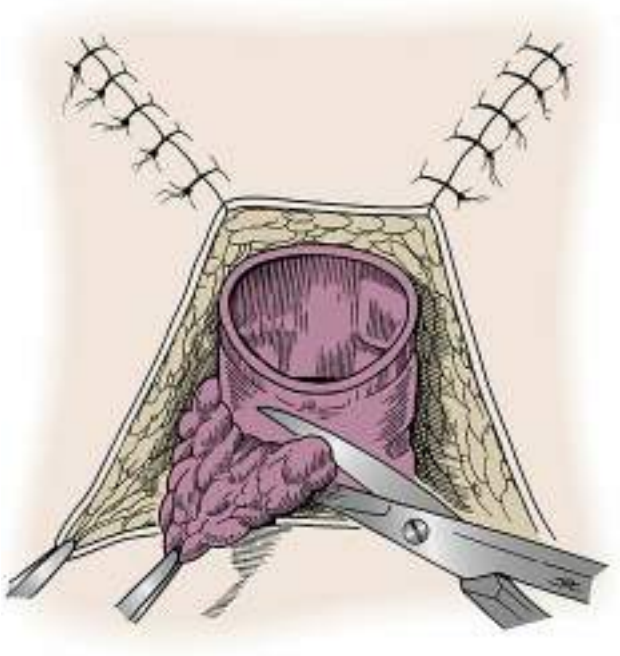

FIG. 24.2 Excision of the peristomal skin and adipose tissue.

Positioning

1. Patient is placed supine position with a shoulder roll to provide adequate neck extension

Perioperative Antibiotic Prophylaxis

1. First-generation cephalosporin is given preoperatively.

Monitoring

1. No special monitoring is required.

Instruments and Equipment to Have Available

1. General head and neck set

Key Anatomic Landmarks

1. Tracheal rings

2. Manubrium of the sternum

Prerequisite Skills

1. Airway management in a total laryngectomy patient

2. Local flap techniques

3. General soft tissue handling

Operative Risks

1. Airway compromise

2. Bleeding

Surgical Technique

1. An incision is made around the periphery of the tracheostoma, which encompasses any scar tissue present.

2. Clamps are applied to the tissue to be excised and the trachea is pulled up into the wound.

3. The trachea is skeletonized 1 to 2 cm inferior to the stoma.

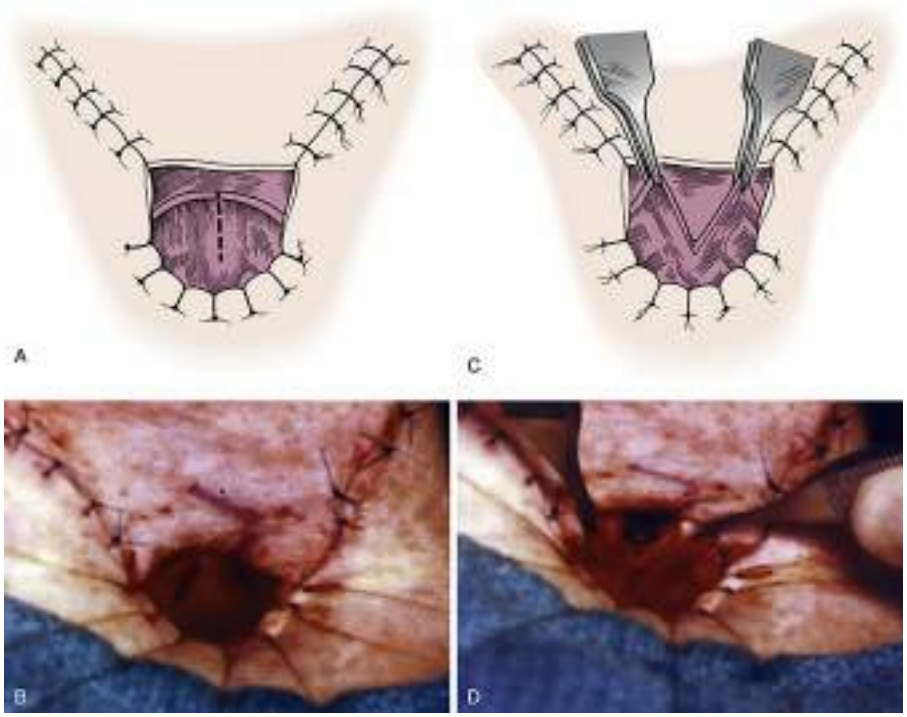

FIG. 24.3 **A** and **B,** An incision is made in the posterior wall of the trachea. **C** and **D,** The defect is opened.

4. The skin inferior to the tracheostoma and overlying the sternum is undermined approximately 2 to 3 cm.

   a. Excise any excess subcutaneous and adipose tissue.

   b. Remove excess skin to promote some tension on the inferior aspect of the tracheostoma, thus widening the stoma (Fig. 24.2).

5. Completely excise the concentric band of scar tissue, which is typically the primary cause of the stenosis.

6. The skin surrounding the stoma is sutured to the trachea using interrupted 3-0 chromic sutures.

   a. Take particular care to ensure that the skin overlaps any raw edges of the cartilage and is in contact with the tracheal mucosa.

   b. Suturing is carried out inferiorly to 3 and 9 o'clock positions on the tracheostoma.

7. Undermine the skin of the neck surrounding the posterior aspect of the stoma.

   a. Remove any adipose tissue and redundant skin.

8. Make an approximately 1-cm vertical incision in the membranous posterior wall of the trachea, thereby expanding the tracheal lumen (Fig. 24.3).

9. Continue suturing the skin to the trachea.

   a. At this point, the circumference of the tracheostoma has been widened considerably.

10. A small incision is made in the redundant skin posterior to the stoma and a small skin flap is developed (Fig. 24.4).

   a. The flap is transposed, inset, and sewn into the incision in the posterior tracheal wall with 3-0 chromic suture (Fig. 24.5).

   b. This modified Z-plasty breaks up the circle, preventing future stenosis, and is one of the most important aspects of this technique.

   c. If this procedure is carried out at the time of total laryngectomy and a tracheoesophageal puncture is to be performed, the flap should be based inferiorly at the 6 o'clock position and inset into an incision made in the inferior aspect of the trachea through the cartilaginous rings (Fig. 24.6).

Common Errors in Technique

1. Inadequate release or excision of concentric scar band

2. Failure to create a flap to inset into the posterior tracheal wall

Postoperative Period

Postoperative Management

1. The patient should keep the peristomal area clean and free of crusts by using hydrogen peroxide on cotton applicators.

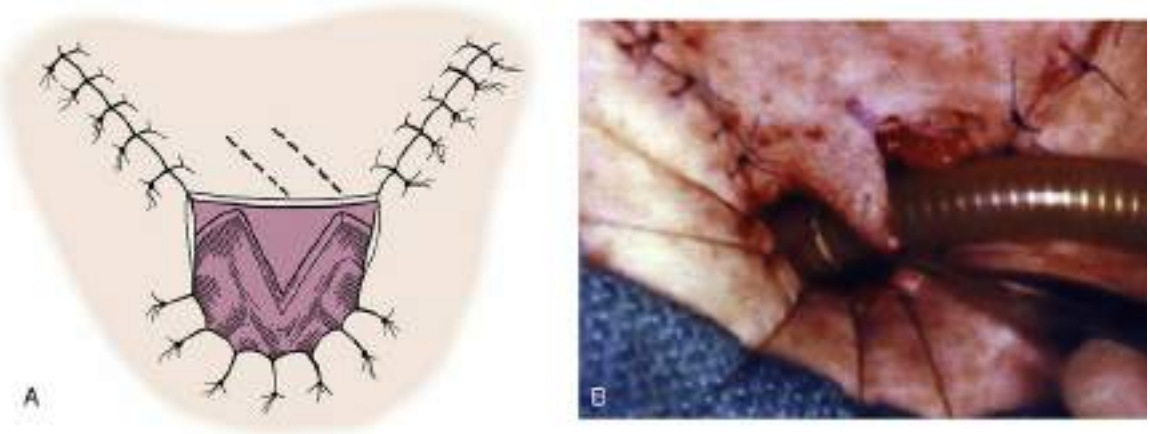

FIG. 24.4. A AND B A flap is formed from redundant skin posterior to the trachea.

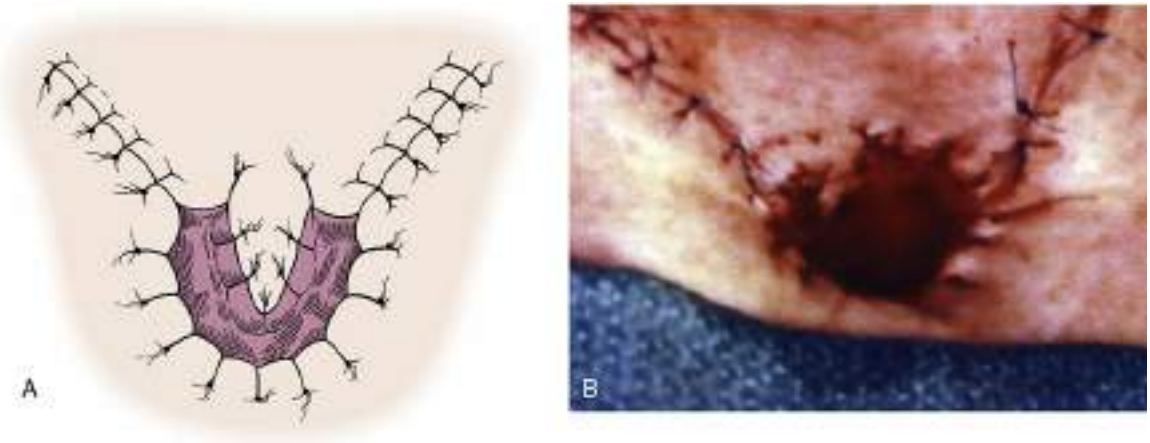

FIG. 24.5. A The skin flap is transposed into the tracheal incision and inset. **B,** The stomal skin closure is completed.

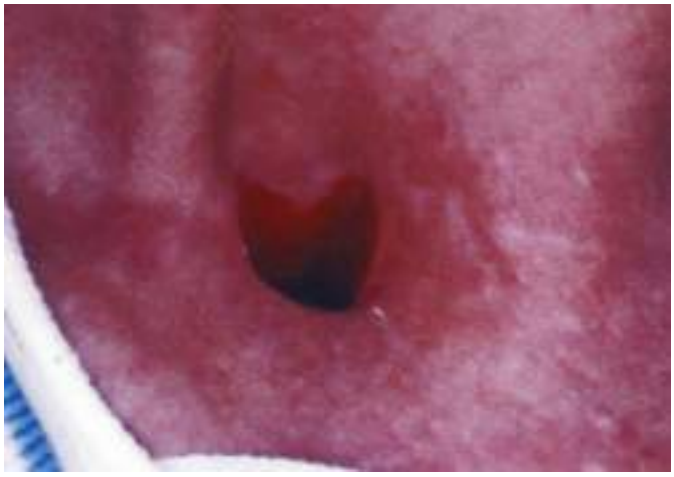

FIG. 24.6 Stomal revision using a superficial-based skin flap.

a. Following application of hydrogen peroxide every several hours, an antibiotic ointment should be applied to the area.

b. This is carried out for several weeks until the sutures have been absorbed and the tracheostoma healed.

2. Following complete healing, the patient should wear a laryngectomy tube only at night during sleep and remove it during the remainder of the day.

a. If there is evidence of shrinkage of the stoma, the laryngectomy tube may be worn for longer periods of time.

Complications

1. Loss of peristomal skin or breakdown

a. Particularly in patients who have received high-dose radiation in the peristomal area

2. Recurrence of stenosis

3. Peristomal infection

Alternative Management Plan

1. This repair may be performed at the time of total laryngectomy if

stenosis is anticipated.

2. Serial dilatation of the trachea by the insertion of increasing-diameter laryngectomy tubes

   a. May be performed in patients with radiation to the peristomal area and at high-risk for peristomal breakdown

Discussion

Evidence-Based Medicine Questions

1. What other techniques have been described to address tracheostomal stenosis after total laryngectomy? (Answer: Many other techniques have been described to address tracheostomal stenosis, including various local flaps, as well as revisions using Z-plasty or V-to-Y plasty. Some techniques, such as described by Giacomarra, combine multiple techniques into one repair to correct the stenosis. This approach combines radial incisions, V-shaped flaps, and interposing flaps to address a patient's tracheostomal stenosis.)

2. What are some different definitions of tracheostomal stenosis? (Answer: Wax et al.[3] define tracheostomal stenosis as a narrowing of the stoma requiring the patient to wear a stent for longer than 3 months after surgery or stenosis requiring revision. Giacomarra et al.[4] define it as presence of respiratory insufficiency at rest or during exercise or if there is difficulty clearing tracheal secretions.)

Editorial Comment

Stenosis of the tracheostoma following total laryngectomy is a vexing and at times a life-threatening problem. There is no completely accepted etiology for this problem, which can occur in the first few months following laryngectomy or years later. The most common site of the stenosis is a concentric scar at the skin-mucosa interface, whereas the remaining trachea is of normal caliber. Less frequently there may be concentric narrowing of the superior aspect of the residual tracheal rings and even less frequently there may be a combination of the two.

The solution to the stenosis should be surgical unless the patients have comorbidities that contraindicate a visit to the operating room or have a history of having radiation to the stomal area. Radiation to the stoma is usually given to patients who are at high risk for stomal recurrence of cancer that is transglottic or subglottic in origin. Glottic or supraglottic cancers have little to no chance for periostomal recurrence. The poor healing associated with a radiated stoma leaves the patient worse off than he or she was in the preoperative period.

The invention of the Blom-Singer valve introduced a potential pitfall in how to treat stomal stenosis in patients who were successful satisfied users of a TEP. If the TEP puncture is a centimeter or more inferior to the mucocutaneous junction in the posterior superior aspect of the stoma, incising the posterior wall of the trachea to insert a flap is not technically possible, although it may be possible to make the incision and insert the flap at the 6 o'clock position.

Review Questions

1. What causes tracheostomal stenosis after total laryngectomy?

   a. Radiation therapy

   b. Hypertrophic scar

   c. Recurrence of tumor

   d. **All of the above**

2. What is a relative contraindication to this procedure?

   a. **Radiation involving the stoma**

   b. Radiation not involving the stoma

   c. Diabetes

   d. a and b

3. Which step is critical in preventing recurrence of the stenosis?

   a. Undermining the peristomal skin

b. **Transposition of a skin flap**

c. Vertical incision in the posterior tracheal wall

d. Covering raw cartilage edges with skin

Voice Restoration After Total Laryngectomy

Vikas Mehta

Introduction

Although nonsurgical methods such as electrolarynx and esophageal speech are available for patients, tracheoesophageal puncture (TEP) is considered the best means of voice restoration after total laryngectomy (TL). A TEP allows a patient to channel air from the lungs through a puncture site in the posterior wall of the trachea, into the esophagus up through the pharynx, where the mucosa acts as a vibrating apparatus and into the oral cavity, where the air is modulated by articulatory mechanisms to produce phonation. TEP has gained in popularity over the past several decades due to the superior speech produced when compared with other methods of communication for laryngectomy patients. Studies in numerous patients who have had a TL reveal that functional indwelling voice prostheses greatly improve the quality of life for the patient, possibly even to a level higher than for those who undergo organ-preservation protocols.[1] Currently, there are several companies that manufacture the prostheses, with InHealth (Carpinteria, CA) making the Blom-Singer device, which is the most widely used in the United States, and Atos Medical (Malmo, Sweden) manufacturing the Provox devices, which are more widely used internationally.

The procedure can be performed either primarily during the TL or secondarily after the patient has healed well, each carrying its own advantages. Primary TEP, performed at the time of the TL, avoids a second operation and allows for more rapid return of phonation. Secondary TEP is often chosen if the patient is considered at high risk for postoperative fistula formation or wound breakdown, which can be complicated by the insertion of an indwelling foreign body into the

fistula tract in the newly created stoma. Often, the considerations are multifactorial and depend on the comfort level and guiding practices of the surgeon, speech language pathology (SLP) team, and patient.

Historically, the TEP was performed as a secondary procedure under anesthesia with the insertion of a catheter to establish the tract, followed by the prosthesis being inserted a week or two late, after the fistula had sufficiently matured. However, techniques have evolved, with well-established evidence supporting primary and secondary insertion of the prosthesis immediately at the time of puncture and the ability to perform a secondary puncture in an office setting to avoid anesthesia and save costs. Thus there are few TEP exclusion criteria for TL patients: (1) physical limitations (i.e., stroke, musculoskeletal disorders, amputations) that preclude manipulation and covering the stoma during phonation, (2) financial considerations with reimbursement and care/maintenance of the prosthesis, (3) access to an speech language pathologist (SLP) who is comfortable with TEP voicing instruction, teaching care for the puncture site, and replacing the prosthesis, and (4) need for concomitant total glossectomy. The author believes that TEP should be offered to all TL patients who do not meet the exclusion criteria because voice restoration with TEP is superior to both electrolarynx and esophageal speech and can dramatically improve the TL patient's quality of life (QOL), function, and psychosocial well-being.

Key Operative Learning Points

- TEP can be done primarily or secondarily.
  - The primary approach is preferred if the patient is undergoing primary surgical management for advanced-stage cancer.
  - Secondary can be used if there are concerns for healing in patients who have had radiation therapy to the neck.
- Insertion of the prosthesis at the time of puncture allows for immediate voicing and avoids the possible dislodgement of the catheter used to keep the fistula patent.
- SLP consultation is essential to achieving and sustaining functional phonation with the TEP.

- Direct visualization of the puncture or placement of a pharyngeal protector is important for avoiding inadvertent violation of the posterior esophageal wall.

Preoperative Period

TEP was traditionally performed as a secondary procedure after the patient had healed from the TL because of concern for increased fistula formation and wound breakdown with a primary puncture. Healing issues are especially prevalent in the salvage setting, where pharyngocutaneous fistula rates can be as high as 33%.[2] However, recent data suggest that the placement of vascularized tissue as part of the pharyngeal reconstruction can reduce fistula formation.[3] More current studies have suggested there are not increased complications with primary TEP placement, regardless of whether the surgery is being performed primarily or in a salvage setting[4,5] and that TEPs can be used and are still effective when microvascular tissue or rotational flap reconstructions are used.[6] However, if the surgeon and his or her team are more comfortable with secondary placement, the procedure can easily be performed in the operating room or office, depending on the availability of equipment, anesthetic risk due to medical comorbidities, and patient financial/travel constraints. For the office setting, a transnasal esophagoscope (TNE) is an absolute requirement to obtain adequate visualization via insufflation. To perform the procedure in the operating room, the patient must be able to tolerate general anesthesia from a cardiopulmonary standpoint.

The first step in decision making should involve an assessment by both the surgeon and the SLP regarding the patient's candidacy. If the patient will be unable to care for and/or use his or her prosthesis due to physical or financial limitations, a TEP should not be undertaken. Although the need for using the thumb to occlude the stoma can be avoided with a secondary valve that covers the stoma, the patient needs to have the ability to adequately clean and care for his or her prosthesis and stoma. The procedure does carry a minimal chance of significant complications, including the risk of aspiration and death from an enlarging, nonhealing fistula and should be avoided if the patient is not a good candidate. Although changing prostheses can be done by either the surgeon or the

SLP, having an SLP who is trained in working with TEPs and TL patients is tantamount to achieving phonation. Before the TL itself, having the SLP meet with the patient and discuss what is involved with using and maintaining the prosthesis is essential for obtaining informed consent. In addition, showing patients pictures and a video helps to establish realistic expectations and eases anxiety about having the larynx removed.

The next step is to decide whether a primary or secondary puncture will be performed. I prefer to perform primary TEP insertion for all TL patients and strongly supports using this approach when a primary TL is being done, as opposed to the salvage setting where the decision can be left to surgeon preference. For a secondary puncture, if the patient is at high risk for complication from general anesthesia or has poor access secondary to trismus, poor neck extension, or other anatomic limitations, then an in-office procedure has been demonstrated to be very effective. If the surgeon does not have a TNE scope available or the patient cannot tolerate the in-office procedure due to anxiety, then performing the procedure in the operating room (OR) can be undertaken. I prefer to place the actual prosthesis at the time of the puncture, regardless of whether in the primary or secondary setting, because this decreases the risk of dislodgement and need for a repeat procedure.

History

1. History of present illness
   a. Interest in obtaining TEP
   b. If secondary TEP, time since laryngectomy and additional procedures performed at the time of surgery (i.e., free flap or rotational flap reconstruction, cricopharyngeal myotomy, glossectomy, pharyngectomy)
   c. Preference regarding in-office versus operating room
   d. Reasonable expectations regarding phonation
   e. Dysphagia
   f. Prior use of electrolarynx or esophageal speech
   g. History of pharyngocutaneous fistula after laryngectomy
2. Past medical history

a. Previous neck surgery

b. Previous radiation to the head and neck

c. Prior esophageal disease

d. History of severe gastroesophageal reflux disease

3. Medical illness

a. Cardiopulmonary disease precluding general anesthesia

4. Medications

a. Anticoagulants

b. Alcohol (risk of perioperative alcohol withdrawal syndrome)

c. Allergies to antibiotics

5. Mental and social status

a. Ability to give informed consent and care for the prosthesis

b. Financial ability/health insurance status to pay for supplies and replacement prostheses

Physical Examination

1. Primary TEP

a. Determine primary site and extent of the tumor

1) Larynx

a) Extension to subglottis and/or trachea

b) Extension into pharynx that may require extensive reconstruction

c) Involvement of the base of the tongue that may require sacrifice of one or both hypoglossal nerves

2) Trachea

a) If there has been a prior tracheostomy, need to identify where the tracheostomy was placed to determine adequate length and to plan for stomal placement

3) Cranial nerve function

2. Secondary TEP
    a. Stoma
        1) Adequate size and patency for placing, changing, and cleaning TEP
        2) Ability to perform digital occlusion of the stoma
        3) Wound healing from laryngectomy
        4) Presence of additional soft tissue from reconstructive procedures that may make digital occlusion challenging
    b. Examination of the head and neck
        1) Perform a transnasal esophagoscopy if in-office secondary TEP being considered
        2) Trismus and neck extension if secondary TEP being considered
3. General health
    a. Nutrition
    b. Cardiovascular
    c. Respiratory
    d. Mental—ability to use and maintain the TEP is key to the success of the procedure

Imaging

1. Chest radiograph
    a. Metastases
    b. Synchronous lung cancer
    c. Pulmonary and cardiac status
2. Computed tomography (CT) scan of the neck with contrast
    a. Only in the setting of primary TEP to determine the extent of the laryngeal cancer
3. Modified barium swallow study
    a. With concurrent dysphagia, rule out cricopharyngeal dysfunction

Indications

- Primary TL for advanced stage laryngeal cancer
- History of TL for secondary TEP

Contraindications

1. Patient factors
   a. Physical limitations (i.e., stroke, musculoskeletal disorders especially advanced rheumatoid arthritis, amputations of digits) that preclude manipulation and occluding the stoma during phonation
   b. Mental limitations that will prevent informed consent and/or impair the use and care of the TEP
   c. Financial limitations that will prevent the patient from obtaining new prostheses/supplies or attending scheduled appointments
   d. Secondary TEP in the OR may not be possible due to severe trismus or limited extension of the neck.
   e. Significant stenosis of the neopharynx
2. Tumor factors
   a. Surgery will require total glossectomy in addition to TL because understandable speech will not be produced.
   b. Gastric pull-up required
3. Surgical factors
   a. In-office TEP requires the use of a TNE.

Preoperative Preparation

1. Evaluations by
   a. Surgeon
   b. SLP
   c. Anesthesiologist (if the procedure is done in the OR)

2. Discontinue antiplatelet drugs if possible.

Operative Period

Primary Tracheoesophageal Puncture

Anesthesia

- General anesthesia will be used for a TL.
- For further specification, please refer to the TL chapter.

Positioning

- See TL chapter.

Perioperative Antibiotic Prophylaxis

- See TL chapter.

Monitoring

- Routine anesthesia monitoring

Instruments and Equipment to Have Available

- Various insertion kits are available (Fig. 25.1).
  - Puncture needle with catheter
  - Guidewire
  - Prosthesis—16 French, 10 mm in length
  - 2-0 silk suture
  - Pharyngeal protector if available

Key Anatomic Landmarks

- Trachea—puncture site should be approximately 5 mm to 1 cm below the superior portion of the tracheostoma
- Esophagus
- Cricopharyngeal muscle

Operative Risks

- False passage
- Injury to cervical esophagus
- Placing the TEP too close to the superior edge of the stoma

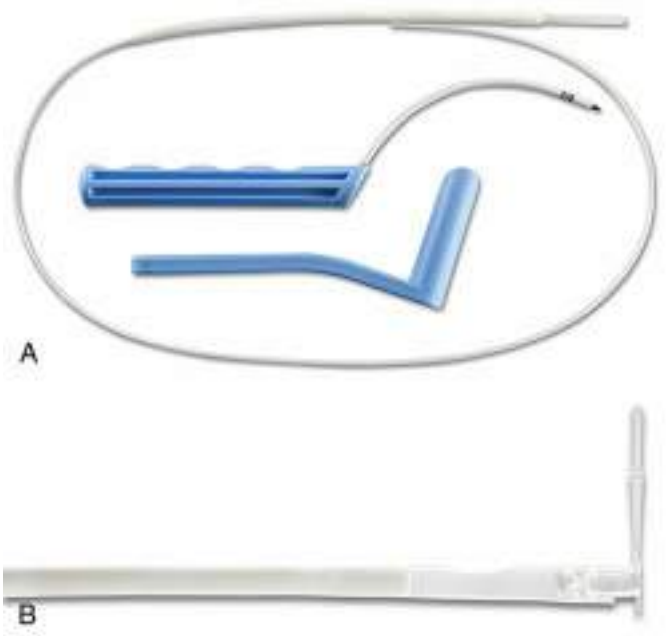

FIG. 25.1 **A,** The contents of a typical insertion kit are displayed. **B,** the prosthesis is loaded and ready for deployment.

Prerequisite Skills

- TL

Surgical Technique

- After TL and neck dissections have been performed but before neopharyngeal closure (Fig. 25.2).
- Insert nasogastric feeding tube if patient does not have a gastrostomy tube.
- Identify the cricopharyngeal muscle on the upper esophageal inlet, and transect the muscle with a #15 blade in several places, taking care not to violate the esophageal mucosa.
- Secure the prosthesis to the guidewire either by suture or use the prefabricated mechanism provided with the kit. If the guidewire is attached to a feeding tube, it will need to be cut about midway up the feeding tube, and the prosthesis is sutured to the feeding tube in two points to ensure that it is secured to the tube.
- Place the pharyngeal protector or an instrument within the esophagus from the opened pharynx.
- Puncture the trachea approximately 0.5 to 1 cm below the superior edge and pass through the party wall, taking care to not enter the posterior esophageal wall.
- Remove the needle, leaving the catheter in place within the puncture site.
- Pass the guidewire through the catheter from the pharyngeal side into the esophagus and then out the tracheal side of the puncture.
- Gently tease the phalange of the prosthesis out on the tracheal side of the puncture, taking care to not pull the entire prosthesis through.
- Confirm that the prosthesis phalanges are present on the esophageal side by either visualization or palpation.

Common Errors in Technique

- Failure to transect the cricopharyngeus muscle
- Pulling too hard on the guidewire and accidentally pulling the prosthesis all the way through
- Improperly securing the prosthesis

- Passing the guidewire from the wrong side
- Puncturing the posterior wall of the esophagus
- Placing the TEP either too close to the superior edge of the stoma or too deep within the trachea impairing the function or making the prosthesis difficult to access for maintenance and changing purposes

Secondary Tracheoesophageal Puncture in the Operating Room

Anesthesia

- General anesthesia is given (Fig. 25.3).
- The anesthesiologist should be advised that the endotracheal tube will periodically be removed during the procedure.

Positioning

- The bed can be turned 90 or 180 degrees from the anesthesia cart, facilitating access to the patient's mouth and keeping the anesthesia tubing out of the way.

Perioperative Antibiotic Prophylaxis

- None necessary

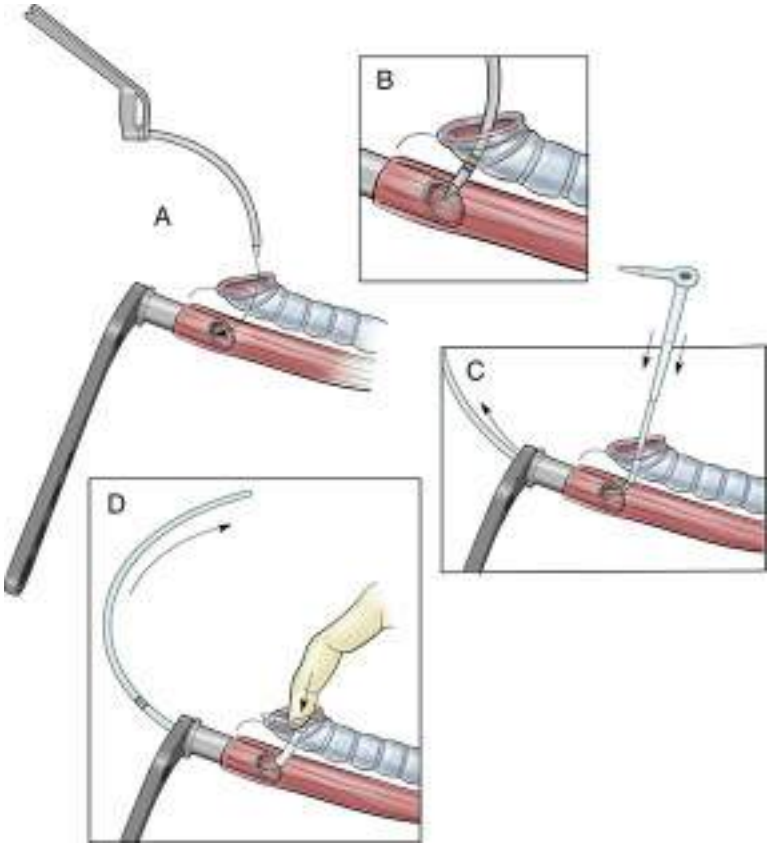

FIG. 25.2 Drawings demonstrating the steps of a primary insertion.

A, Pharyngeal protector is placed inside the upper esophagus, and the needle/catheter is inserted from the trachea into the esophagus/pharyngeal protector. **B,** The colored bands help determine the width of the party wall and can guide in selecting the size of the prosthesis. Typically, 16-Fr 10 mm is chosen in the primary tracheoesophageal puncture setting. **C,** The prosthesis is loaded onto the guidewire. The needle is withdrawn, and the wire is passed into the catheter. **D,** The prosthesis is deployed within the puncture site.

Monitoring

- Routine anesthesia monitoring
- The patient can be paralyzed if necessary to gain access.

Instruments and Equipment to Have Available

- Rigid esophagoscope of sufficient length to reach the stoma
- Long grasper capable of extending beyond the length of the esophagoscope
- Tooth guard
- Puncture kit
  - Puncture needle with catheter
  - Guidewire
  - Prosthesis—16 French, 10 mm in length
  - 2-0 silk suture

Key Anatomic Landmarks

- Esophageal inlet
- Stoma

Prerequisite Skills

- Rigid esophagoscopy

Surgical Technique

- Place the tooth guard on the maxillary dentition, or if the patient is edentulous place a moistened sponge on the upper alveolar ridge.
- Introduce the rigid esophagoscope into the patient's mouth, with the bevel facing down, and advance it until the assistant sees the light and/or palpates the scope at the level of the stoma.
- Turn the bevel of the esophagoscope so that the bevel faces up to allow the longer end of the scope to protect the posterior wall of the esophagus.
- Have the assistant palpate the esophagoscope from the trachea and place pressure at the spot where he or she will place the TEP. The surgeon at the head of the OR table should be able to view the spot where the TEP will be placed through the esophagoscope.

- The assistant then places a needle with the catheter through the back of the tracheal wall, approximately 0.5 to 1 cm below the superior edge of the stoma.
- The surgeon will visualize the needle entering the esophageal mucosa and will direct the assistant to advance into the lumen of the esophagoscope.
- The assistant then withdraws the needle, leaving the catheter in place. The guidewire is then passed through the catheter, and the surgeon visualizes it coming into the esophagoscope.
- The surgeon then grasps the wire and pulls it out through the mouth.
- If the kit used has a mechanism in place for attaching the prosthesis to the guidewire, it can be deployed into the puncture site from the tracheal side.
- If the kit used simply has a feeding tube attached the wire, the wire is cut off the feeding tube outside the mouth, and the prosthesis is secured to the tube using a 2-0 silk suture at two points and then placed from the esophageal side with the phalanges gently teased out of the tracheal side, as with the primary TEP.
- Placement is confirmed by direct visualization of the prosthesis.

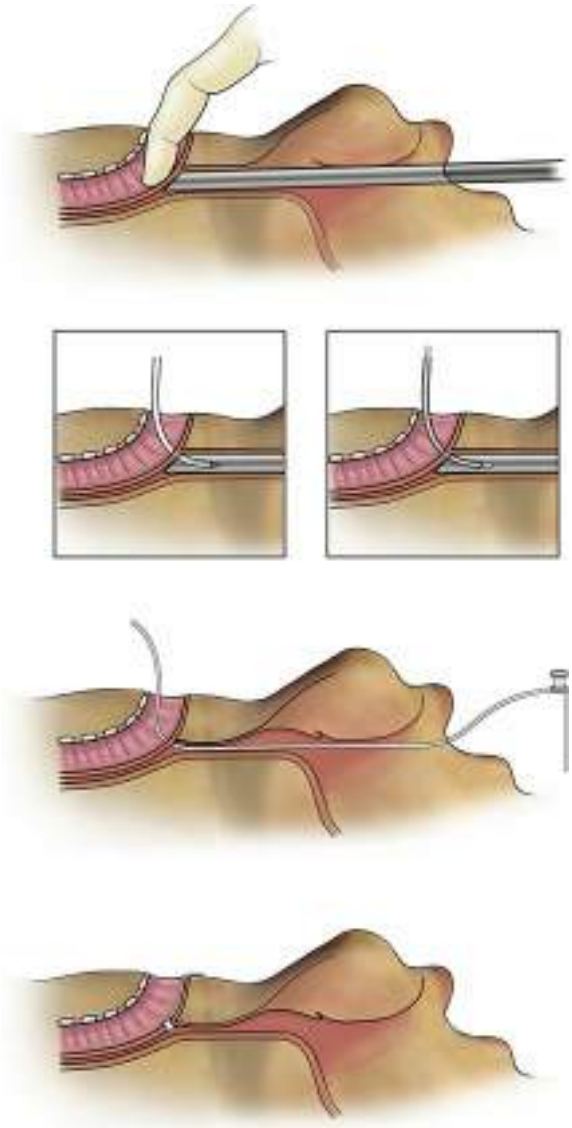

FIG. 25.3 Figure depicting the insertion of the esophagoscope and introduction of the needle into the esophagoscope. The steps of insertion are then similar to the primary technique.

Common Errors in Technique

- Failure to visualize the potential spot of placement prior to introduction
- Accidentally withdrawing the catheter with the needle creating a fistula
- Injuring the posterior wall of the esophagus

Secondary Tracheoesophageal Puncture (In-Office)

Anesthesia

- The nasal cavity is anesthetized and decongested with topical 4% lidocaine and 1% neosynephrine (Fig. 25.4).
- The tracheostoma is also sprayed with topical 4% lidocaine solution.
- Less than 1 mL of 1% lidocaine with 1:100,000 parts epinephrine is injected into the posterior wall of the trachea at the proposed puncture site.
- Five milliliters of viscous 2% lidocaine is also applied to the base of the tongue for several minutes and then swallowed by the patient. Nebulized lidocaine can also be used if available.

Positioning

- The surgery is performed with the patient sitting in the examination chair.

Perioperative Antibiotic Prophylaxis

- Not indicated

Monitoring

- Not indicated

Instruments and Equipment to Have Available

- TNE
- 22-gauge needle
- A scalpel with a #11 blade
- Hemostat

- 18-Fr TEP dilator
- Prosthesis sizer
- Standard insertion system present in TEP changing kits

Key Anatomic Landmarks

- Stoma
- Esophageal inlet

Prerequisite Skills

- Transnasal esophagoscopy

Surgical Technique

- After applying the anesthesia as detailed previously, the TNE is passed from the nasopharynx into the cervical esophagus.
- The esophagus is insufflated.
- The 22-gauge needle is placed through the proposed puncture site into the esophagus under direct TNE visualization.
- The #11 blade is then used to make a stab incision next to the needle and can be turned 180 degrees to enlarge the opening.
- The hemostat is then passed through the stab incision and spread widely.
- The puncture site is then dilated, and the sizer is used to estimate the appropriate size prosthesis to be placed.
- The voice prosthesis is then placed using the introducer contained within the kit.

Common Errors in Technique

- Failure to properly visualize the puncture site
- Wrong sizing of TEP

- Inadequate topical anesthesia
- Injury to the posterior wall of the esophagus
- Creating a false tract due to poor visualization of the puncture site/instrumentation

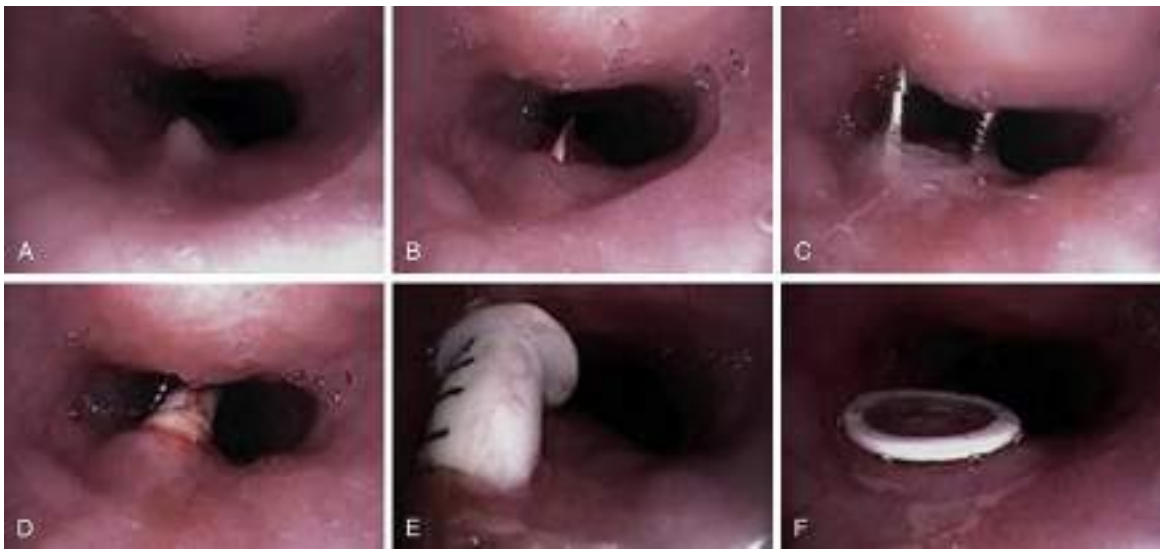

FIG. 25.4 View of surgical steps as seen from the transnasal esophagoscope.

A, A 22-gauge needle is placed at proposed tracheoesophageal puncture (TEP) site. **B,** A #11 blade is passed through the party wall into esophageal lumen. **C,** Hemostat is spread widely within puncture site. **D,** 18-French TEP dilator is passed through puncture site. **E,** TEP prosthesis sizer is placed to determine the size of prosthesis. **F,** Prosthesis is placed and visualized.

Postoperative Period

- Antibiotics are not indicated for the TEP.
- The patient can be discharged on a regular diet if a secondary TEP is placed.
- The patient may start using the prosthesis immediately if a secondary TEP is placed.

- If primary TEP, I suggest waiting until the wounds are fully matured before attempting speech because the extra pressure can place undue strain on the pharyngeal closure.
- SLP consultation is essential to the success of the TEP and should be used immediately.

Complications

- False tract
- Cricopharyngeal spasm—should be identified preoperatively, if possible, and can be avoided if a cricopharyngeal myotomy is performed at the time of the laryngectomy. If cricopharyngeal dysfunction is noted, it can be addressed with an endoscopic myotomy or an injection of botulinum toxin.
- Enlarging of the fistula tract—occurs in approximately 7% of patients.[7] This can be addressed by inserting a larger prosthesis or injecting collagen into the enlarging area to shrink the fistula tract. Provox tends to make larger prostheses that can be used for this purpose. If this is not possible, the fistula may need to be closed with a rotational or microvascular flap reconstruction. Failure to address a tracheoesophageal fistula can lead to severe aspiration and death.
- Migration of the prosthesis/overgrowth of the mucosa. This can be caused by a contact granuloma on the esophageal or tracheal side and can result in dislodgement of the prosthesis. Careful attention should be paid to any granulomatous changes seen on examination and should be addressed with cauterization/removal.
- Esophageal injury during placement—can lead to mediastinitis
- If the TEP falls out, it may not be replaced in time, resulting in closure of the fistula. Often, if the patient realizes it has been removed within 24 hours, the tract can be dilated and a catheter or prosthesis can be reinserted to establish the fistula tract. However, if the tract closes fully, the patient may require another puncture.
- Occasionally, the TEP dislodges and becomes inhaled into the trachea or bronchial tree, requiring bronchoscopy for removal.

Alternative Management Plan

The patient can learn to use an electrolarynx or esophageal speech. Esophageal speech is difficult to learn and occurs successfully in only a minority of patients. As mentioned previously, TEP speech consistently performs better than the other modalities in terms of function and effect on patient QOL.

Discussion

Evidence-Based Medicine Question

What are the risks and benefits of inserting a TEP at the time of laryngectomy?

Primary TEP is a safe and successful procedure that is generally preferable in patients receiving TL as the initial treatment for cancer of the larynx. Historically, TEP speech-outcome success rates were reported to be greater than 80%, with primary TEP speech-outcome success rate reported as high as 93% to 96% and secondary TEP speech-outcome success rate listed as 78% to 83%.[8,9] More recently, the success rates of TEPs have been overall lower, likely due to the increase in the relative percentage of salvage laryngectomies performed. However, primary TEP still maintains a slightly higher success rate with equivalent complication rates.[5] In larger series, primary TEP has not been shown to increase the rates of pharyngocutaneous fistula,[10] and it has been successful in both the salvage setting[4,5] and when free flap reconstruction is used.[6] The benefits of performing the TEP at the time of the TL are that the patient avoids a second operation and the patient experiences a more rapid return of phonation.

Editorial Comment

When I was a resident, esophageal speech was the only means of voice restoration following TL. The technique was usually taught by laryngectomies who volunteered their services. Unfortunately, few of the patients learned to speak intelligibly. The study carried out by Dr.

George Gates[11] on esophageal speakers indicated that less than 20% of laryngectomies were successful in using esophageal speech to communicate, thereby relegating the remainder of laryngectomy patients to a lifetime of communicating by writing (if they knew how), gesticulating, and using buccal speech, which was not very understandable.

Over the years several forms of vibrating devices, such as the electrolarynx, were developed, which when held against the neck and activated produced relatively understandable speech. A variation on this theme was a device called the "Talking Teeth," which incorporated the vibrating element in an upper denture. The voice was judged to be like Darth Vader and never became popular. The Cooper Rand device used a different mechanism, in which a small tube was inserted into the mouth and, when activated by a handheld device, air was blown into the mouth when the patient was articulating, thereby producing reasonably understandable speech.

It was a real "game changer" for laryngectomies when more than three decades ago Eric Blom, Ph.D., a SLP, and Mark Singer M.D., an otolaryngologist, introduced the voice prosthesis that is known as the Blom-Singer valve.[2] A small hollow tube is introduced through the posterior wall of the trachea and into the cervical esophagus after the larynx has been removed. By occluding the tracheostoma with the thumb, a voice is produced by pulmonary-driven air, resulting in highly understandable speech and thereby restoring the patient's ability to communicate. The quality of life was remarkably enhanced through this simple mechanism of forcing pulmonary driven air into the mouth through the pharynx. TEP speech consistently performs better than any of the mechanical devices. The importance of the participation of the SPL in this process cannot be overestimated. They provide help in improving articulation and in teaching the patient to be able to install the valve him or herself.

Blom and Singer originally described this procedure as a secondary one, performed several months after the laryngectomy wound had healed. In my practice, I followed this same scheme until a patient was referred to me for a laryngectomy, and when I described the benefit of having the second operation to install the TEP he said, "Dr. Myers, my wife is an invalid and I'm the sole source of her care and I need my voice

right away when I go home so why can't you just put the valve in when you take out my voice box?" I could not think of any reason why I could not, so I did successfully, and the primary TEP was born. The obvious benefits of the primary TEP are that it avoids a second operation, and it provides the patient with a rapid return of his or her ability to communicate vocally.

Eugene N. Myers

Review Questions

1. Which of the following methods of voice restoration would be best for a patient who has a history of a total laryngectomy (TL) for advanced laryngeal cancer with a mouth opening of 2.5 cm?

   a. Secondary TEP in the OR

   b. **Secondary TEP in-office**

   c. Electrolarynx

   d. Esophageal speech

2. All of the following are contraindications to performing a tracheoesophageal puncture (TEP), except

   a. **Partial pharyngectomy requiring free flap reconstruction**

   b. History of stroke with poor upper limb function/strength

   c. Total glossectomy

   d. History of severe schizophrenia preventing care of the prosthesis

3. All of the following are complications of performing a TEP, except

   a. Enlarging tract causing aspiration

   b. Posterior esophageal wall injury leading to mediastinitis

   c. **Tumor seeding of the esophagus**

   d. Overgrowth of the esophageal mucosa preventing phonation

Closure of the Tracheoesophageal Fistula Site

Phillip Huyett, and Eugene N. Myers

Introduction

Speech restoration is of great significance for the social and economic welfare of patients who undergo total laryngectomy.[1] As outlined in Chapter 75, Voice Restoration After Total Laryngectomy, speech restoration is most often accomplished with the use of the electrolarynx or by placement of a primary or secondary tracheoesophageal puncture (TEP), allowing for esophageal speech. More than 80% of patients with a TEP develop intelligible speech and voice restoration with a TEP, and is of superior quality to that of the electrolarynx.[2-4] Although most patients do well with their tracheoesophageal speech, there are certain problems associated with the valve[5-7]:

- Poorly fitting valve leading to frequent displacement
- Spontaneous closure of the fistula following loss of the valve
- Aspiration of the valve into the tracheobronchial tree
- Leakage of saliva and food into the tracheobronchial tree
- Aspiration pneumonia from severe leakage, which could be life threatening in patients with pre-existing chronic lung disease
- Yeast infection of the valve[8]
- Lack of patient acceptance of the valve

Many of these problems can be successfully managed with medical therapy, adjustment of the prosthesis itself, or by narrowing the tracheoesophageal fistula with injectable materials. In the minority of patients, the decision is made to remove the TEP due to continued

complications related to the valve or fistula or simply patient preference. Given that a well-formed tracheoesophageal fistula is epithelialized circumferentially, the tract does not necessarily close spontaneously after prosthesis removal, especially when the fistula is large or in the patient who has been radiated, is malnourished, or continues to smoke heavily. This chapter describes the technique for definitive closure of the fistula after valve removal.

Key Operative Learning Points

- Conservative measures of closure for salivary leakage such as TEP site injections and size adjustments of the prosthesis should be tried before definitive surgical closure.
- Efforts to improve swallowing and voicing by pharyngoesophageal dilation, cricopharyngeus myotomy, or Botox treatment should be exhausted before closing the TEP in patients who are dissatisfied with their voice or swallowing ability.
- Patients need to be counseled about alternative methods of communication such as the electrolarynx and esophageal speech.

Preoperative Period

History

History of Present Illness

- The patient who has had a total laryngectomy generally has long-term care with the head and neck surgeon and speech language pathologist.
- The patient will often present in follow-up with speech or swallowing problems, a prosthesis that repeatedly becomes dislodged, or a history of recurrent aspiration pneumonias.

Past Medical History

- Past medical history

    - Prior interventions for improvement of speech, swallowing, and leakage
    - Serious comorbidities
- Cancer treatment history
    - Date of total laryngectomy and TEP placement
    - Use of radiation therapy before or after total laryngectomy
- Social history
    - Continued alcohol and tobacco use
    - Assess voice use goals in social and professional settings.
- Medications
    - Use of anticoagulants
    - Use of herbal products

Physical Examination

- A complete examination of the head and neck is performed to rule out peristomal recurrence or second primary malignancies as a cause for TEP site complications.
- Evaluation of the fit of the TEP, often performed in conjunction with the speech language pathologist
- Evaluate the size of the laryngectomy stoma and the relative location of the TEP.
- Assess the quality of the peristomal tissues, especially in the radiated patient.

Imaging/Diagnostics

- No imaging is indicated if the patient is undergoing closure of the tracheoesophageal fistula for leakage.
- A fluoroscopic evaluation of the pharynx and esophagus may be useful in evaluation of the total laryngectomy patient with difficulty voicing and/or swallowing.

Indications

- The absolute indication for closure of the TEP is severe leakage with aspiration. Most salivary leakage responds to conservative measures such as reduction in the size of the valve to allow shrinkage of the fistulous tract. Cauterization of the fistula has also been used to promote shrinkage of the tract.[9]
- Another indication for surgical closure of a TEP is poor voicing refractory to optimal teaching, therapy, and treatment of underlying etiologies. Poor voicing may be caused by spasm of the cricopharyngeus muscle or pharyngeal stenosis. Treatment for these conditions includes Botox injection of the cricopharyngeus muscle, cricopharyngeal myotomy, cervical neurectomy, dilation, and pharyngoplasty (Chapter 54).
- We have also encountered a few patients who have none of the previously listed problems but simply wanted the fistula closed because they either did not like the idea of a fistula and the valve or just did not like the quality of their voice.
- We have been doing primary TEPs at the time of total laryngectomy since shortly after the introduction of the Singer-Blom valve. We try to carefully select patients who we feel would not succeed with a Singer-Blom valve, such as those who have poor manual dexterity (e.g., rheumatoid arthritis), low level of motivation, chronic neurologic syndrome, and inability to maintain the prosthesis.

Contraindications

- Proceeding to closure of the TEP without prior attempts to troubleshoot leakage, speech, and swallowing problems more conservatively. Patients whose stoma has been heavily radiated

Preoperative Preparation

- Patients who are candidates for closure of the TEP should be counseled by the speech language pathologist about the use of alternative methods of communication, such as the electrolarynx or esophageal

speech.

- If the stoma is quite small, then stomaplasty should be included at the time of the closure of the TEP. The technique of stomaplasty, which includes creation of a small local flap in the superior aspect of the stoma, is described in Chapter 83.[10] If the size of the fistula is quite large or the TEP is located superiorly near the cutaneous junction, then stomaplasty with a flap is not feasible. Patients who have a stoma that has been heavily radiated present a unique problem. These patients do not tend to do well when stomaplasty is performed and have marked difficulty in healing.

Operative Period

Anesthesia

- Local anesthesia
- General anesthesia with small flexible endotracheal tube (anode tube)

Positioning

- Supine, shoulder roll to improve visualization
- Prep and drape the neck.

Perioperative Antibiotic Prophylaxis

- No antibiotics are indicated.

Monitoring

- No routine monitoring is indicated.

Instruments and Equipment

- Standard head and neck set

Key Anatomic Landmarks

- Tracheostoma
- Tracheoesophageal party wall
- Tracheoesophageal fistula tract
- Esophagus

Prerequisite Skills

- Total laryngectomy
- TEP (Chapter 25)

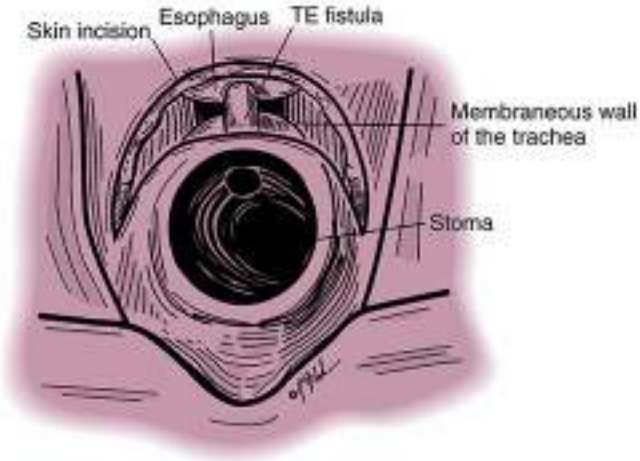

FIG. 26.2 Exposure of the fistula. Reprinted with permission from Hosal SA, Myers EN: Closure of tracheoesophageal puncture site. *Head Neck* 23:215, 2001.

Operative Risks

- Failure of closure to heal, especially in the radiated patient

Surgical Technique

- The area that surrounds the superior aspect of the tracheostoma is infiltrated with 1% lidocaine with epinephrine 1:100,000.
- An incision is made in the mucocutaneous junction of the tracheal stoma from the 9-o'clock to the 3-o'clock position (Fig. 26.1).
- The posterior wall of the trachea is undermined inferiorly and separated from the esophagus down to and just beyond the tracheoesophageal fistula (Fig. 26.2).
- The tracheoesophageal tract is divided and the mucosa of the esophagus is closed with inverted interrupted sutures using 4-0 absorbable Vicryl on a P-2 (small circle) lacrimal needle (Figs. 26.3 and 26.4).
- A multiple-layer closure of the esophageal fistula is carried out to prevent leakage.
- Subsequently, the mucosa of the tracheal lumen is freshened and

closed with everted sutures in a single layer with the same suture material. After the complete closure, the stomal incision is closed without a drain.

- Rosen et al. describe a technique for closure of TEP, which is performed under general anesthesia with a small flexible endotracheal tube.[1] A

34F dilator is introduced into the esophagus to elevate the tracheoesophageal party wall. A circumferential circular incision is made in the tracheal mucosa 2 to 3 mm lateral to the fistula. The tracheal mucosa is undermined toward the center of the fistula and then inverted into the esophageal lumen and sutured closed. A tracheal mucosal flap is created. A 3- × 3-cm thin dermis graft from the thigh is trimmed to size and sutured in to resurface the trachea.

- Issing et al. followed up on 103 patients with total laryngectomy and voice rehabilitation, three of whom eventually required closure of the TEP because of severe leakage. The authors state that the TEP was closed with muscle skin flaps, but details of the surgical technique were not described.
- Annyas and Escajadillo described a technique in which an interposition dermal graft was placed between the trachea and the esophagus, with separate skin incisions just superior to the stoma.
- Various soft tissue flaps have been described in the closure of a TEP site, including deltopectoral flap, sternocleidomastoid muscle flap, and radial forearm free flap. These techniques are particularly useful in the radiated total laryngectomy patient.

Common Errors in Technique

- Every effort should be made to ensure proper patient selection so that the degree of satisfaction with the valve is as high as possible.
- Patients with only a mild degree of difficulty in voicing may also be dissatisfied with closure because they will have no voice at all.
- Patients who have been heavily radiated to the stoma have a major risk of not healing and may require major reconstructive surgery if this is carried out.
- Patients should not return to a regular diet immediately, because this may disrupt the wound.
- Patients who have been heavily radiated may undergo closure of the TEP fistula, but muscle should be interposed between the trachea and esophagus because the radiation interferes with healing and an even larger fistula may be produced. This unfortunate complication would

require major reconstructive surgery.

Postoperative Period

Postoperative Management

- The patients are usually discharged the day of the surgery.
- The patient is encouraged to keep the area of the stoma clean and apply antibiotic ointment to the incision.
- The patient is encouraged to eat a puréed diet for 1 week and then progress to a normal diet over the next few weeks.

Complications

- Failure of tracheoesophageal fistula closure

Alternative Management Plan

- The TEP site can be temporarily closed with the placement of a septal button. This will simulate aphonia for the patient, but in the long term the epithelialized tract is maintained and may lead to continued problems.

Discussion

Evidence-Based Medicine Question

What is the incidence of enlarging TEP site following total laryngectomy and TEP placement?

A systematic review conducted by Hutcheson and co-authors (5) in 2011 found the mean incidence of TEP site enlargement after total laryngectomy and TEP to be 7.2% (range 1-29% across 23 primary articles). TEP diameter and timing of the TEP were not found to be statistically predictive of TEP site enlargement. The use of radiation therapy was not reported consistently in the articles reviewed which

ranged from 1978 to 2008. In the same year, the MD Anderson group published their 5-year experience and found that 18.6% of patients (36/194) had enlargement of the TEP site (6). The most common resulting complications were pneumonia and aspiration of the TEP device. Two patients eventually required complete TEP site closure, the remainder were managed successfully with conservative measures including upsizing of the prosthesis, TEP site injection or temporary device removal.

Editorial Comment

Eric Blom and Mark Singer introduced the "Surgical Prosthetic Approach for Post-Laryngectomy Voice Restoration" in 1979 and changed the world for laryngectomy patients. Prior to this innovation, which requires the establishment of a tracheoesophageal fistula with the insertion of a tiny valve, the patient with a laryngectomy only had the choice of learning esophageal speech or using an electrolarynx. Less than 20% of patients are able to communicate satisfactorily with esophageal speech, and while most could communicate satisfactorily with an electrolarynx, it had the significant downside of the patient having to hold the device in one hand, thereby presenting the problem of being aphonic while working with two hands. The quality of the voice was poor and described by patients as sounding like a robot.

More than 80% of patients using the Singer-Blom valve develop intelligible speech, producing results superior to the electrolarynx in terms of the quality of the voice. However, there are certain problems associated with the valve directly or indirectly and with the tracheoesophageal fistula. These are listed in the introduction to this chapter. Otolaryngologists and speech language pathologists, who work most directly with these patients, have become quite nimble in being able to solve these problems as they arise.

There are a small percentage of patients who for one reason or another no longer want to use the valve. Since the tracheoesophageal fistula is epithelialized circumferentially, it usually does not close spontaneously when the valve is removed. The technique described here was developed by the senior author as a solution to the problem. It is simple and addresses closure of the fistula in a straightforward manner by restoring

the normal anatomy of the trachea and esophagus. We have had good results with this technique but offer a word of caution in patients who have had radiation to the stomal area. These cases require bringing in fresh tissue to strengthen the closure in order to avoid tissue necrosis and the creation of a larger fistula.

Eugene N. Myers

Review Questions

1. Which of the following is not an appropriate first step in the management of a leaking TEP without evidence of aspiration pneumonia?

   a. Upsizing the TEP device

   b. Injection of calcium hydroxyapatite or micronized Alloderm

   c. **Immediate surgical closure of the TEP site**

   d. Temporary closure with a septal button

2. What percentage of patients will not achieve satisfactory voicing with a TEP prosthesis in place?

   a. 0%

   b. **20%**

   c. 60%

   d. 80%

3. Which of the following is not an appropriate initial option in the management of a patient with a TEP and poor voicing and swallowing?

   a. Injection of Botox to the cricopharyngeus muscle

   b. Pharyngoesophageal dilation

   c. Cricopharyngeus myotomy

   d. **Immediate surgical closure of the TEP site**

4. Which method of speech rehabilitation following total laryngectomy results in the best voice quality?

   a. Esophageal speech

   b. **Tracheoesophageal speech**

   c. Esophageal speech

   d. American sign language

Cancer of the Lip

Jeffrey A Steitz, and Paul Tennant

Introduction

The lip is the most common site of origin for squamous cell carcinoma of the oral cavity. Unlike other cancers of the oral cavity, the etiology and clinical outcomes of squamous cell carcinoma more closely resemble squamous cell carcinoma of the skin. Cancer of the lips accounts for 0.6% of all malignancies diagnosed in the United States. The primary risk factor for cancer of the lip is sun exposure. As with other skin malignancies, fair skin complexion increases the risk for lip cancer. A study of Canadian farmers showed that these sun-exposed workers had a threefold increased risk of cancer of the lip compared with people with indoor occupations after controlling for smoking history. Also implicating the powerful role of sun exposure in development of cancer of the lip is the finding that cancer of the lip is 40 times more prevalent on the external than the inner lip.[1,2]

The risk of cancer of the lip increases with age; the average age at diagnosis is in the sixth decade of life. The lower lip is 12 times more likely to be affected than the upper lip, as it sustains greater exposure to sunlight. Of all cancers of the lip, squamous cell carcinoma represents the vast majority. A large epidemiological analysis revealed that up to 95% of nonmelanoma cancers of the lower lip are squamous cell carcinoma. Basal cell carcinoma, the second most common nonmelanoma cancer of the lip, is more likely to be found on the external upper lip and in females. Other types of cancer occur less commonly on the lip, including malignant melanoma and malignant tumors of minor salivary gland origin, such as adenoid cystic carcinoma and adenocarcinoma.[2]

The role of human papillomavirus in the development of squamous cell carcinoma of the head and neck continues to be clarified, but no

evidence has been found to date that implicates this virus as a cause of lip cancer. Immunosuppressed populations are at significantly increased risk for lip cancer. Patients who have undergone kidney transplant have a 30-fold increased risk on account of immunosuppressive antirejection drug regimens. The degree of immunosuppression appears to be important, as patients on higher doses demonstrate a higher risk of skin cancer than patients on low-dose regimens. Patients with HIV infection also have a greater risk for development of lip cancer.[3]

Patients with lip cancers generally present at an early stage, as the location is a cosmetically obvious area. Tumors less than 2 cm in size (T1 stage) account for 75% to 80% of lip cancer diagnoses. The staging guidelines for cancer of the lip follow the guidelines for cancer of the oral cavity. These patients generally do well, and surgical excision is curative. In the current literature, the reported 5-year survival rates in patients with squamous cell cancer of the lip without lymph node metastases are between 85% and 99%. A small number of patients present with more advanced primary cancers, characterized by invasion into deeper structures.

While patients with cancer of the lip without cervical metastasis can expect excellent rates of survival, the prognosis is guarded for patients who have lymph node metastasis; the survival rate for these patients decreases to 25% to 50%. Therefore, identification and management of occult neck metastasis are critical. A number of prognostic factors for lymph node metastasis for squamous cell carcinoma of the lip have previously been reported: tumor size/T-stage, tumor grade, depth of invasion, perineural invasion, extreme mitotic activity, positive surgical margins, commissure involvement, and local recurrence.

Management of the N0 neck is controversial; the recent literature has suggested that "high-risk" patients should receive consideration for management of the regional lymphatic basin. Sentinel lymph node biopsy is a surgical option already widely applied as a tool to assess the at-risk lymph node basin in skin cancer. Its role in treatment of squamous cell carcinoma of the oral cavity is also gaining acceptance. This option is especially attractive in lip cancer, as the primary tumor is readily accessible for injection of radioisotope and small neck incisions minimize interference with reconstructive options for the lip.

A chapter on cancer of the lip is incomplete without addressing

reconstructive techniques. Reconstruction of defects of the lip can be complex, especially when resection involves the vermillion border or oral commissure. Reconstructive techniques are used to minimize microstomia, retain oral competence, and optimize the cosmetic result. While reconstruction of the lip can be complex, there are several basic principles to guide the surgeon toward the appropriate technique.[4,5]

- Defects amounting to one-half of the lip can and should be closed primarily.
- Meticulous reapproximation of the vermillion border should be achieved.
- If greater than one-half of the lip is resected, consideration should be given to advancement flaps or "lip-switch" procedures (described later).
- If resection involves the oral commissure, the Estlander flap can be used.
- For larger resections (greater than two-thirds), local tissue rearrangement is possible with the Karapandzic flap; however, consideration should be also given to free tissue transfer techniques.

Surgical technique is described as follows for the aforementioned types of lip reconstruction.

Key Operative Learning Points

1. Discuss ablative techniques for removal of cancer of the lip with consideration of optimal reconstruction.

2. Understand the reconstructive ladder and how it may be used in reconstruction of the lip.

3. For full-thickness reconstruction of the lip involving greater than two-thirds of the lip, consideration of the use of free tissue transfer should also be given.

Preoperative Period

History

1. History of present illness
    a. Approximate date of onset of lesion
        1) Many patients present early in the course of the disease; a smaller number of patients may present with deep invasion and ulceration present.
    b. Skin changes elsewhere on the face, neck, or body
        1) History of severe sunburns or radiation exposure
        2) History of chronic sun exposure (e.g., farmers)
    c. Numbness/hypesthesia of the lip or chin
2. Past medical history
    a. Medical illness
        1) Medical or immunologic immunosuppression
        2) Prior history of other head and neck malignancy
    b. Surgery
        1) Previous head or neck surgery
            a) Primarily focusing on the lower face and neck
        2) History of organ transplant, especially renal transplants indicating immunosuppression
        3) Any other surgeries that may indicate a patient may be high risk for operative intervention
    c. Family history
        1) Cutaneous malignancies
        2) Coagulopathy
    d. Medications
        1) Anticoagulation with antiplatelet agents or NSAID use
        2) Herbal supplementation
        3) Alcohol use

4) Immunosuppressive medications

Physical Examination

1. Palpation and examination of the lip lesion
   a. Location
      1) Involvement of the upper or lower lip
      2) Involvement or extension beyond the vermillion border
      3) Involvement of the oral commissure
   b. Characteristics of the lesion
      1) Ulceration
      2) Depth of invasion
         a) Extension into surrounding subcutaneous tissues or muscle
         b) Perineural involvement of the mental nerve may present as hypesthesia/paresthesia of the chin or lower lip
   c. Examination of the neck
      1) Assess for lymphadenopathy in the neck
         a) Upper lip with primary lymphatic drainage patterns to levels Ia and Ib
         b) Lower lip with primary lymphatic drainage patterns to levels Ia, Ib, and jugulodigastric chain
         c) Cancers involving the upper lip or oral commissure are more likely to have lymphatic spread.
         d) Most lymphatic metastases to the neck are isolated to levels I–III (Fig. 27.1).
      2) Any previous surgical incisions

Imaging

None—Routine imaging is not recommended for early stage cancers.

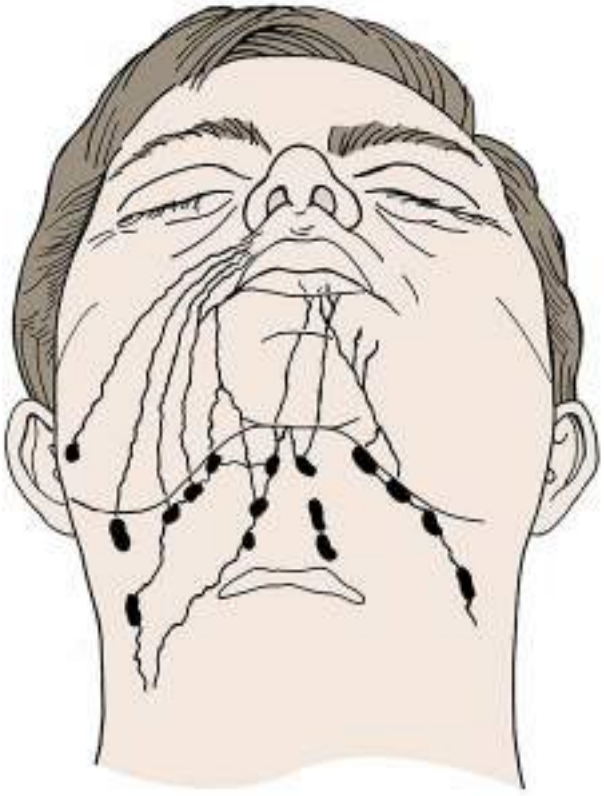

FIG. 27.1 Lymphatic drainage pathways of the lip.

Computed tomography (CT) scan is a commonly performed imaging modality for advanced stage cancer not only to assess characteristics of the primary site but also to assess for lymphadenopathy within the neck.

Magnetic resonance imaging (MRI) has similar ability to detect pathologic cervical lymphadenopathy as CT and ultrasound. If there is concern for perineural or bony invasion, MRI is a more sensitive study.

Positron emission tomography CT scan—Ultrasound has been shown to be equally effective in identifying pathologic cervical lymphadenopathy as CT scan and MRI. In some centers, it is the study of choice due to lower cost and lack of radiation exposure.

Indications

1. Biopsy proven malignancy of the upper or lower lip

2. Sentinel lymph node biopsy or elective neck dissection may be considered in patients who have risk factors for regional metastasis.

3. Therapeutic neck dissection is indicated when clinical evidence of

regional metastasis is prevent.

Contraindications

1. Distant metastatic disease

2. Prohibitive medical risk

Preoperative Preparation

1. Adequate assessment of lymphadenopathy and surgical planning regarding whether and how to address the at-risk lymphatic basin

2. Appropriate patient counseling regarding risk of microstomia and oral competence

Operative Period

Anesthesia

General: Preferred method for patient comfort and protection of the airway if there is active bleeding

Monitored anesthesia care (MAC)

Local anesthesia

Positioning

Supine: In addition to supine positioning, proper neck extension and shoulder roll placement are important if sentinel lymph node biopsy or neck dissection is to be performed in conjunction with excision of the primary.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin: We prefer cefazolin, 1 mg if under 75 kg, 2 mg if greater than 75 kg.

Second-generation cephalosporin

Clindamycin if allergic to penicillins

Monitoring

If neck dissection is performed in conjunction, avoid long-acting paralytic agents until all pertinent cranial nerves are identified.

Instruments and Equipment to Have Available

1. Basic head and neck surgery set

2. Plastic surgery set

3. If sentinel lymph node biopsy is performed, gamma probe would be necessary, and injectable dye such as isosulfan blue is optional.

Key Anatomic Landmarks

1. Superior and inferior labial arteries lie deep to the vermillion border of the upper and lower lip.

   a. This is especially important when resection is performed. These vessels should be manually compressed to minimize hemorrhage as the incision is carried through the lip.

2. Vermillion border—The junction between the squamous mucosa of the upper/lower lip and the stratified squamous epithelium of the epidermis. This border is especially important in reconstruction for optimal cosmesis.

3. Wet-dry line—The junction between the keratinized squamous mucosa of the body of the lip and the nonkeratinized labial mucosa

Prerequisite Skills

1. General skin and soft tissue dissection

2. Sentinel lymph node excision techniques (if performed)

3. Selective or therapeutic neck dissection (if performed)

Operative Risks

1. Intraoperative bleeding

2. Postoperative infection

3. Microstomia

4. Loss of oral competence, which may lead to drooling

5. Hypesthesia or paresthesia of the lower face, depending on the extent of resection

6. Poor cosmetic outcome

Surgical Technique

Ablative Surgery

- Lip resection
  - Degree of lip resection is dependent upon the pathologic basis of disease.
    - Squamous cell carcinoma is the predominant malignancy of the upper and lower lip. Unlike other sites in the oral cavity, margins of less than 1 cm are routinely planned. Many surgeons rely on frozen section analysis for intraoperative margin assessment. The lip is a cosmetically sensitive area, but the malignancy must be removed with adequate surgical margins.
    - Basal cell carcinoma is the second most common malignancy of the lip; 3-mm margins are usually sufficient for this type of malignancy.
    - Melanoma may occur, though rarely, on the lip. The management of melanoma is dependent on tumor thickness and other pathologic characteristics, similar to other subsites of the head and neck.

- When planning resection, it is important to consider options for reconstruction, which are discussed at length later. Design will focus on the shape of resection, whether it be wedge shaped or rectangular.
- First the incision is inked with a marking pen taking into consideration adequate margins of resection. The vermillion border is then scratched with the back of a #15 blade scalpel for later reapproximation.
- Incisions are made through the skin and subcutaneous soft tissue with a #11 or #15 blade scalpel.
- Once the skin incisions are made, the upper or lower lip is manually grasped lateral to the incision to tamponade bleeding. Bovie or 3-0 silk ties can be used for hemostasis.
- Frozen sections may be sent either from the specimen itself or from selected margins taken from the patient.

- Lymphadenectomy
  - Degree of cervical lymphadenectomy will be dependent on presence of pathologic lymphadenopathy as well as the characteristics of the primary lesion.
  - Usually a selective neck dissection of levels 1 to 3 will be adequate, but this is dependent on site of lymphatic metastases. The lower lip has bilateral lymphatic drainage pattern, and cancers of the lip involving the midline occur commonly.

Lip Reconstruction

- Defects less than half of the lip
  - If the resection is less than half of the lower or upper lip, this defect can be reapproximated primarily (Fig. 27.2A to C).
  - Any necessary undermining and hemostasis should be obtained prior to reapproximation.
  - First step should be to reapproximate the vermillion border of the lip. We prefer a simple 6-0 prolene suture for reapproximation.
  - A multilayer closure is then performed, first reapproximating the

orbicularis oris muscle to recreate the oral sphincter, followed by the subcutaneous tissue and skin. We prefer a horizontal mattress suture for adequate eversion of the skin and mucosa of the lip to optimize long-term cosmetic outcome. Alternatively a vertical mattress technique can be used.

- Defects affecting one-half to two-thirds of the lip
  - Advancement flaps
    - For advancement flaps, the resection bed should have a rectangular configuration.
    - For the lower lip, horizontal releasing incisions are made from the inferior aspect of the resection. Wide undermining performed overlying the orbicularis oris muscle. Burrow's triangles are then excised for an optimal result (Fig. 27.3A to C).

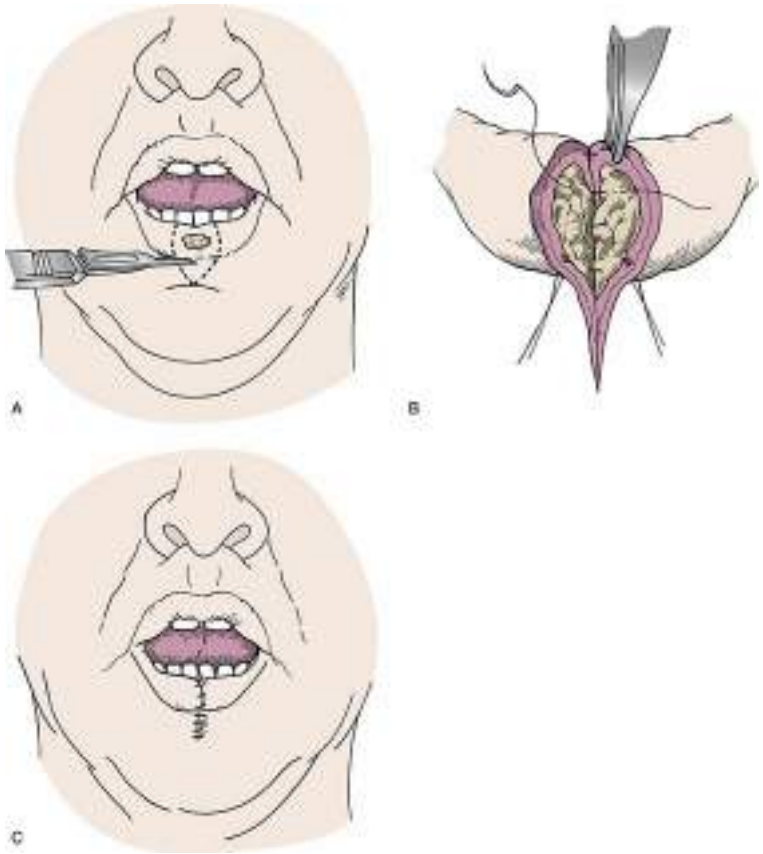

FIG. 27.2 **A,** Wedge incision is used for excision of lower lip lesion. **B,** The skin, muscle, and mucosa are closed, minimizing tension. **C,** Closure includes accurate

reapproximation of the vermillion border and eversion of skin and lip edges.

- Undermining the mucosa is often necessary for closure.
- Once undermining is complete, a multilayer closure is performed as described previously.
- Similarly, bilateral advancement flaps may be used in upper lip reconstruction. Incisions are carried from the edge of the resection in the perialar region, remaining mindful of the facial subunits. This allows for cheek advancement for closure of defect. This technique is used in lesions that involve the central upper lip as opposed to lateral lip. The use of Burrow's triangles is mandatory in upper lip excisions.

- Abbe flap (Fig. 27.4A to D)
  - The Abbe flap is a "lip switch" flap from the unaffected to the affected lip. The neurovascular supply is based on branches of the superior and inferior labial arteries, which lie immediately deep to the vermillion border.

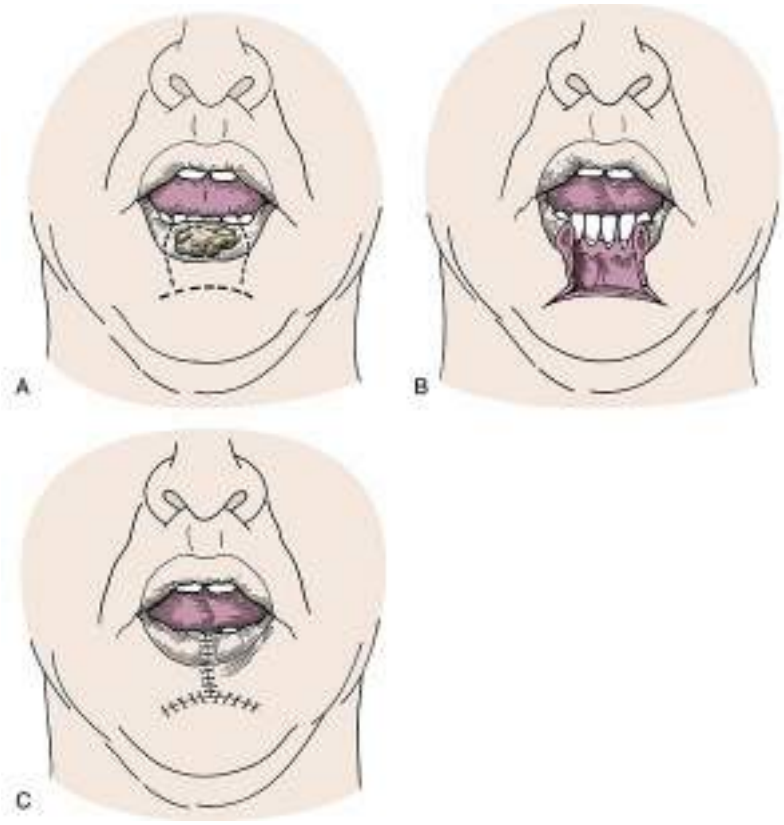

FIG. 27.3 **A,** Rectangular resection designed in preparation for horizontal advancement flaps. **B,** Relaxing incisions are made horizontally (not shown would be Burrow's triangle excisions). **C,** Wound closure.

FIG. 27.4 **A,** Extensive cancer of the upper lip. **B,** Defect

following excision. **C,** Defect reconstructed with an Abbe flap and cheek advancement flaps facilitated by use of Burrow's triangles. **D,** Appearance after release and inset of the Abbe flap.

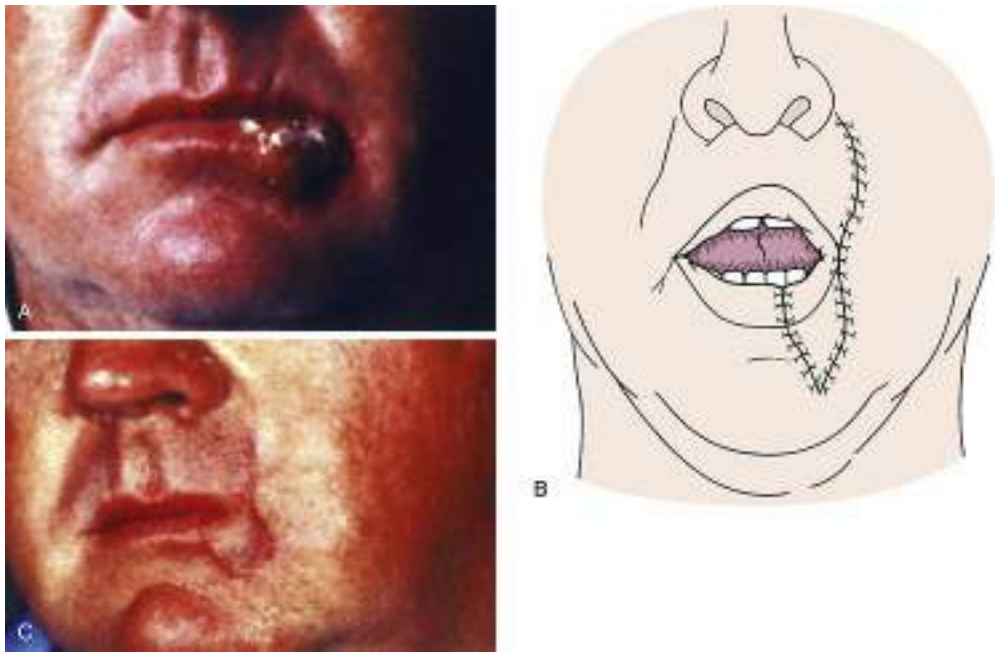

FIG. 27.5 **A,** Recurrent squamous cell carcinoma of the lower lip involving oral commissure. **B,** Scheme for an Estlander flap. **C,** Acceptable cosmetic and functional results at the commissure with an Estlander flap.

- In harvesting the flap, the height of the defect should determine the height of the harvested flap. If undermining can be performed of the skin surrounding the defect, this should be performed to minimize the amount of soft tissue required to fill the defect.
- The width of the flap should be half the size of the defect, reducing the length of each lip equally.
- Once the flap has been appropriately designed and marked on the skin, incisions are made through skin, lip, and mucosa, leaving an attachment to the lip laterally. The lateral attachment will serve as the vascular supply to the flap.
- The superior and inferior labial arteries lie deep to the vermillion border, and care must be taken to preserve this vessel at the base of the flap.

- Once the flap has been harvested, it is repositioned into the resection bed, and a multilayer closure is performed with careful attention given to reapproximation of the vermillion border.
- The pedicle is then divided after 2 to 3 weeks, erring on the longer side in active smokers.

- Estlander flap (Fig. 27.5A to C)
  - The Estlander flap is another "lip switch" flap from the unaffected to the affected lip. This flap is laterally based and utilizes the oral commissure.
  - Similar to the Abbe flap, the vascular pedicle is based on branches of the superior or inferior labial arteries.
  - The height of the flap should match the height of the defect. The width should approximate half of the defect of the recipient site.
  - Once the flap design is complete, incisions are made through skin, lip, and mucosa in order to elevate the flap. Care is taken to the leave attachment to the unaffected lip, as this is the attachment to the vascular pedicle. Hemostasis is obtained with bipolar cautery.
  - Once the flap has been raised and rotated into the defect, multilayer closure is performed, paying close attention to reapproximation of the vermillion border.
  - While pedicle division is not required, as this flap is laterally based, some rounding of the oral commissure may occur, which may require commissuroplasty. The authors recommend waiting at least 3 months before to performing commissuroplasty.

- Karapandzic flap (Fig. 27.6A to E)
  - While theoretically suitable for both upper and lower lip reconstruction, the Karapandzic flap is most suitable to central, rectangular defects of the lower lip. This may produce profound microstomia, but by maintaining neurovascular supply to the orbicular oris muscle, oral competence is usually maintained.
  - This is a rotation-advancement cheek flap based on the superior or inferior labial arteries.
  - Curvilinear incisions are made toward the base of the alae in the nasolabial fold, encompassing the superior or inferior labial

arteries. The orbicularis oris and skin paddle are then undermined toward the base of the flap. Care is taken not to disturb the neurovascular attachments of the skin paddle to the orbicularis oris muscle.

- Minor undermining and elevation of the mucosa may be necessary.
- The flaps are then rotated toward midline and reapproximated centrally. A multilayer closure is performed with close attention paid to reapproximation of the vermillion border.

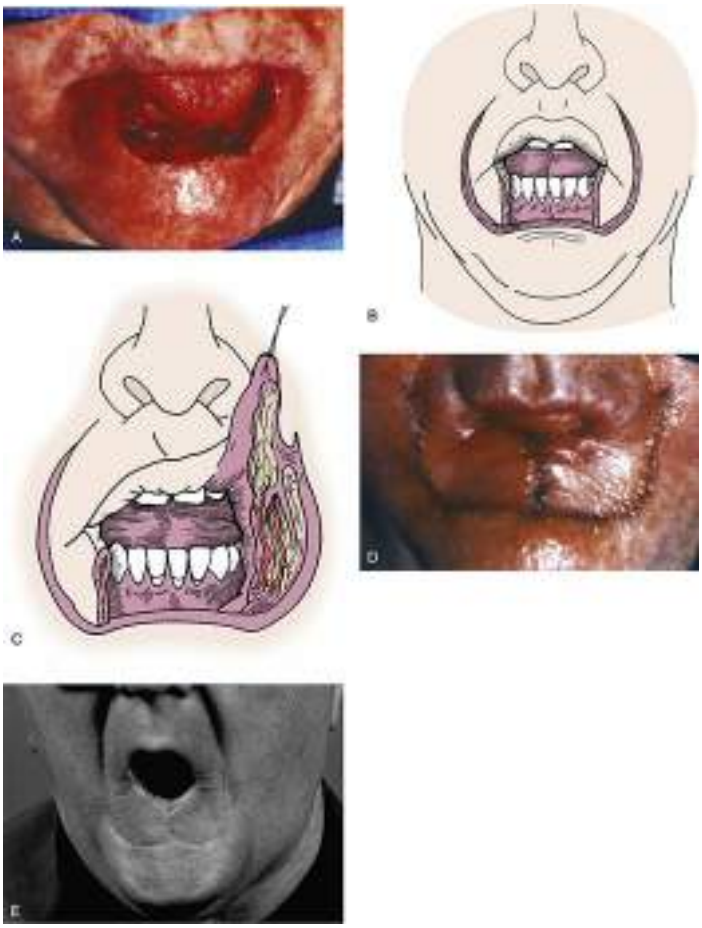

FIG. 27.6 **A,** Defect after excision of a cancer of the lower lip. **B,** Karapandzic flaps incised. **C,** Flaps incorporate new vascular components. **D,** The flaps are advanced and closed in multiple layers. **E,** Long-term result after Karapandzic flap reconstruction.

- Defects greater than two-thirds of the lip
  - Bernard-Burrow-Webster flap
    - The Bernard-Burrow-Webster flap is another cheek advancement flap for large defects of the lower lip. It is most suitable for central, rectangular defects with the oral commissures intact.
    - Horizontal incisions are extended from the oral commissure out laterally, as well as from the inferior aspect of the defect. The length of each incision should approximate 50% of the size of the defect for adequate closure.
    - Once the horizontal incisions are made, Burrows triangles are excised at the superior incisions for adequate mobilization of cheek tissue. Burrows triangles may be removed from the inferior incisions, but usually this is not necessary due to mobility of lower cheek skin.
    - The skin and subcutaneous soft tissue are then undermined without lifting or removing the orbicularis oris muscle.
    - Similarly, horizontal incisions are made in the mucosa for advancement of the mucosal edges. Undermining of the mucosa is performed in order to close it primarily in the midline. This may not be necessary if used in smaller defects.
    - A multilayer closure is then performed.
    - The vermillion border can be recreated the using a mucosal advancement flap.
  - Full thickness nasolabial transposition flap
    - Nasolabial transposition flaps can be used for large defects of the upper or lower lip. A unilateral flap can be used for reconstruction of a laterally based defect of the upper or lower lip. Bilateral flaps can be harvested in order to reconstruct subtotal defects.
    - This is an axial flap based on branches of the angular artery.
    - Incisions are designed in the nasolabial groove of the affected side of the face. The nasolabial flap can be superiorly or inferiorly based, whichever best suits the reconstruction.
    - The incision is carried down through the skin and subcutaneous

soft tissue, taking care not to incise the orbicular oris or other facial mimetic muscles. Undermining is then performed, and the nasolabial flap is rotated into the surgical defect.

- Multilayer closure is then performed.
- The vermillion border can be recreated using a mucosal advancement flap.

- Free tissue transfer
  - With refinements in technique and success rates greater than 95% with free tissue transfer, consideration may be given toward free flap reconstruction of large full-thickness lip defects.
  - In surgical planning for free tissue transfer, the radial forearm free flap has the most appropriate tissue match for lower lip defects. The thickness of the flap as well as the ability to cover both the mucosal and skin surfaces makes it an excellent donor site for full-thickness defects (Fig. 27.7A and B).
  - The palmaris longus tendon can be harvested with the fasciocutaneous paddle as a composite flap. This tendon can then be secured to the orbicularis oris muscle bilaterally, which restores oral competence.
  - Further discussion on free tissue transfer and reconstruction is outside the scope of this chapter. Refer to Chapter 162 for details on free tissue transfer.

FIG. 27.7 **A,** Large cancer of the lip marked with ink pen including frozen section margins. **B,** Postoperative result from radial forearm free tissue transfer.

Common Errors in Technique

1. Direct pressure should be placed over the superior or inferior labial artery while incisions are made. If this is not done, there will be an increase in intraoperative blood loss as well as staining of tissues.

2. Consideration toward reconstruction should be done prior to making incisions, as the shape of the defect created will alter reconstructive technique utilized.

Postoperative Period

Postoperative Management

1. A single dose of intraoperative antibiotics is used. No long-term antibiotic is necessary. Some surgeons advocate for 24 hours of antibiotics following surgery, due to contamination with oral flora.

2. Chlorhexidine mouthwash used for 7 to 10 days following surgery, 3 times daily

3. The incisions should be cleaned with a 50:50 mixture of peroxide and water twice daily. Bacitracin should be applied to the incisions twice daily for 3 to 5 days.

4. Sutures are removed 1 week after the procedure.

5. Patients will be kept on a full liquid diet for up to 48 hours postoperatively, followed by advancement to a soft diet for 7 to 10 days. Patients who undergo a lip-switch procedure will require a liquid diet until division of the pedicle takes place.

Complications

1. Bleeding, less than 1% risk

2. Infection, less than 1% risk if intraoperative antibiotics are given

3. Skin/lip necrosis

Alternative Management Plan

While surgery is the mainstay of management, consideration can be given toward radiation therapy for patients who are not surgical candidates, though outcomes are not as good compared with surgery.

Discussion

Evidence-Based Medicine Question

What is the incidence of occult nodal metastasis in lip cancer?

While the incidence of nodal metastasis is dependent on tumor grade and pathologic characteristics of the primary site, several easily identified factors contribute significantly to occult nodal metastasis in the neck. It has been shown that occult metastases are much more likely in T3 and T4 tumors, especially with involvement of the oral commissure. The overall incidence approaches just over 20%. In these cancers, it is recommended to perform a supra-omohyoid (level 1 to 3) neck dissection due to the high risk of occult metastasis.

Editorial Comment

Paramount to the appropriate management of lip cancers is attaining tumor-free margins, having a reconstructive plan that optimizes form and function, appropriate assessment and management of the neck, and risk factor–driven application of adjuvant radiation and chemotherapy. Intraoperative frozen section examination of margins improves confidence in securing negative margins. Reconstruction, in principle, should attempt to retain or restore the sphincteric function of the lip and oral competence. Primary reconstruction with local, regional, or microvascular free flaps may need to be supplemented with secondary commisuroplasty operations in order to enhance oral competence and appearance. Surgical attention to detail is imperative in optimizing cosmesis. Additional scar revision procedures may complement primary reconstructive efforts. In general, squamous cell carcinoma with limited depth of invasion (less than 4 mm) has a lower risk of nodal involvement in the N0 neck. Recurrent cancers, cancers with greater than 4 mm depth of invasion, and cancers with ulceration have higher rates of occult nodal disease. Level Ia, Ib, and the jugular chain nodes of levels II and III are the most common nodal basins involved in lip cancer. Selective node dissection of these basins provides important prognostic information in high-risk cases. Sentinel lymph node biopsy using radiopharmaceuticals such as Technetium 99m-sulfur colloid and supravital dyes (i.e., lymphazuran) may be particularly useful in lip cancers, due to the technical ease of injection in these anterior lesions. Sentinel lymph node biopsy should be used judiciously and may be less reliable in larger T3 and T4 lesions. Adjuvant radiation therapy should be delivered in cases in which final margins are positive or close (within 2 mm), lymphovascular or perineural invasion are present, or multiple lymph

nodes are positive. Chemotherapy is indicated in cases exhibiting positive margins or extracapsular spread in nodal disease. Tumor surveillance and survivorship issues are vitally important. Close follow-up with physical examination for local and regional recurrence is of greatest value. Patients with lip cancer may require psychologic and social support after management, due to changes in appearance and function.

Review Questions

1. For a central lower lip defect that involves less than 50% of the lip, sparing the oral commissure, what is the ideal reconstruction?

   a. Radial forearm free flap

   b. Karapandzic flap

   c. **Primary closure**

   d. Estlander flap

2. For a laterally based upper lip defect that approximates 50% of the upper lip, abutting the philtrum but sparing the oral commissure, what is the ideal reconstruction?

   a. **Nasolabial transposition flap**

   b. Perialar crescentic advancement flaps

   c. Primary closure

   d. Abbe flap

3. For a centrally based upper lip defect that involves the philtrum and approximates 50% of the upper lip, what is the ideal reconstruction?

   a. Primary closure

   b. **Perialar crescentic advancement flaps**

   c. Bilateral transposed nasolabial flap

   d. Abbe flap

28

Partial Glossectomy

Miriam N Lango

Introduction

Cancer of the tongue is most common in 60- to 70-year-old male drinkers and smokers but is also encountered in much younger and older individuals without a history of smoking or ethanol use. Most cancers of the tongue are squamous cell carcinomas, which arise on the lateral aspect of the tongue and exhibit a propensity for early spread to the lymph nodes of the neck. Early stage cancers (stages 1 and 2) are equally well controlled with surgery or radiation; however, surgery is associated with less long-term side effects. For advanced cancer, multiple treatment modalities, most commonly surgery followed by radiation, are usually necessary.

In evaluating a patient with a newly diagnosed cancer of the tongue, several questions must be addressed prior to surgery: (1) How extensive is the cancer, and can it be removed through the mouth? (2) Has the cancer spread to the lymph nodes of the neck, and what type of neck dissection, if any, should be undertaken? (3) After the cancer is removed, should the defect be reconstructed?

The office examination and selected radiographic studies are important in assigning an initial tumor stage. The physical examination provides important information regarding the local extent of the cancer, both in its size and depth. Lymph node metastases can often be detected by careful palpation of the neck. Imaging studies such as computed tomography (CT) scans or magnetic resonance imaging (MRI) may identify invasion of the deep muscles of the tongue and small cervical lymph node metastases not appreciated on office examination alone, improve the accuracy of the initial tumor staging, and facilitate the development of a treatment plan.

Most early stage cancers of the tongue can be managed by means of a partial glossectomy and a neck dissection (Fig. 28.1A and B).[1] A larger, deeply infiltrating cancer may require greater exposure than that achieved through the mouth alone. A transcervical delivery or mandibulotomy may be necessary for an oncologically sound extirpation. Larger resections are also more likely to require surgical reconstruction, most often with microvascular transfer of soft tissue from the forearm or thigh to enhance healing and postoperative function. A neck dissection may be omitted in small tongue cancers with minimal invasion but is recommended for thicker cancers even in the absence of clinical or radiographic evidence of lymph node metastases, due to the high frequency of micrometastatic disease.[2-4] In a large randomized study, patients without detectable metastases prior to surgery who underwent elective neck dissection at the time of the surgery for cancer of the tongue had improved overall and cancer-related survival than those who waited until signs of metastatic disease became clinically evident.[5] Neck dissection is more effective earlier in the course of the disease.[6] Additional treatment such as radiation and chemotherapy is added based on the final pathologic review of the resected surgical specimen. Lymphoscintigraphy with sentinel lymph node biopsy effectively identifies micrometastases when performed by experienced surgeons and may be considered as an alternative to a selective neck dissection for cN0 oral cancer in some cases. However, while the survival benefit of selective neck dissection in this setting has been confirmed in a randomized clinical trial, the equivalence of sentinel lymph node biopsy to neck dissection has not.

The overall recurrence rate and survival after surgery for early stage cancer are favorable, with 85% to 90% 5-year rates of cancer-free survival reported. The presence of metastasis to lymph nodes in the neck decreases cancer-free survival rate by 50%, providing justification for additional treatment to improve outcome.[7]

Key Operative Learning Points

1. Preoperative staging helps in developing a suitable surgical treatment plan. Patients with stage 1 to 2 cancer of the tongue are usually managed with a partial glossectomy and selective neck dissection, including levels

I, II, III, and possibly IV. Sentinel lymph node biopsy may be considered as an alternative in select cases, as noted previously.

2. Inspection and palpation usually differentiate thin, minimally invasive cancers of the tongue (and those less than 2 to 3 mm thick) from more deeply infiltrating cancers that are associated with higher rates of cervical lymph node metastases.

3. Locally advanced cancers, particularly those classified as T4, with deep muscle invasion often require greater exposure than that afforded by a transoral approach. Transcervical delivery or manibulotomy may be needed. Bone invasion by cancer is an indication for a segmental mandibulectomy.

4. Imaging with CT or MRI scan confirms deep infiltration of tongue muscles (Fig. 28.2B) and is more accurate than clinical examination alone in identifying cervical metastases. The presence of metastatic cancer on imaging clinically upstages the cancer and requires a comprehensive rather than a selective neck dissection.

5. Infiltrative cancers may be more extensive than appreciated on inspection alone. Intraoperatively, the use of palpation to define the clinical extent of the cancer is critical in achieving an adequate resection margin and preventing incising into the cancer and a positive margin.

6. Most T1 and many T2 cancers of the oral tongue may be left open to heal without specific reconstruction (see Fig. 28.1B). Significant extension onto the ventral tongue and floor of the mouth suggests the need for reconstruction with a radial forearm fasciocutaneous flap or a split-thickness skin graft. For larger cancers requiring a hemiglossectomy or a subtotal glossectomy, microvascular soft tissue transfer is usually employed to enhance long-term function.

7. A close or positive margin is best managed if identified at the time of the initial surgery. Suspicion of a close or positive margin should prompt a complete, circumferential, peripheral, and deep margin assessment. Blue dye is used to ink the surgical defect on the patient side. An additional layer of soft tissue measuring 2 to 4 mm thick is excised and oriented, representing the new margin. A complete margin assessment will diminish the likelihood of a false negative margin and improve local control.

8. Careful ligation of the lingual artery at the posterior lateral glossectomy wound site may diminish the likelihood of a severe postoperative hemorrhage.

FIG. 28.1 **A,** Irregular plaque with raised edges suggests the depth of invasion is at least 2 to 3 mm. Palpation provides additional information regarding the depth of invasion. **B,** A partial glossectomy involves removing an adequate margin of mucosa and muscle. A partial glossectomy of the posterior oral tongue frequently does not require a formal reconstruction.

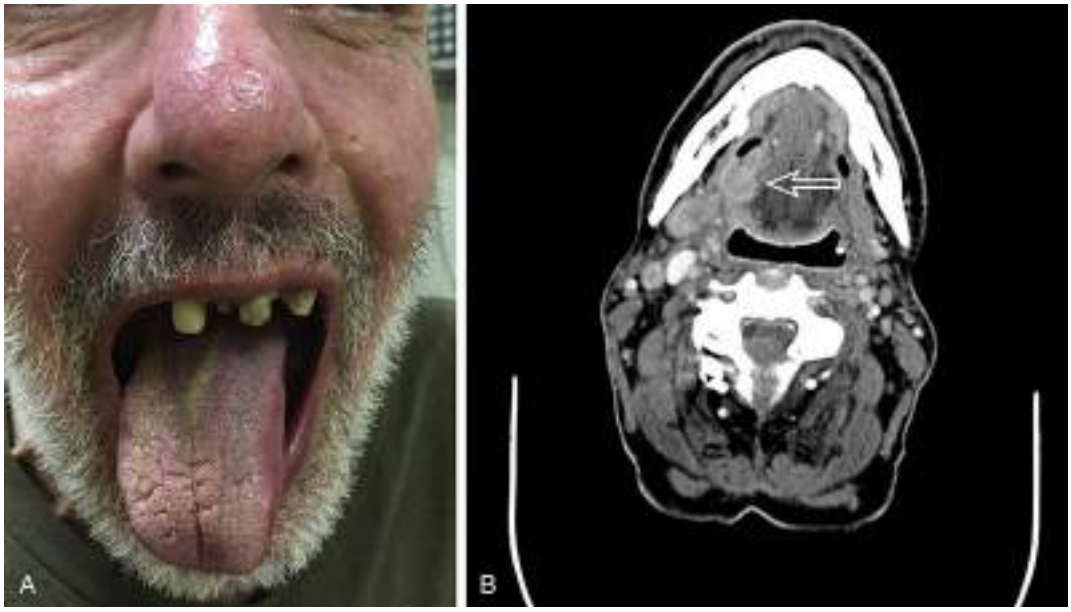

FIG. 28.2 **A,** Deviation of the tongue should raise concerns about deep infiltration of the cancer into the muscles of the tongue. **B,** CT scan confirms extension to involve the deep muscles of the tongue.

Preoperative Period

History

1. History of present illness

   a. The duration of an abnormal lesion on the tongue is a key element in the patient history. Was the abnormality found by the patient, a dentist, or on routine clinical examination? Has a biopsy been done?

   b. Associated symptoms and signs provide additional information about the abnormality.

      1) Is the ulcer or mass tender? The quality, timing, and duration of pain should be described. Cancer-related pain is dull and persistent over weeks or months, often described as "a sore." Is there associated otalgia, suggesting referred pain from deep infiltration

      2) Is there associated dysphagia? Has there been a change in the consistency of the diet? Has there been weight loss? Cancers

associated with a greater symptom burden prior to treatment are associated with worse survival, independent of initial tumor staging.[8]

3) Presence of dysarthria

4) Presence of a neck mass

c. Prior therapies or treatments and use of pain medication

d. Risk factors for tongue cancer, including current and prior smoking and ethanol use—particularly the amount

2. Past medical history

A complete past medical, surgical, and social history is a mandatory part of any preoperative assessment. Medical comorbid conditions can affect a patient's tolerance for surgery. In particular, symptoms of pulmonary and cardiac disease must be elicited. Detailed history of alcohol and tobacco use must be carefully reviewed. The social support available to a patient must also be assessed, as this will have a great impact on the patient's rehabilitation after surgery.

Physical Examination

1. Oral cavity (see Fig. 28.1A)

a. Size and depth of the cancer

b. Exophytic, infiltrative. or ulcerated cancer

c. Deviation of the tongue (see Fig. 28.2A)

d. Cancer extension to the floor of mouth

e. Presence and condition of dentition

f. Presence of trismus

g. Invasion of the mandible—via direct extension or by means of tooth sockets

2. Oropharynx

a. Base of tongue extension on palpation

3. Nasal cavity and nasopharynx

a. Mirror examination or endoscopy

4. Larynx and hypopharynx

a. Mirror examination or endoscopy

5. Neck

a. Cervical lymphadenopathy, including nodal size and level

Cancer of the tongue may appear as a beefy red patch or ulceration but can also originate in an area of leukoplakia (see Fig. 28.1A). Finger palpation of the area may suggest submucosal infiltration and extension. Deviation of the tongue suggests infiltration of the hypoglossal nerve or deep extrinsic muscle invasion (see Fig. 28.2A and B). A hard mass may be palpable under normal appearing mucosa of the ventral area and base of the tongue. Larger size and greater depth of invasion are associated with a higher risk of nodal metastases. Lateralized tongue cancers usually spread to the ipsilateral neck; however, as the cancer approaches the midline, the risk of contralateral metastases increases. Involvement of the anterior floor of mouth and base of tongue involvement are associated with higher frequencies of bilateral or contralateral lymph node metastases and prompt bilateral neck dissection.

Imaging

1. Chest radiograph

2. CT scan with intravenous contrast or MRI with gadolinium is indicated if deep muscle (extrinsic) muscle involvement or cervical metastatic disease is suspected. CT scans should be obtained if there is a concern about bone invasion.

Indications

1. T1-T2 oral tongue squamous cell carcinoma

2. Other tumors or cancers originating in the oral tongue

Contraindications

1. Patient does not consent

2. Locally advanced cancer—most T3 to T4 cancers require a hemiglossectomy or subtotal glossectomy

3. Unacceptable medical comorbidities

4. Poor functional status

5. Lack of social support

Preoperative Preparation

1. Chest radiograph and neck imaging as indicated

2. Evaluate alcohol use history and consider formal detoxification for patients with a high alcohol intake and a history of delirium tremens.

3. Tobacco cessation counseling for active smokers.

4. Discontinue antiplatelet drugs if possible.

5. Type and screen is not usually necessary.

6. Medical or anesthesia preoperative evaluation

7. Dental evaluation with extraction as needed

8. Review all medical records, especially biopsy and scans from outside hospitals

9. Consent

Speech and swallowing outcomes are best if patients adhere to speech and swallowing exercises after surgery. Consent for surgery should include counseling regarding the need for postoperative rehabilitation. Exercises to prevent trismus and preserve tongue mobility as well as neck and shoulder mobility are most effective if started prior to the development of chronic dysfunction. Routine perioperative consultation with speech pathology and physical therapy may enhance adherence with standard postoperative rehabilitation recommendations.

Operative Period

Anesthesia

Under a general anesthesia the patient is placed in the supine position.

Positioning

None necessary

Perioperative Antibiotic Prophylaxis

None necessary

Antibiotics may be withheld if no communication between the oral cavity and the neck is anticipated.

Monitoring

None necessary

Instruments and Equipment to Have Available

1. Neck dissection soft tissue set
2. Side mouth retractor/bite block
3. Guarded Bovie tip

Key Anatomic Landmarks

1. Lingual artery
2. Lingual nerve

Prerequisite Skills

1. Experience with diagnostic endoscopy

2. Experience with anatomy of oral cavity

3. Experience with neck dissection

Operative Risks

Intraoperative

1. Intraoperative hemorrhage from the lingual artery

2. Inadvertent communication with the neck dissection

3. Edema of the tongue

Intraoperative hemorrhage is rarely severe enough to require transfusion. Nevertheless, hemorrhage can hamper visualization. Early identification and ligation of the lingual artery is recommended. Electrocautery alone is usually not sufficient for hemostasis. Suspected communication with the neck contents should be managed with repair, antibiotics, and drain placement. Edema of the residual tongue is rare after partial glossectomy without reconstruction. An elective tracheostomy is recommended if a skin graft or microvascular reconstruction is planned.

Surgical Technique

Oral or nasal intubation by the anesthesia service may be used, depending on the need for exposure, the presence of dentition, the location and extent of the cancer, and the preference of the surgeon. Tracheostomy is rarely needed in the absence of skin grafts or microvascular soft tissue transfer reconstruction.

If microvascular reconstruction is planned, in which the oral cavity is in continuity with the neck, antibiotics with coverage against oral flora are indicated. Having the patient fully relaxed during this procedure is helpful in mouth opening and limiting tongue movement during electrocauterization.

Direct laryngoscopy and esophagoscopy are performed to evaluate the upper aerodigestive tract for synchronous primary cancers.

Retractors are used to keep the mouth open and retract the cheek. Headlights provide added illumination. A suture in the midline of the anterior tongue may be used to maximally expose the tongue. Finger palpation along the cancer approximates a 1-cm margin of normal tongue muscle around the cancer during the initial incisions. A silk suture placed on the anterior aspect of the specimen facilitates retraction intraoperatively and orientation of the specimen postoperatively. Posterolaterally in the tongue, the lingual artery is encountered, clamped, and ligated. Placement of deep sutures in the posterior tongue musculature looping around the lingual artery diminishes the likelihood of a severe postoperative hemorrhage. Primary closure of the residual tongue does not decrease the risk of postoperative hemorrhage and has little impact on subsequent tongue function.

Following excision of the cancer, the glossectomy specimen may be inked and transected with the pathologist, providing valuable information regarding the adequacy of the gross tumor-free margin. A close gross margin (<5 mm) should prompt additional resection. In order to avoid sampling error, blue dye may be used to mark the residual tongue on the patient side, and an additional layer of soft tissue encompassing the mucosal surface as well as the deep tongue muscle may be excised, providing another 2 to 4 mm of soft tissue as the true resection margin. Once the specimen is sent for frozen section, the neck dissection may be performed.

With substantial resection of the floor of mouth mucosa, tethering of the tongue may contribute to dysarthria. A split-thickness skin graft or fasciocutaneous free flap diminishes contracture during wound healing and ameliorates this problem. A split-thickness skin graft harvested from the thigh (0.016 to 0.018 inches) is firmly secured over a bolster.[9,10] Skin-grafting techniques have even been proven effective in reconstructing mandibulectomy defects.[9] Currently microvascular reconstruction is more commonly employed. If reconstruction is planned, the tracheotomy is completed prior to the resection to enhance exposure. Securing an endotracheal tube to the skin of the neck keeps tubing tucked out of the way during the subsequent procedures.

Common Errors in Technique

1. Improper diagnosis or inadequate preoperative staging
2. Inadequate margins or positive margins, tumor cut-through
3. Inadequate hemostasis
4. Injury to lips, dentition

A diagnosis of cancer should be confirmed prior to undertaking a glossectomy. A resection with a close or positive margin is not an uncommon technical error, and the patient should be readmitted for further resection to provide clear margins. Intraoperative hemorrhage may contribute to suboptimal resection by decreasing visualization. Such problems may be avoided by using an index finger over the palpable abnormality to guide the initial incisions. Frequent palpation, not simply visualization, is necessary to confirm an adequate tumor-free margin on the specimen. In the face of a questionable margin, a re-resection of an additional 2- to 4-mm slice of soft tissue may be helpful in achieving a true negative margin. Clamping and ligating the lingual artery is more effective hemostasis than extensive cauterization and associated with less postoperative pain and dysphagia. The use of protected Bovie tips prevents cautery-related lip injuries.

Postoperative Period

Postoperative Management

1. Diet
2. Pain medication:
   a. Narcotics
   b. Nonsteroidal anti-inflammatory drugs (NSAIDs)
3. Nutritional supplementation
4. Speech therapy rehabilitation

In the absence of reconstruction, most patients can resume a modified oral diet shortly after a partial glossectomy, provided that adequate pain control is provided. High-calorie shakes can supplement nutrition and prevent excessive weight loss. Patients who have undergone

reconstruction with a split-thickness skin graft or microvascular reconstruction require temporary nasogastric tube feedings until the wound is healed well enough for the patient to start an oral diet. Narcotics are usually employed to diminish the bleeding risk associated with the use of nonsteroidal anti-inflammatory agents. A routine follow-up speech evaluation is helpful in identifying swallowing-related problems early and instituting a speech and swallowing program as needed.

Complications

1. Edema of the tongue
2. Postoperative hemorrhage
3. Neck infection
4. Aspiration pneumonia
5. Dehydration, weight loss
6. Pain, dysphagia
7. Dysarthria
8. Constipation
9. Other medical complications—cardiac event, deep venous thrombosis

Significant edema of the tongue following glossectomy is uncommon in the absence of reconstruction. A temporary tracheostomy should be performed at the time of the glossectomy if reconstruction is planned or edema of the tongue is encountered. Edema of the tongue can interfere with swallowing and engender an aspiration pneumonia. An elective temporary tracheostomy will facilitate pulmonary toilet in the postoperative period.

Postoperative hemorrhage from the tongue may occur within 2 to 3 weeks of surgery. Patients who call from home and report that they are spitting up bright red blood or clots should be instructed to call the ambulance to take them to the nearest emergency room. Hemorrhage often requires operative management. With good visualization of the bleeding site in a cooperative, stable patient, suture ligation may

occasionally be performed without the need to return to the operating room. However, ligation of a bleeding vessel in the operating room with an established airway is typically the safest and most effective approach.

The tongue is rarely the site of a significant infection; however, unintended communication of the oral cavity with the neck may lead to an infection in the neck. Exploration of the wound and deliberate placement of drains may be needed.

Pain, dysphagia, and dysarthria following partial glossectomy are expected. Narcotics may ease discomfort but should be used with a bowel regimen, including stool softeners, adequate hydration, and laxatives, to prevent constipation. Long-term dysphagia and dysarthria may be minimized by early implementation of a speech and swallowing rehabilitation program.

Alternative Management Plan

1. External beam radiation

2. Supportive or palliative care

In some patients, the use of external radiation or supportive or palliative care may be preferred to a partial glossectomy.

Discussion

Evidence-Based Medicine Question

Under what circumstances can a neck dissection for a tongue cancer be safely omitted?

Neck dissection has been shown to improve disease-free and overall survival in a large randomized study of patients with stage 1 to 2 tongue cancer.[5] Nevertheless, the risk of metastases has repeatedly been linked to the depth of invasion of the cancer, suggesting that elective neck dissection may not be necessary in thin tongue cancers, because the frequency of occult metastatic disease is very low. In the large study reported by D'Cruz et al., the frequency of metastatic cancer in the neck decreased from 16.9% in tongue cancers with a depth of invasion of 4

mm to 5.6% in 3-mm deep tongue cancers. The authors suggest that patients with a minimal depth (≤3 mm) of invasion of the primary tumor may not benefit from elective neck dissection, but additional study is warranted.

Editorial Comment

Squamous cell carcinoma of the oral tongue generally occurs in males in the 60- to 70-year age range who have smoked two to three packs of cigarettes per day and consumed a great deal of alcohol over a long period of time. In the past, these patients have been treated by local excision and a neck dissection only if the patient had a clinically positive neck. If the patient did not have any clinically positive nodes, then a "watch and wait" policy was adopted.

There were two problems associated with this policy. One problem was that 30% to 40% of these patients returned with obvious metastasis, usually to levels I/II, and these patients received a classic radical neck dissection and postoperative radiation therapy. In our department, since the early 1990s, all patients with squamous cell carcinoma of the tongue (including T1) receive an elective neck dissection with findings of approximately 30% to 40% node positivity. Indications for adjunctive therapy include chemoradiation for lymph nodes exhibiting extracapsular spread (ECS), even in one node, and radiation alone for more than two positive lymph nodes or perineural invasion in the primary.[1]

The second problem associated with this "watch and wait" policy was that some of the patients returned with lymph node metastases, fixed and inoperable, or metastasis to the lungs, or both. Adapting the systematic use of the elective neck dissection instead of the "watch and wait" has eliminated this problem.

We include level IV in all elective neck dissections for patients with cancer of the lateral aspect of the tongue. Byers et al. at MD Anderson Cancer Center described a small percentage of patients who had "skip" metastasis. This situation includes metastasis to level IV without positive nodes at level I to III. If this level is not included, recurrence at this level may be expected.

Review Questions

1. A 54-year-old smoker who developed a 1.5-cm squamous cell carcinoma of the posterior right oral tongue, at 4 mm depth, will require all of the following, except

   a. A neck dissection

   b. A right partial glossectomy

   c. **Postoperative radiation therapy**

   d. A preoperative chest radiograph

   e. Smoking cessation counseling for active smokers

2. Potential complications of a partial glossectomy include all of the following, except

   a. Hemorrhage

   b. Neck infection

   c. Aspiration pneumonia

   d. Dysarthria

   e. **Oral pain**

3. A 54-year-old male with a 70 pack per year smoking history presents with a tender ulcerated mass on the right oral tongue associated with tongue fixation and extrinsic tongue muscle involvement on imaging. He requires all of the following, except

   a. Chest imaging

   b. Free tissue transfer

   c. **Partial glossectomy**

   d. Neck dissection

   e. Subtotal glossectomy

Total Glossectomy

Johan Fagan

Introduction

Total glossectomy is used for advanced cancers of the tongue, mostly squamous cell, either as a primary surgical resection or as salvage following previous (chemo)radiation when partial glossectomy will not achieve adequate resection margins. A key clinical decision is whether a laryngectomy is required. This decision is based on whether a patient is likely to cope with some degree of aspiration and whether extension of cancer into the pre-epiglottic space requires a laryngectomy to achieve an adequate margin. Total glossectomy may incur significant morbidity relating to speech, mastication, swallowing, and in some cases, aspiration. Therefore many centers elect to treat advanced cancers of the tongue with chemoradiation and to reserve surgery for treatment failures.

I consider total glossectomy to be a good primary treatment for advanced cancer of the tongue, provided that patients are carefully selected and that the surgical and reconstructive steps described in the following text are followed to optimize function and quality of life.

Patient selection is critical, both for favorable oncologic and functional outcomes. The majority of patients require a combination of surgery and postoperative (chemo)radiation; hence there is little point in embarking on surgery if a patient is unlikely to complete postoperative adjuvant therapy. To give properly informed consent, patients must have the ability to consider the potential oncologic benefits of surgery against the morbidity relating to speech, dietary modification, mastication, deglutition, and aspiration. If the larynx is to be preserved, then patients must have sufficient cardiopulmonary reserve to cope with some aspiration. As many such patients are malnourished, patients should be

assessed from a nutritional perspective to determine whether they are suitable to undergo such surgery. Synchronous primaries or cervical and distant metastases must be excluded by clinical examination, chest radiograph or computed tomography (CT) scan of the lungs, panendoscopy, and PET-CT.

Before contemplating total glossectomy, the surgeon must be confident of being able to achieve clear surgical margins, especially if doing a salvage operation, and the patient should not have known distant metastases. Determine whether the cancer of the tongue is resectable; it may be difficult to assess the extent of the primary cancer due to pain, tenderness, and trismus. If in doubt about resectability, then proceed to image the cancer with CT and/or magnetic resonance imaging (MRI) or even examination under anesthesia.

A number of major nerves are in close proximity to the tongue; examine the patient for neurologic deficits of the hypoglossal, mental, inferior alveolar, and lingual nerves caused by perineural invasion. Widening of the inferior alveolar canal on mandibular orthopantomography (panorex) may suggest involvement of the inferior alveolar nerve. MRI may demonstrate perineural invasion. Should there be evidence of perineural invasion, then the affected nerve must be resected proximally until a clear surgical margin is obtained on frozen section.

Preoperative planning relating to the mandible is important because the cancer may extend across the floor of the mouth to involve the periosteum, invade the inner cortex, or involve the medullary bone. If only the periosteum is involved, then a marginal mandibulectomy (removal of cortical bone) may suffice. After the cortex is invaded, then segmental mandibulectomy is required. However, after the medulla is invaded, then segmental or hemimandibulectomy is done that includes at least a 2-cm length of mandible on either side of visible cancer. Although panorex or CT scan will show gross bony destruction, MRI is preferred to assess involvement of medullary bone. Should marginal mandibulectomy be considered, then the vertical height of the mandible should be assessed clinically or by panorex to predict whether a free composite flap is required.

The next major decision to make is whether total laryngectomy is required. Laryngectomy is indicated in patients who are unlikely to

tolerate a degree of aspiration and when the cancer extends to the pre-epiglottic space and/or epiglottis (Fig. 29.1). Whether a patient can tolerate aspiration depends on his or her physical fitness, pulmonary reserve, cognitive function, and attitude, all of which should be considered when selecting patients for total glossectomy, especially if it is to be followed by chemoradiation. Pre-epiglottic space involvement is diagnosed radiologically on CT or MRI (sagittal views) or intraoperatively by palpating for thickening of the pre-epiglottic space between a finger placed in the vallecula and a finger placed on the skin of the neck just below the hyoid bone (Fig. 29.2). If in doubt, the patient has to be consented for possible total laryngectomy based on intraoperative surgical and frozen section findings.

Patients with advanced cancer of the tongue generally have poor dentition and should have preoperative dental radiographs done and either be referred to a dentist or have carious teeth removed at the time of surgery to prevent subsequent osteoradionecrosis.

Finally, the reconstructive team must plan how best to reconstruct the tongue defect and possibly the mandible. Although many techniques are used, it is essential to select a bulky flap to create a convex floor of mouth that bulges up to the hard palate to avoid pooling of secretions and to facilitate articulation and swallowing.

Key Operative Learning Points

- Careful patient selection is the key to maximizing oncologic and functional outcomes.
- Intubation may be difficult.
- Temporary tracheostomy is essential.
- Perform panendoscopy to rule out synchronous primaries.
- Marginal mandibulectomy is done for both oncologic and functional reasons.
- The mylohyoid muscle forms the floor of the mouth; this muscle and its attachment to the mandible along the mylohyoid line is resected to ensure adequate margins.

- Frozen section is advisable, particularly at the base of the tongue, where it may be difficult to distinguish between tumor and the thick, irregular normal mucosa.
- Total laryngectomy is required when the cancer extends to the pre-epiglottic space and/or epiglottis.
- Optimize function by
  - Preserving as much base of tongue tissue as is possible
  - Ensuring that the reconstructive flap has sufficient bulk to create a convex floor of mouth that permits contact between the flap and the palate during phonation to facilitate articulation, to assist deglutition, and to avoid pooling of secretions
  - Suspending the hyoid bone from the anterior arch of the mandible to facilitate breathing and swallowing
  - Considering using a sensate flap
  - Preserving the superior laryngeal nerves
  - Performing total laryngectomy in patients who are unlikely to tolerate some degree of aspiration

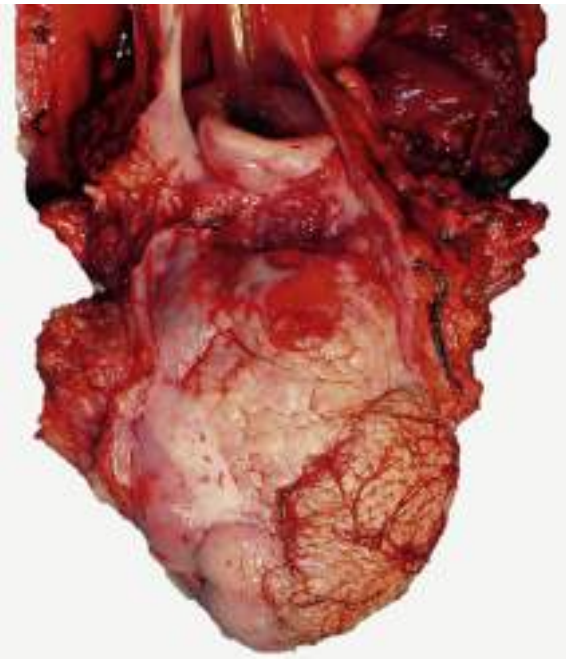

FIG. 29.1 Second primary tongue cancer involving

vallecula and epiglottis and requiring total glossectomy with laryngectomy. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

- Bilateral neck dissection (elective or therapeutic) is essential due to the high likelihood of harboring cervical nodal metastases.

Preoperative Period

History

1. History of present illness
   a. Risk factors: smoking, alcohol, human papilloma virus (HPV) infection
   b. Weight loss, nutritional status
   c. Is pain control adequate?
   d. Pointers to synchronous primaries
   e. Pulmonary status—aspiration, smoking
   f. Neurologic deficits of lingual, hypoglossal, and mental nerves
   g. Pointers to extension to larynx (e.g. dysphonia, stridor)
2. Past medical history
   a. Previous squamous cell carcinomas
   b. Previous radiation to the head and neck
   c. Past surgery, trauma, or claudication that may affect the choice of reconstructive flap
3. Prior treatment of tongue or neck
   a. Previous (chemo)radiation
   b. Previous surgery
4. Medical illness

a. Cardiopulmonary disease: ability to walk up a flight of stairs

b. Immunosuppression (e.g. acquired immunodeficiency syndrome [AIDS])

c. Alcoholism and substance abuse

5. Medications

a. Anticoagulants

b. Alcohol (risk of perioperative alcohol withdrawal syndrome)

c. Allergies to antibiotics

6. Mental and social status

a. Ability to overcome challenges related to speech and swallowing

b. Ability to give informed consent

c. Social support

d. Employment (unlikely to return to full employment)

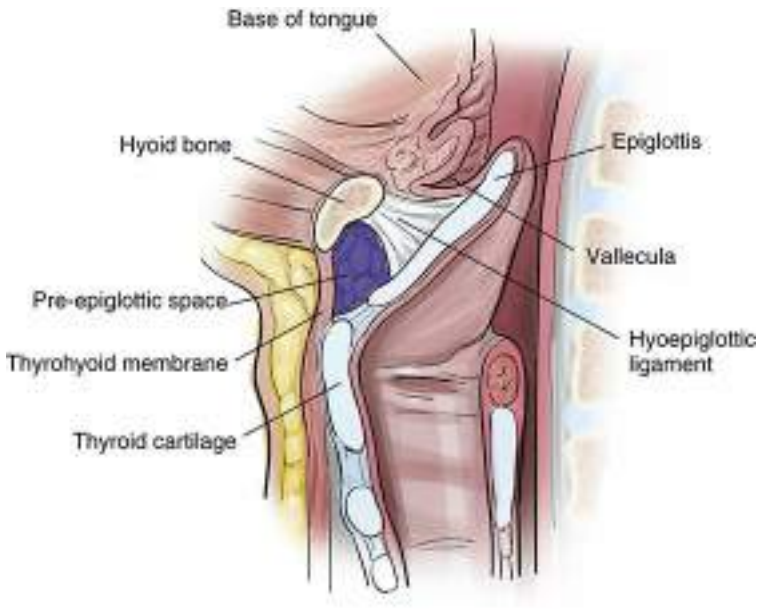

FIG. 29.2 Relations of hyoid, epiglottis, vallecula, and pre-epiglottic space.

Physical Examination

1. Cancer of the tongue
    a. Pain, salivary pooling, bleeding, and trismus may hamper assessment; therefore consider administering morphine prior to examination to improve examination.
    b. Determine the extent of the cancer.
        1) Posterior margin
            a) Vallecula
            b) Supraglottic larynx
        2) Floor of mouth
        3) Mandible: free/abutting/adherent/invading
        4) Deep margins
            a) Extrinsic tongue muscles
            b) Suprahyoid strap muscles
        5) Invasion of major nerves
            a) Lingual (loss of sensation of anterior tongue and floor of mouth)
            b) Inferior alveolar (loss of sensory function of mental nerve)
            c) Hypoglossal (may be difficult to assess due to pain and cancer)
2. Mandible
    a. Thickness/height: Thin mandible may preclude marginal mandibulectomy and require segmental mandibulectomy and free fibula flap
    b. Dentition
3. Necks
    a. Palpate both necks for cervical metastases.
    b. Examine necks for previous surgery and scars that may affect surgery.
4. Examine oral cavity, pharynx, and larynx for synchronous primaries.

5. Potential donor sites for flaps
    a. Anterolateral thigh and rectus abdominis: Obesity may preclude their use.
    b. Free fibula (Leg vein harvest and peripheral vascular disease may preclude its use.)
    c. Pectoralis major
    d. Latissimus dorsi
6. General health
    a. Nutrition
    b. Cardiovascular
    c. Respiratory
    d. Mental

Imaging

1. Chest radiograph
    a. Metastases
    b. Synchronous cancer of the lung
    c. Pulmonary and cardiac status
2. Contrast swallow: if there is a suspicion of cancer of the esophagus
3. Panorex
    a. Dentition
    b. Bone invasion
    c. Height of mandible
        1) To plan marginal mandibulectomy
        2) To determine whether segmental mandibulectomy is required
    d. Perineural invasion of the inferior alveolar nerve may cause widening of the inferior alveolar canal.
4. CT scan

a. Not required in all

b. If concern that mandible is invaded

c. Is pre-epiglottic space involved?

d. Not required for cervical metastases as elective neck dissection is always done

e. If chest radiograph is inconclusive to exclude pulmonary metastases

5. MRI

a. Not required in all

b. If concerned about invasion of extrinsic muscles of tongue and suprahyoid straps muscles

c. Mandibular marrow space invasion

d. Perineural invasion

6. PET-CT

a. To exclude distant metastases

b. Not required in all

Indications for Surgery

- Advanced cancers of the tongue (primary surgical resection)
- Partial glossectomy will not achieve adequate resection margins.
- Salvage following previous (chemo)radiation

Contraindications to Surgery

1. Patient factors

a. Medically unfit

b. Malnourished

c. Inability to give informed consent

d. Inability to overcome challenges related to speech and swallowing

e. Inadequate social support

f. Inability to complete adjuvant therapy

2. Tumor factors

a. Unable to achieve clear margins (especially with salvage surgery)

b. Distant metastases

3. Surgical factors

a. Inadequate surgical expertise

b. Inadequate reconstructive surgical expertise

Preoperative Preparation

1. Evaluations by

a. Oncologic surgeon

b. Oncologist

c. Reconstructive surgeon

d. Speech and swallowing therapist

e. Anesthesiology

2. Postoperative intensive care

3. Discontinue antiplatelet drugs if possible.

Operative Period

Anesthesia

- Ask anesthesiologist to insert a nasal endotracheal tube.
- Surgeon should always stand by during induction of anesthesia because bulky cancers may preclude elevation of the tongue to visualize the larynx and make it difficult or impossible to intubate the patient without fiberoptic intubation.
- Should the anesthesiologist still be unable to intubate the larynx, the surgeon may have to intubate through an operating laryngoscope or do an emergency tracheostomy or cricothyroidotomy.

- A temporary tracheostomy is always done during the course of the operation for potential airway compromise due to bleeding, soft tissue swelling, a bulky flap, and loss of anterior laryngeal suspension following division of the mylohyoid, geniohyoid, and digastric muscles.
- Insert a nasogastric tube for postoperative feeding.
- The anesthetic machine is positioned at the foot of the table to create space around the head for the surgeons.

Positioning

- Position the patient so that both the resection and reconstruction surgical teams can work simultaneously to reduce the length of the surgery.
- The surgery is done with the patient in a supine position with neck extended.
- The lower face, neck, and selected donor site for the flap are sterilized and appropriately draped.

Perioperative Antibiotic Prophylaxis

- Clean contaminated surgery
- Antibiotics are administered during induction of anesthesia and continued for 24 hours.
- Choices
  - Clindamycin
  - Amoxicillin-clavulanate
  - Cephalosporin and metronidazole

Monitoring

- Patient should not be paralyzed to facilitate preserving the spinal accessory and marginal mandibular nerves.

- Routine anesthesia monitoring
- Optimize conditions for a free microvascular transfer flap by regulating core temperature, hydration, and hemoglobin.
- Insert a Foley catheter and rectal thermometer.

Instruments and Equipment to Have Available

- Two sets of monopolar and bipolar electrocautery for the two surgical teams
- Resection and neck dissections
  - Standard head and neck cancer surgery set
  - Oscillating saw for marginal mandibulectomy or osteotomies
  - Mandibular plating set (if required)
  - Powered drill
  - Tracheostomy tubes and anesthetic tubing for tracheostomy
- Reconstructive surgery (microvascular)
  - Microvascular instrument set
  - Microvascular sutures
  - Ligaclips
  - Heparin-saline solution
  - Operating loupes and/or operating microscope
  - Tourniquet (if free fibula flap used)

Key Anatomic Landmarks

- Neck dissection: See neck dissection chapters.
- Laryngectomy: See laryngectomy chapter.
- Total glossectomy
  - Mylohyoid line

- Insertion of genioglossus onto superior genial tubercle (Fig. 29.3)
- Insertion of geniohyoid onto inferior genial tubercle (see Fig. 29.3)
- Insertion of anterior belly of digastric onto mandible (see Fig. 29.3)
- Sublingual salivary glands between submandibular duct and mandible
- Lingual arteries emerge behind hyoglossus to enter the tongue posterolaterally
- Pre-epiglottic space
- Hyoid bone
- Superior laryngeal nerves traverse thyrohyoid membrane
- Mental nerve is at risk, especially in edentulous older patients where it exits the mental foramen.

Prerequisite Skills

- Neck dissection: selective levels 1 to 4; modified; and radical
- Total laryngectomy
- Mandibulectomy: marginal or segmental
- Reconstruction of tongue defect
  - Pedicled flap: pectoralis major or latissimus dorsi
  - Free microvascular transfer flap: anterolateral thigh, rectus abdominis
- Reconstruction of mandible
  - Plating
  - Free fibula flap
- Tracheostomy

Surgical Technique

- Intraoperative evaluation after patient has been intubated

- Panendoscopy to exclude synchronous cancers in upper aerodigestive tract
- Reassess extent of primary cancer, especially posterior and lateral limits.
- Reassess the neck for cervical metastases.

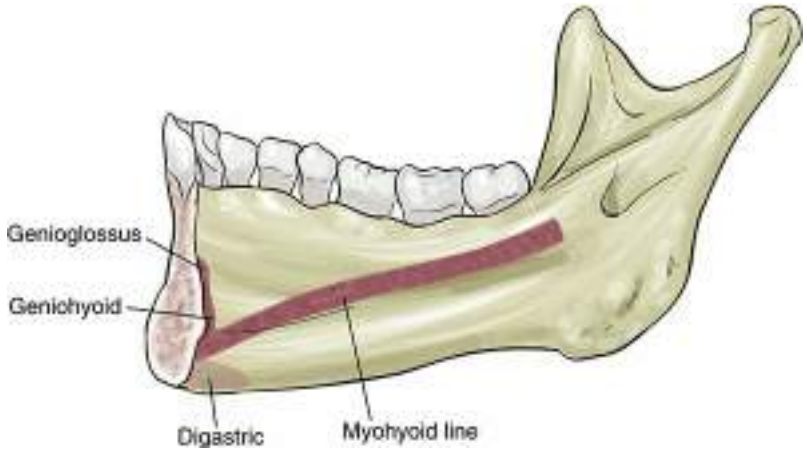

FIG. 29.3 Mylohyoid line and attachments of geniohyoid and genioglossus to inferior and superior genial tubercles and insertion of digastric muscle.

- Surgical approach
  - Good access is essential to attain adequate resection margins, to control bleeding, and for reconstruction.
  - Open the necks bilaterally along incisions as indicated in Fig. 29.4.
  - My preference to resect the tongue by a combination of transcervical and transoral approaches will be described. Others prefer a midline lip-split incision with median or paramedian mandibulotomy.
- Neck dissections
  - Advanced cancers of the tongue are highly likely to harbor clinically apparent or occult cervical nodal metastases, therefore bilateral selective (levels 1 to 4) or comprehensive neck dissections are routinely performed as indicated.

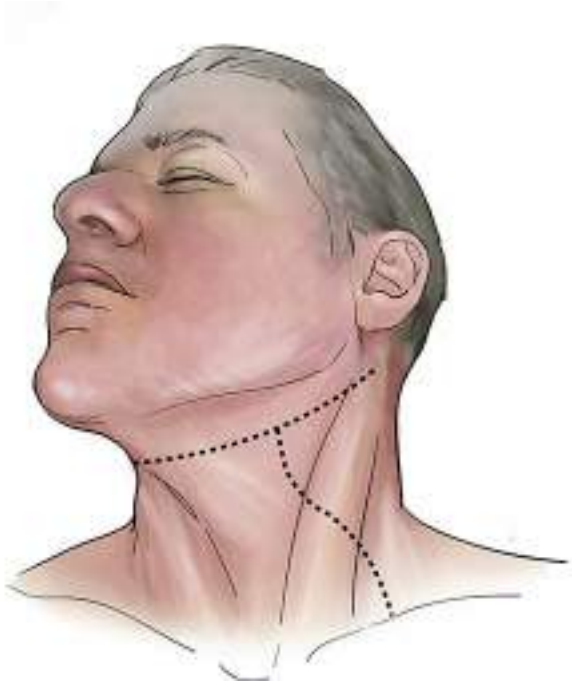

FIG. 29.4 Skin incisions (on both sides of the neck).

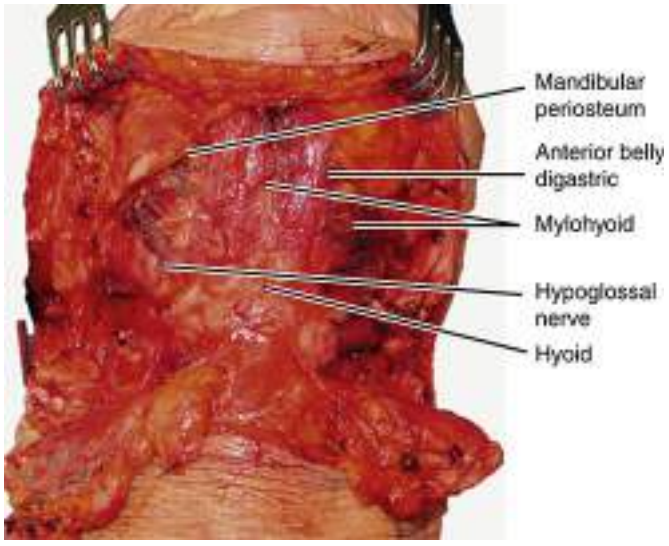

FIG. 29.5 Exposure following completed bilateral selective neck dissections From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

- Neck dissections are completed prior to resecting the primary

cancer (Fig. 29.5).

- Total glossectomy: cervical dissection
  - Incise the periosteum along the inferior margin of the mandible from angle to angle (Fig. 29.6).
  - Transect the anterior bellies of digastric and divide the mylohyoid with electrocautery (see Fig. 29.6).
  - Free them from the mandible.
  - Strip the soft tissues off the inner aspect of the mandible in a subperiosteal plane with a periosteal elevator.
  - If the cancer extends to the lateral floor of the mouth, then strip the periosteum from the bone up to the mylohyoid line (Fig. 29.7).
  - Divide and free the insertion of the geniohyoid muscle at the inferior mental spine (see Fig. 29.7).
- Total glossectomy: transoral dissection
  - When tumor abuts the mandible, first do a marginal mandibulectomy because this greatly facilitates subsequent tongue resection.
  - Incise the gingiva along the alveolar ridge (Fig. 29.8).
  - Strip the soft tissue off the outer aspect of the mandible without exposing the inferior half of the mandible to maintain its blood supply.
  - Take care not to injure the mental nerves where they exit the mental foramina.
  - Perform a marginal mandibulectomy along the superior aspect of the horizontal ramus of the mandible, as indicated in Figs. 29.7 and 29.9.
  - Angle the osteotomy obliquely to include the mylohyoid line; this is especially important if the cancer extends to the lateral floor of mouth and abuts bone.
  - Not only does the marginal mandibulectomy have oncologic relevance in terms of resection margins, but it avoids a sump effect of having a concavity along the medial border of the mandible, as will become apparent later.

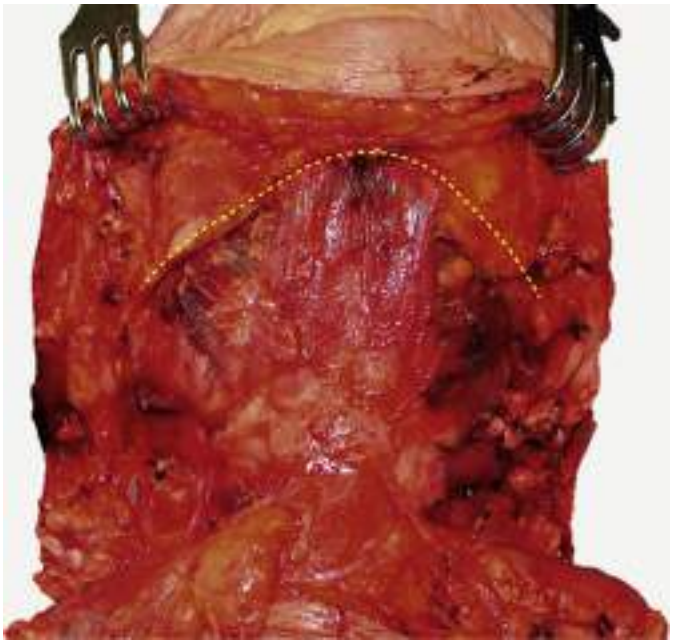

FIG. 29.6 Incise periosteum along inferior margin of mandible from angle to angle *(yellow line)*, and transect anterior belly of digastric muscle *(green line)*. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

- Glossectomy
  - Deliver the marginal mandibulectomy, floor of mouth, and tongue into the neck as a unit (Fig. 29.10).
  - This permits excellent exposure of the entire tongue, vallecula, and epiglottis.
  - Resect the cancer with sufficient margins, using monopolar electrocautery (Fig. 29.11).
  - Preserve as much base of tongue mucosa as possible to facilitate swallowing.
  - Preserve the superior laryngeal nerves during resection to facilitate swallowing.
  - Ligate the lingual arteries as they are encountered posterolaterally during the dissection.
  - Carefully examine the specimen for adequacy of margins (Fig. 29.12).

- Send the specimen for frozen section (if available) to determine the adequacy of the margins.

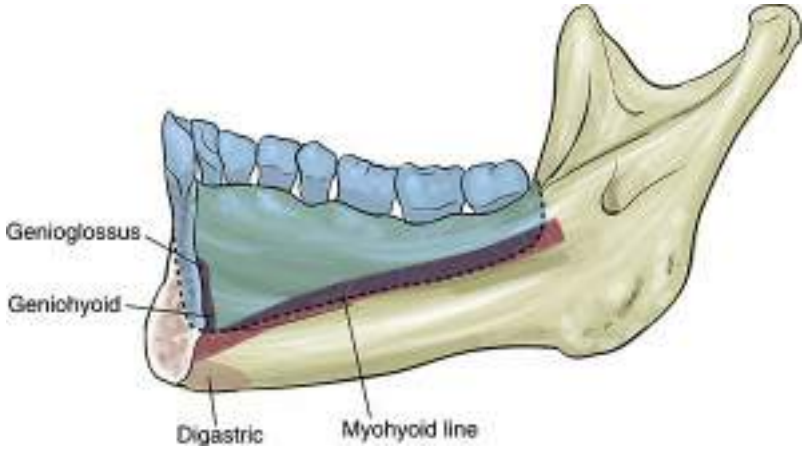

FIG. 29.7 Mylohyoid line and attachments of geniohyoid and genioglossus to inferior and superior mental spines; *broken line* indicates marginal mandibulectomy.

- Laryngectomy
  - If laryngectomy was preplanned, the larynx is resected in continuity with the tongue.
  - If it was not preplanned, then assess the need for total laryngectomy intraoperatively.
  - Examine the posterior resection margin; should the epiglottis and pre-epiglottic adipose tissue be uninvolved and if the patient is mentally and physically fit enough to tolerate some aspiration, omit the laryngectomy and proceed to reconstructing the defect (Fig. 29.13).
- Reconstruction
  - Reconstructing the defect is key to optimizing function.
  - Important elements from a functional perspective
    - To avoid a sump that collects food and saliva in the mouth, I favor the marginal mandibulectomy technique described previously, which allows one to suture the edges of the flap to the gingivobuccal and gingivolabial mucosae with continuous

absorbable sutures (Figs. 29.14 and 29.15).

FIG. 29.8 Incise along gingival margin. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

FIG. 29.12 Total glossectomy with marginal mandibulectomy. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

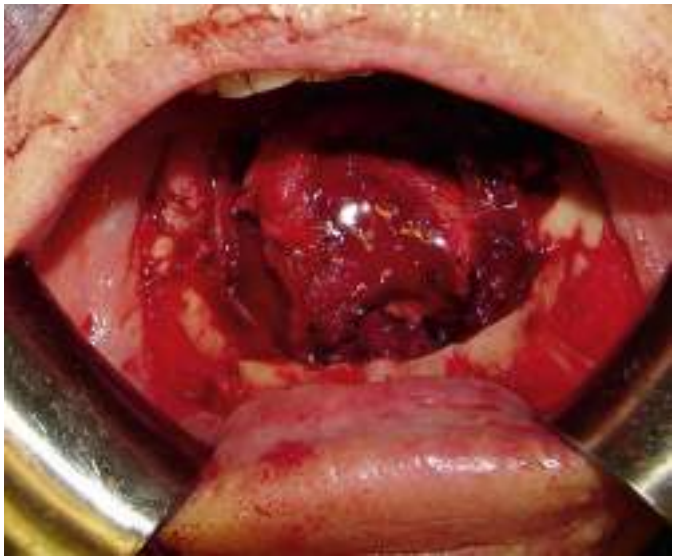

FIG. 29.13 Completed resection with small amount of residual base of tongue. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

FIG. 29.14 Large flap creates convex floor of mouth. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

FIG. 29.15 Long-term result of pectoralis major flap used to create a convex floor of mouth without sump caused by retaining the lower teeth. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

- The flap should have sufficient bulk to create a convex floor of mouth that permits palate-neoglossal contact during phonation and deglutition to facilitate articulation and to avoid pooling of secretions.
- The flap should be large enough that it bulges up to the hard palate with the knowledge that it will both descend and lose some muscle bulk and hence flatten out with time (see Figs. 29.14 and 29.15).
- A variety of flaps provide sufficient tissue volume (i.e., pectoralis major and latissimus dorsi pedicled flaps or anterolateral thigh and rectus abdominis free microvascular transfer flaps).
- Radial free forearm flaps should be avoided because they provide insufficient bulk and result in a concave floor of mouth and a sump that interferes with deglutition, causes pooling and spillage of saliva and food, and poor articulation, because the flap cannot abut the palate on elevation of the mandible.

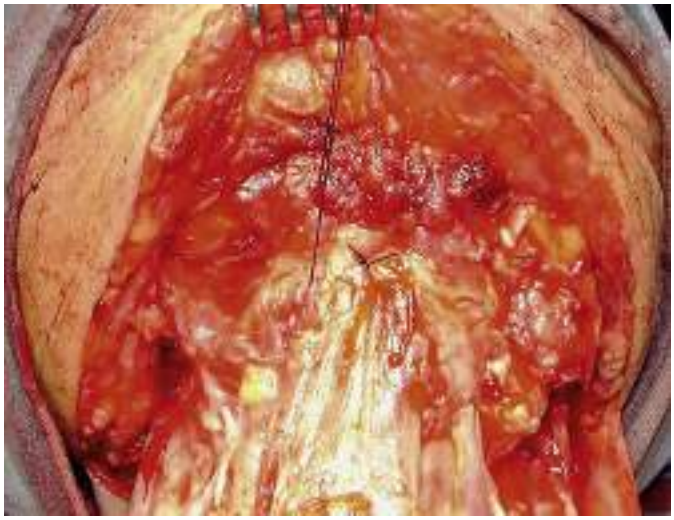

FIG. 29.16 Laryngeal suspension with nonabsorbable sutures. From Fagan JJ: Total glossectomy for tongue cancer. In Fagan JJ (ed): The Open Access Atlas of Otolaryngology Head and Neck Operative Surgery. Available at https://vula.uct.ac.za/access/content/group/ba5fb1bd-be95-48e5-81be-586fbaeba29d/Total%20glossectomy%20for%20tongue%20cancer.pdf.

  - Mandibulectomy may require free fibula flap reconstruction, but like the forearm flap, the soft tissue component is generally inadequate.
  - Consider using a sensate flap.
- Laryngeal suspension
  - Dividing all the attachments of the larynx to the mandible (anterior bellies of digastrics, mylohyoids, geniohyoids, and genioglossi) promotes aspiration, impairs swallowing, and may cause obstructive sleep apnea.
  - Therefore the hyoid bone is suspended from the anterior arch of the mandible by two strong nonabsorbable sutures passed between the hyoid and the anterior arch of the mandible (Fig. 29.16).
- Closure
  - The neck is closed over two suction drains.
  - A temporary tracheostomy is done.

Common Errors in Technique

- Omitting a marginal mandibulectomy and preserving the lower teeth: The aesthetic benefit of preserving the lower teeth needs to be weighed against the fact that the teeth have limited functional value in the absence of a functioning tongue and that the lateral floor of the mouth will serve as a sump for saliva and food.
- Insufficient bulk of the flap: The flap should virtually touch the palate at conclusion of surgery.

Postoperative Period

- Antibiotics for 24 hours
- Monitor viability of the flap.
- Remove suction drains when less than 50 mL drainage/24 hours.
- Tracheostomy
  - Maintain until certainty that patient does not need to be returned to the operating room for surgical complications (e.g., ischemia of the flap)
  - After there is thought to be an adequate airway
    - Cork tracheostomy overnight
    - Remove if airway is maintained
- Feeding
  - Enteral feeding via nasogastric tube the morning after surgery
  - Oral feeding
    - Delay until decannulated
    - Speech and swallowing therapist assists the patient with swallowing
    - Because of impairment of the oral phase of swallowing, this initially involves placing thickened liquids and pureed food in the back of the mouth with a syringe or spoon until the patient learns to throw the head back and use gravity to assist with the oral phase of swallowing.
- Postoperative (chemo)radiation generally started within 6 weeks of

surgery

Complications

- Hematoma: Return the patient to the operating room as soon as possible to avoid failure of flap.
- Alcohol withdrawal syndrome
  - Onset on days 2 and 3
  - Causes additional morbidity and mortality and prolongs hospitalization
  - Involve internist or intensivist in care
  - May require sedation and ventilation
- Tracheostomy
  - Occlusion
  - Dislodgement
  - Delayed decannulation if very bulky flap
- Flap
  - Loss due to perfusion failure
  - Too bulky: delayed decannulation
  - Too small: poor articulation and pooling of saliva and food in mouth
- Dysphagia and aspiration
- Omitting a laryngectomy in a patient that subsequently aspirates significantly

Alternative Management Plan

Patients with advanced cancer of the tongue should always be offered nonsurgical treatment options.

Discussion

Evidence-Based Medicine Question

What are the quality of life and survival benefits of total glossectomy for advanced tongue cancer?

Patients with advanced cancers of the tongue generally have severe pain and impaired speech, have lost a great deal of weight, and may be cachectic. This might partly explain why Dziegielewski et al. (2013) reported favorable speech and swallowing outcomes compared with patients' preoperative status in a study of objective functional outcomes and a systematic review of the literature relating to total glossectomy.[1] This is similar to my own experience in which eight of eight patients returned to a full oral diet.[2] Dziegielewski et al. also reported that postoperative quality of life scores were only marginally reduced despite swallowing and speech function having deteriorated; the authors attributed this to "improved pain control, peace of mind after tumor ablation or due to strong social supports."[1] Van Lierop et al. reported oncologic outcomes of primary total glossectomy with postoperative radiation therapy on eight patients with stage 4 tongue cancers; at 2, 3, and 5 years, 63%, 38%, and 25% of patients, respectively, were alive without disease. Navach et al. reported 5-year overall and disease-free survivals of primary total glossectomy of 79% and 61% in a review of a number of studies.[3] However, case series are small, and the reported oncologic outcomes may be skewed by patient selection.

Editorial Comment

The decision to proceed with a total glossectomy for advanced tongue cancer is never taken lightly. In particular, complete surveillance for both locoregional and potential distant metastatic disease must be carefully attended to preoperatively. After the decision is made to proceed with total glossectomy, the surgeon must have considered carefully whether laryngeal preservation with the glossectomy is either possible or desirable. In my opinion, if significant amounts of the supraglottic larynx require resection or the patient has poor pulmonary reserve that would make tolerance of aspiration poor, total laryngectomy should be performed in conjunction with the glossectomy. The decision to perform a laryngectomy (or not) will also influence the decision regarding the

type of flap reconstruction. Bulk of flap becomes of less concern in the patient who has a laryngectomy performed in conjunction with the total glossectomy. If the larynx is preserved, free tissue transfer is the preferred reconstructive technique, whereas pectoralis major myocutaneous flaps represent a viable strategy in appropriately selected patients. The pectoralis flap is less desirable in female patients due to donor site appearance, as well as a potentially less reliable skin flap than in males. Because of the long donor pedicle length and high reliability of the flap, coupled with potentially less donor site morbidity (hernias and closure issues in obese patients), the anterior lateral thigh flap is quickly eclipsing the rectus abdominus and latissimus dorsi flap in our practice.

Review Questions

1. Total glossectomy for cancer of the tongue
   a. Always is combined with laryngectomy
   b. Markedly reduces quality of life
   c. Can be done without using a flap
   d. **May be considered in adenoid cystic carcinoma with distant metastases**
2. Appropriate flaps following total glossectomy include
   a. **Anterolateral thigh**
   b. Radial forearm
   c. **Pectoralis major**
   d. **Latissimus dorsi**
3. Contraindications for primary total glossectomy include
   a. **Unable to achieve clear margins**
   b. **Inability to complete adjuvant therapy**
   c. **Poor social support**

d. Cervical metastases

Excision of Cancer of the Floor of the Mouth

David D. Walker, and Elizabeth A. Blair

Introduction

Cancer of the floor of the mouth accounts for approximately one-third of all cancers of the oral cavity, with squamous cell carcinoma accounting for more than 95% of cases. Affected patients tend to reflect many of the epidemiologic features that have come to define squamous cell carcinoma of the head and neck as a whole, including a male predilection, advanced age at the time of diagnosis, and a well-established etiologic association with tobacco, alcohol, and human papillomavirus (HPV) (Fig. 30.1). Despite these similarities, cancers of the floor of the mouth distinguish themselves from other cancers of the head and neck in several key ways. Perhaps most notable is its propensity for early occult metastasis to the cervical lymph nodes. Although positive nodal status is anticipated and even expected with advanced-stage cancers (T3/T4), occult nodal metastasis is a relatively common finding, even with early-stage cancer of the floor of the mouth (T1/T2). Retrospective reviews have demonstrated that as many as 30% of patients with a cancer of the floor of the mouth have evidence of occult nodal metastasis following elective neck dissection. This unique finding makes the treatment of the clinically negative neck a pivotal decision. Advanced-stage cancers of the floor of the mouth pose further challenges, as the intimate anatomic relationship between the floor of mouth and adjacent structures—namely the tongue and mandible—increases the risk of locoregional invasion. As the extent of the cancer increases, so does the associated morbidity of surgical intervention, including compromise of speech, mastication, and oral competence. Together, these distinct oncologic features combine to make cancer of the floor of the mouth one of the more aggressive and potentially lethal

neoplasms of the oral cavity.

Key Objective Learning Points

1. Patient selection and careful preoperative planning are essential for optimizing oncologic and functional outcomes.

2. Reconstructive efforts should aim to provide reasonable cosmesis while restoring competent physiologic function to both speech and swallowing.

3. Airway planning, both at the time of surgery and during the postoperative recovery, is critical for limiting morbidity and mortality.

4. The role of the elective neck dissection remains controversial but appears to offer a survival benefit.

Preoperative Period

A careless preoperative evaluation can compromise even the most elegantly performed surgery. Thus a systematic approach to patient selection is critical not only for determining surgical candidacy but also for maximizing oncologic and functional surgical outcomes. The foundation of the preoperative evaluation is the history and physical examination. The information obtained here should form a complete appreciation of the patient's overall condition and thus his or her ability to undergo surgery safely. Although age itself is not a contraindication to surgery, numerous studies have demonstrated a relationship between the severity of medical comorbidities and postoperative survival.[1] Those patients with numerous comorbidities will require medical evaluation and clearance as well as risk stratification. Thus assessment of surgical candidacy typically requires a multidisciplinary approach, which includes evaluations by internal medical specialists, medical and radiation oncologists, speech and swallow therapists, nutritionists, and anesthesiologists.

For those deemed fit enough to undergo surgical resection, the surgeon must next assess the resectability of the cancer. The history and physical examination along with a panorex computed tomography (CT), and magnetic resonance imaging (MRI) should allow for accurate staging of

the tumor. Particular attention is paid to the presence of local invasion into surrounding structures of the oral cavity. An accurate assessment of the relationship of the cancer to the lingual surface of the mandible helps to define surgical planning and approach. Conversely, failure to recognize periosteal or cortical involvement preoperatively can not only compromise the primary ablative surgery but also drastically alter the plan for reconstruction.

In the immediate preoperative setting, clear and concise communication between surgeon and anesthesiologist is paramount for safe airway management. A retrospective review of 320 patients with cancer of the floor of the mouth by Shaha et al. attributed half of the postoperative mortalities to airway compromise.[2] This underscores the importance of a coordinated approach between the anesthesiologist and the surgeon to provide the safest airway plan possible both at the time of initial induction and in the postoperative setting.

Approaching patient selection as a perfunctory preoperative exercise is a grave disservice to the patient. Such efforts risk poor oncologic control or compromised reconstruction. However, a diligent history and physical examination, along with a multidisciplinary approach toward surgical optimization, can position the patient for a successful surgical outcome.

History

1. History of present illness
   a. Characterization of lesion: size, onset, growth, pain
   b. Complaint of an ill-fitting lower denture
   c. Assessment of speech, swallowing, and mastication
   d. Evidence of perineural invasion: immobility of the tongue, dysgeusia, numbness
   e. Screen for odynophagia, dysphagia, otalgia, oral bleeding
   f. Weight loss, malnutrition
   g. History of recent biopsy of an intraoral lesion
2. Past medical history
   a. History of oral cavity leukoplakia, dysplasia, or lichen planus

b. History of obstructive sleep apnea or cardiopulmonary disease

c. History of radiation therapy

d. History of cancer of the head and neck

e. History of previous treatment to the area of the primary cancer, ipsilateral or contralateral neck

FIG. 30.1 Squamous cell carcinoma of the floor of the mouth is highly associated with the consumption of tobacco and alcohol.

f. History of immunosuppression

3. Past surgical history

a. History of surgical intervention of the oral cavity

b. History of surgical intervention of the neck

c. History of dental surgery

d. History of mandibular fracture with reconstruction

e. History of prior tracheostomy

4. Family history

a. History of difficulty with anesthesia

b. History of bleeding diathesis

5. Medications

a. Anticoagulants

b. Herbal products

c. Immunosuppressants

d. Allergies

6. Social

a. Alcohol

b. Tobacco use

c. Betel quid

d. Review of occupational demands, particularly of those in the culinary industry, and of speech requirements

e. Social support structure

f. Jehovah's Witness

Physical Examination

1. General appearance

a. Malnutrition, cachexia

1) Present in 50% of head and neck cancer patients[3]

2) Independent predictor of survival[4]

2. Complete examination of the head and neck

a. Oral cavity

1) Observation

a) Exophytic

b) Deep infiltration

c) Ulcerations

d) Papillary

2) Thorough assessment of the location and extent of the cancer

a) Proximity or invasion of intrinsic tongue musculature

i) Midline or unilateral

ii) Anterior or lateral

b) Assessment of tongue mobility

c) Diameter—measure for staging (e.g., T1–T4)

3) Relationship between cancer margin and ductal papilla

4) Dental evaluation, including evidence of carious or loose teeth

b. Mandible

1) Bimanual palpation of the cancer and mandible has been demonstrated to be superior to imaging in predicting cortical invasion.[5]

2) Proximity of cancer to the lingual surface of the mandibular periosteum

3) Evidence of invasion through the mandibular cortex

4) Evidence of cancer on the alveolar ridge or the buccal surface of the mandible

5) Presence of a pathologic fracture

6) Assess dimensions including mandibular height and anteroposterior thickness

7) Involvement of the skin (Fig. 30.2)

8) Presence of previous reconstruction/plating

c. Cranial nerves

1) Evidence of intraoral perineural invasion including

a) Mental nerve hypoesthesia

b) Numbness of the tongue

c) Dysgeusia

d) Impaired mobility of the tongue

2) Complete assessment of cranial nerves II to XII

d. Neck

1) Palpation of both necks in the evaluation of nodal metastasis

2) Postradiation skin changes, which may indicate the presence of neck fibrosis

3) Previous neck incisions, which may indicate prior surgeries

e. Evidence of synchronous primary (Fig. 30.3)

1) Unilateral otitis media with effusion

2) Stridor

3) Dysphonia

3. Potential donor site

a. Fibula

b. Radial forearm

c. Supraclavicular region

d. Pectoralis/anterior chest wall

4. General physical examination

a. Cardiovascular

b. Pulmonary

c. Mental

Imaging

1. CT scan with contrast enhancement

a. First-line examination with high reliability and ease of testing

b. High-resolution, fine-cut, multiplanar CT to assess the integrity of the mandibular cortex

2. MRI

a. Improved soft tissue delineation

b. Rarely indicated

3. 18-F-fludeoxyglucose positron emission tomography (18F-FDG PET

CT)

a. Reveals cervical metastasis

b. Reveals distant metastasis

FIG. 30.2 **A,** Advanced cancer of the floor of the mouth. **B,** Invasion of the mandible and the skin of the mentum.

4. Panorex

a. Dentition

b. Invasion of the mandible

5. Chest CT

a. Cardiopulmonary evaluation

b. Pulmonary metastasis

c. Second primary in the lungs

6. 18-F-fludeoxyglucose positron emission tomography (18F-FDG PET CT)

a. More accurate at detecting metastatic lymph nodes and distant metastasis than either CT or MRI

b. Unfortunately its high cost prohibits 18F-FDG PET CT from being a frontline screening tool.

Indications

1. Wide local three-dimensional excision of soft tissue only; cancer not approaching or involving the mandible

2. Marginal mandibulectomy

a. Cancer involving mandibular periosteum but not invading cortex

b. Cancer in close proximity to the mandibular periosteum with no evidence of bone invasion

c. Cancer abutting healthy dentition without involvement of the periodontal ligament

3. Segmental mandibulectomy

a. Cancer invasion into the medullary matrix

b. Cancer invasion to the occlusal surface of the mandible in an edentulous patient

FIG. 30.3 Patient referred for laryngectomy. Routine examination of the oral cavity revealed an early cancer of the floor of the mouth. This was managed by excision of the cancer and reconstruction with a split-thickness skin graft at the time of the laryngectomy.

c. Edentulous patient with hypoplastic mandible with cancer that would otherwise meet criteria for marginal mandibulectomy

d. Cancer abutting diseased dentition with involvement of the periodontal ligament

4. Mandibulotomy

a. Improved access to the anteriorly based cancer of the floor of the mouth

Contraindications

1. Patient factors

a. Medical comorbidities

2. Marginal mandibulectomy

a. Invasion of the mandible

b. Gross invasion of bone marrow

c. Cancer recurrence after radiation

d. Hypoplastic mandible

e. Planned remnant of bone less than 1 cm

3. Segmental mandibulectomy

a. To improve surgical exposure

4. Mandibulotomy

a. Atrophic mandible

Preoperative Preparation

1. Consultations

a. Anesthesia

b. Reconstructive Surgeon

c. Speech and Swallow Therapist

d. Medical Oncologist

e. Radiation Oncologist

f. General surgeon if a feeding tube is anticipated

2. Preoperative pathology

a. Ultrasound-guided fine-needle aspiration of suspicious cervical lymph node

b. Biopsy of primary lesion

c. Independent institutional review of biopsy performed at an outside hospital

3. Further preoperative preparation

a. Panendoscopy—can be performed at the time of ablative surgery

b. Extraction of carious teeth—may be extracted at time of ablative surgery

c. Preoperative laboratory testing

1) Nutrition

a) Gross abnormalities may delay surgery or restructure postoperative nutrition planning.

b) Albumin: surrogate marker of long-term nutritional status,

half-life of 20 days

c) Prealbumin: surrogate marker of recent nutritional status, half-life of 8 days

2) Hemoglobin/hematocrit:

a) If comorbidities such as anemia or significant cardiopulmonary history are present

Operative Period

Anesthesia

1. Airway management

a. Nasotracheal intubation—better exposure without the endotracheal tube in the oral cavity

b. Tracheostomy

Positioning

1. The bed is turned 180 degrees.

2. A shoulder roll is placed, and the head is positioned on a foam pillow.

3. The patient's neck, lower face, and skin graft, free flap, or rotational flap sites are prepped and draped.

Perioperative Antibiotic Prophylaxis

1. Administered at the beginning of the operation and redosed every 6 hours

2. Continued for a full 24 hours postoperatively

3. Ampicillin/sulbactam

4. Clindamycin if the patient is allergic to penicillin

Monitoring

1. Muscle paralysis must be avoided during the neck dissection.

2. A nondepolarizing neuromuscular agent is usually required in order to gain appropriate access to the floor of mouth.

Instruments and Equipment to Have Available

1.
   a. Major head and neck set
   b. Oral retractor set
   c. Saw with both reciprocating blade and oscillating blade
   d. Tracheostomy set
   e. Free flap set
   f. Dental extraction set
   g. Otologic drill for bone contouring
2. Medications
   a. 1% lidocaine with 1:100,000 epinephrine
   b. Decadron 10 mg administered at the beginning of the operation
3. Other equipment
   a. Headlight
   b. Loupe magnification
   c. Operating microscope

Key Anatomic Landmarks

1. Extrinsic tongue muscles
   a. Hyoglossus muscle
   b. Geniohyoid muscle
2. Floor-of-mouth contents

a. Mylohyoid muscle

1) Forms the diaphragm of the floor of mouth

b. Salivary glands

1) Submandibular glands

2) Sublingual glands

c. Nerves

1) Lingual nerve

2) Hypoglossal nerve

3) Mental nerve

d. Vasculature

1) Lingual artery

e. Mandible

Prerequisite Skills

1. Neck dissection
   a. Selective—levels 1 to 4
   b. Modified radical
   c. Radical
2. Skin graft harvest
3. Reconstruction of mandible
   a. Plating
   b. Fibula free flap
   c. Scapular flap
4. Local rotational flaps
   a. Supraclavicular island flap
   b. Submental island flap
   c. Platysma flap

d. Pectoralis major myocutaneous flap

5. Tracheostomy

Surgical Technique

1. The neck dissection first

2. Soft tissue resection only

   a. Dental bite block placed

   b. Plastic cheek retractor placed to retract buccal mucosa

   c. 2-0 silk suture placed through the tip of the tongue to provide dynamic traction of the tongue

   d. Bimanual palpation of the cancer is performed to confirm staging and (Fig. 30.4A) the operative plan.

   e. Marking pen used to draw at least a 1-cm margin of normal mucosa surrounding the cancer

   f. 1% lidocaine with 1:100,000 epinephrine is injected in the line of the incision only after bimanual palpation and planning of incision

   g. If the submandibular gland is not included with the neck dissection, care is taken to identify the opening of Wharton's duct and to plan the incision appropriately.

   h. If the papilla is within the area marked for surgical resections, the duct can be canalized with a lacrimal probe to aid in successful rerouting of the ductal architecture.

   i. After adequate time for the local vasoconstriction to take place, the mucosa is incised with either monothermy or needle-tip cautery.

   j. A 2-0 silk suture is placed in the anterior edge of the specimen to mark the anterior margin.

   k. The soft tissue is sharply dissected in an anteroposterior direction.

   l. The deep margin of resection is established at the level of the sublingual glands. The specimen is removed and sent to pathology for frozen section analysis (see Fig. 30.4B).

   m. Bleeding is addressed as it is encountered, and meticulous

hemostasis is obtained either by way of individual vessel ligation or bipolar cautery (monothermy is to be avoided).

n. If the submandibular gland is to be removed with the neck dissection, no attempt is made to preserve or reconstruct Wharton's duct.

FIG. 30.4 **A,** A 2- by 2-cm ulcerated exophytic squamous cell cancer. **B,** The specimen is removed, and complete hemostasis is obtained. **C,** A split-thickness skin graft is used to resurface the floor of the mouth. Some 2-0 silk sutures are left long as tie-overs to secure the Xeroform bolster. A few tacking sutures are placed through the graft to secure it to the defect. **D,** The skin graft healed to the floor of the mouth. **E,** Full dentures can be accommodated by the healed operative site.

o. If the submandibular gland is preserved and the proximal ductal architecture is contained within the resection, ductal rerouting should be performed.

p. This is most easily achieved by following the lacrimal probe placed in the duct at the beginning of the case.

q. The end of the transected duct is then sutured to the remnant floor of the mouth mucosa.

1) An 8- to 10-mm incision is then made along the length of the duct.

2) The ductotomy is then brought cephalad toward the floor of the mouth mucosa and marsupialized to the surrounding tissue using 4-0 chromic sutures.

r. Reconstruction

1) Split-thickness skin graft (see Fig. 30.4C)

2) Xeroform packing is used as a bolster and secured to the surrounding mucosa with 2.0 silk sutures.

s. An orogastric tube is used to remove stomach contents.

t. A Dobhoff feeding tube is then passed and secured with a 3-0 silk secured to the nasal septum.

u. The procedure is terminated.

3. Transoral soft tissue resection plus marginal mandibulectomy

a. A dental bite block is placed.

b. A disposable plastic cheek retractor is placed to retract the buccal mucosa.

c. The mucosal margins of resection are outlined at the beginning of the case with a surgical marker.

d. The lateral margins of resection should include 1.0 to 1.5 cm of normal bone.

e. Although the primary cancer can be resected separately from the mandible, every effort should be made to resect both the mandible and soft tissue en bloc to aid in the orientation for the pathologist.

f. If the patient is dentulous, the tooth adjacent to the planned margin is extracted in preparation for vertical osteotomies, which are carried out in the tooth socket, preserving as much bone as possible to support the residual tooth without compromising the surgical margins.

g. A needle-tip bovie is used to make the index incisions through the

mucosa and carried down through periosteum onto the mandibular cortex.

h. The incisions are extended over the alveolar ridge and connected anteriorly.

i. A Freer or periosteal elevator is used to gently elevate the mucoperiosteum to expose the mandibular cortex.

j. The osteotomies are then drawn on the bone with a marking pen.

k. A horizontal reciprocating saw is positioned at the anterior aspect of the canine extraction site in preparation for the vertical osteotomy.

l. In planning the inferior extent of the vertical osteotomy, care is taken to remove only the alveolar process while preserving at least 1.0 cm of residual bone along the inferior margin of the mandible.

m. The horizontal osteotomy is then created to connect the two vertical osteotomies.

n. It is important that the buccal and lingual plates of bone be cut all the way through so as to prevent splintering or fracturing the bone.

o. Once the lingual cortex is cut through and the mandibular fragment is freed, the bone is retracted superiorly and posteriorly along with the soft tissue and the rest of the resection is then carried out.

p. The bony margins of the mandible are smoothed with a cutting bur to remove any spicules of bone or sharp corners.

q. A split-thickness skin graft can be used to resurface both the soft tissue and the residual mandibular bone.

r. Reconstruction

1) Split-thickness skin graft (Fig. 30.5)

2) Submental island flap

3) Supraclavicular island flap

4) Radial forearm free flap (Fig. 30.6)

s. An orogastric tube is passed to remove the stomach contents.

t. A Dobhoff feeding tube is then passed and secured to the nasal septum with a 3-0 silk.

u. The procedure is terminated.

4. Extensive lesions of the floor of the mouth without bone involvement

a. The tracheostomy is performed, and the patient is prepared and draped.

b. Bilateral neck dissections are performed.

c. Two main surgical approaches are available: intraoral/cervical "pull through" or mandibulotomy.

d. Intraoral/transcervical "pull through"

1) The lateral margins surrounding the cancer are established with a monothermy needle tip and extended with sharp dissection.

2) At the level of the sublingual glands, the cancer is then reached via a cervical approach.

3) A subplatysmal anterior cervical facial flap is raised to the level of the inferior mandible.

4) The mylohyoid and digastric muscles are transected to enter the deep aspect of the floor of the mouth.

FIG. 30.5 **A,** Patient with a second primary cancer of the floor of the mouth. A first primary cancer had been excised elsewhere from the left floor of the mouth 25 years before this second primary appeared. The defect had been reconstructed with a deltopectoral flap. **B,** Photo revealing the previous donor site of the deltopectoral flap. **C,** Left: Floor of mouth reconstructed with deltopectoral flap. Right: Floor of mouth reconstructed with split-thickness skin graft.

5) The floor-of-mouth specimen is then delivered into the neck, and the cancer is resected.

6) The hypoglossal and lingual nerves, which were identified during the neck dissection, can be safely protected and preserved as long as this does not compromise ultimate

oncologic control.

7) Reconstruction

a) Pectorals major myocutaneous flap

b) Radial forearm free flap

c) Supraclavicular island flap

8) An orogastric tube is passed to remove stomach contents.

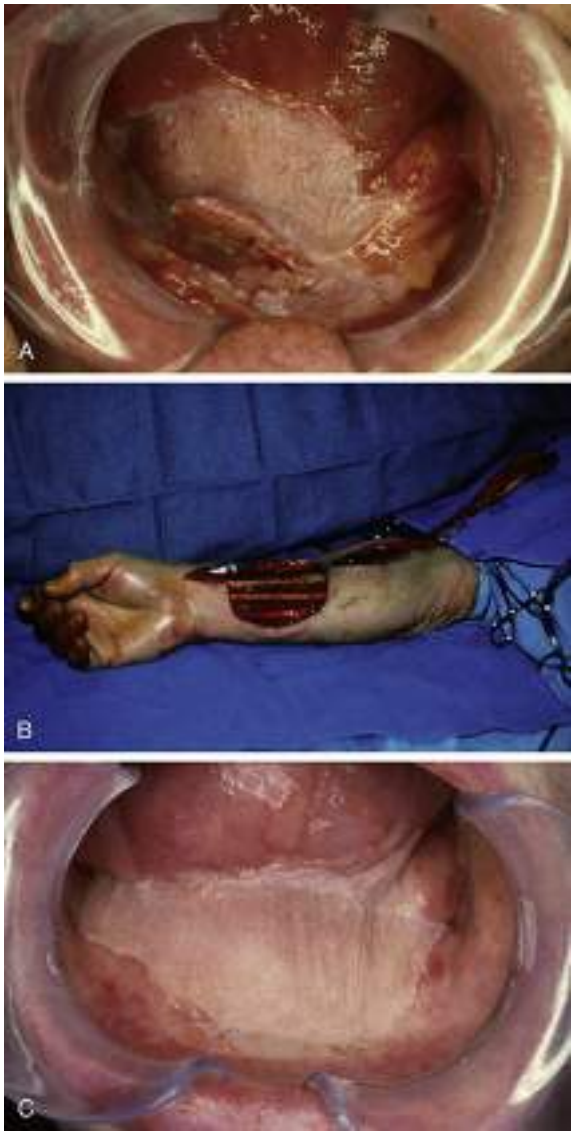

FIG. 30.6 **A,** Patient with recurrent squamous cell cancer. The remains of the skin graft are seen posterior to the recurrent cancer. Excision of the recurrent cancer and a marginal mandibulectomy of the anterior segment of the mandible were carried out en bloc. **B,** A radial forearm free

flap being harvested. **C,** The radial forearm flap is soft and pliable; it does not restrict the mobility of the tongue.

9) If g-tube is not present, a Dobhoff feeding tube is then placed and secured to the nasal septum with 3-0 silk.

10) The procedure is terminated.

e. Mandibulotomy

1) Visor flap

a) A superior cervical facial flap is elevated up to the level of the inferior mandible

b) The gingival-buccal sulcus is incised using needle-tip monothermy cautery 1 cm away from the mandible.

c) Care is taken to avoid removing the periosteum off of the anterior table of the mandible or to injure the mental nerves.

d) The cervical facial flap is then connected to the gingival-buccal sulcus incision.

e) The periosteum on the anterior tables of the mandible is then incised to expose the underlying cortex.

2) Lip split

a) A notched incision is designed within the midline of the lower lip to aid in aesthetic camouflage.

b) The incision is extended inferiorly until it meets the underlying neck dissection incision.

c) The plane is dissected toward the periosteum, which is then incised to expose the cortex of the underlying mandible.

3) After exposure of the mandible, the reconstruction plate is prebent over the native contour of the mandible.

a) An oscillating Stryker saw is then used to perform a midline mandibulotomy through both the anterior and posterior tables.

b) This exposes the cancer anteriorly, at which point the cancer can be resected completely.

4) Reconstruction

a) Mandibular plating

b) Split-thickness skin graft

c) Pectoralis major myocutaneous flap

d) Radial forearm free flap

e) Supraclavicular island flap

5. Segmental mandibulectomy

a. A visor flap or lip-split procedure is performed for access. Some patients will have destruction of the anterior segment of the mandible with infiltration of the skin of the chin, which is taken with the specimen.

b. Dental extractions are performed in the dentulous patient at the site of osteotomy.

c. Vertical osteotomies are planned at least 1 cm from the tumor edge.

d. The mucosa is incised with monothermy cautery.

e. A periosteal or Freer elevator is used to free the periosteum from the underlying mandibular cortex.

f. Osteotomies are made with a reciprocating saw positioned at the anterior aspect of the tooth extraction site.

g. The cancer, the mandible, and overlying skin, if necessary, can then be resected en bloc as previously described (Fig. 30.7).

Common Errors in Technique

1. Failure to properly orient the specimen

2. Overly aggressive marginal mandibulectomy, leaving an inferior alveolar ridge of less than 1 cm of remaining bone

3. Failure to fully release both the buccal and lingual surfaces of the mandible with the osteotomies, leading to splintering or fracture of the surrounding remnant bone

4. Placement of the vertical osteotomy on the posterior aspect of the tooth

extraction socket, leaving poor bone support for residual teeth

Postoperative Period

Postoperative Management

1. Skin graft or rotational flap
   a. Bolster removed on day 5
   b. 15 mL oral rinse 4 times daily for 1 week
   c. Trickle tube feedings via nasogastric tube started on postoperative day 1
   d. PO regimen
      1) Clear liquids at 1 week for nonirradiated patients
      2) Clear liquids at 2 weeks for irradiated patients

FIG. 30.7 **A,** Patient with a squamous cell cancer of the floor of the mouth, which destroyed the anterior segment of the mandible and infiltrating the skin of the chin. **B,** A scapular osteocutaneous

free flap was bivalved, and the bone used to replace the resected anterior segment of the mandible. **C,** One skin flap was used to resurface the floor of the mouth. **D,** The other flap was used to resurface the chin.

e. Drain in place until less than 30 mL collected in a 24-hour period

f. Speech and swallow rehabilitation consult

g. Pain control

h. Skin graft healed and full dentures fabricated (see Fig. 30.4). Patients who have had a marginal mandibulectomy may need dental implants to stabilize the lower dentures.

2. Free flap

a. Intensive care unit (ICU) for 48 hours postoperatively with hourly flap checks

b. Routine tracheostomy care

c. Soft tissue postoperative management as above

d. After 1 week of clear liquid diet, 6 weeks of soft diet

e. Drain in place until less than 30 mL is collected in 24 hours

f. ICU for 48 hours postoperatively with hourly flap checks

g. Drain in place until less than 30 mL is collected in 24 hours

Complications

1. Orocutaneous fistula

a. Monitor drain output.

b. Examination of suture line and surrounding skin

2. Hematoma

a. Monitor for soft tissue swelling intraorally and in the neck.

b. Monitor for changes in skin color.

3. Wound infection

a. Monitor drain output for purulence.

b. Monitor skin incision for erythema and discharge.

4. Systemic infection

a. Monitor vital signs.

5. Damage to hypoglossal nerve

a. Postoperative examination of tongue for midline and lateral mobility

6. Damage to lingual nerve

a. Postoperative assessment of tongue sensation

7. Pathologic mandibular fracture

a. Bimanual palpation of mandible

b. Postoperative Panorex with increased clinical suspicion

8. Mandibular nonunion

a. Bimanual palpation of mandible

b. Postoperative Panorex with increased clinical suspicion

Alternative Treatment Regimens

1. Radiation
2. Chemoradiation
3. Brachytherapy

Discussion

Evidence-Based Medicine Question

How should the clinically negative neck (cN0) be addressed in early-stage cancers of the floor of the mouth?

In advanced-stage cancers (T3–T4), bilateral neck dissections have become the standard of care. Likewise, early-stage (T1–T2) floor-of-mouth cancers with either clinical or radiologic evidence of cervical metastasis will receive an ipsilateral neck dissection at the time of surgery. However, in early-stage cancers (T1–T2) with a cN0 neck, the

role of neck dissection remains a controversial topic. There are currently three competing options for these patients: active surveillance, sentinel lymph node biopsy, and elective neck dissection. For many practitioners and patients, active surveillance is a seductive treatment option. It avoids the high cost of unnecessary treatment and complications associated with surgical intervention. Moreover, nearly 70% of patients who choose watchful waiting will ultimately require no further intervention.[6] Unfortunately the remaining 30% of patients will eventually develop cervical lymph node metastasis.[6] The development of nodal relapse is devastating, as only about half of these patients can be successfully salvaged.[6] Sentinel lymph node biopsy (SLNB) is a relatively new method of addressing the neck. The primary advantage of SLNB, like active surveillance, is the avoidance of the morbidity associated with an elective neck dissection. In many oral cavity cancers, the utility of SLNB is promising. However, conflicting results have been reported for its role within the management of early floor-of-mouth carcinoma. Ross et al. demonstrated that the sensitivity of SLNB in floor-of-mouth cancer was only 80%, greatly decreased from other oral cavity subsites (near 100%).[7] The same study found that nearly 4% of patients treated with SLNB developed metastatic neck disease within 24 months, casting doubt on its efficacy with floor-of-mouth neoplasms.[7] The final treatment option is elective neck dissection. Patients within this treatment arm are subject to higher treatment costs, longer hospitalizations, and increased morbidity. However, a prospective randomized control trial of T1–T2 oral cavity cancers demonstrated a survival benefit of 23.6% by undergoing elective neck dissection at the time of surgery.[8] The study found that eight patients would have to undergo elective neck dissection to prevent one death, while four patients would have to be treated to prevent one nodal relapse.[8] The findings of this study support our own institutional practice of performing elective neck dissection for all early-stage cancers of the floor of the mouth.

Editorial Comment

Cancers of the floor of the mouth are particularly challenging due to the anatomic proximity to the mandible, the lingual and hypoglossal nerves, and a rich lymphatic network extending to both sides of the neck. Careful surgical planning must account for all of these structures. Furthermore,

due to tongue suspension to the mandible by the genioglossus muscles at the genial tubercle and the need for bilateral lymph node assessment, edema and structural loss of natural airway support must be acknowledged, with a low threshold for tracheostomy. Assessment of the lymphatics surgically is typically done by selective neck dissections bilaterally of levels I to III for the clinically negative neck (N0), especially for primary cancers with greater than 4 mm depth of invasion. SLNB is emerging as a potentially effective minimally invasive assessment of the neck for these cancers. The positive neck may require additional levels of dissection depending on the extent of nodal disease, but with an emphasis on preservation of uninvolved nonlymphatic structures. Reconstruction should be predicated upon maximizing speech and swallowing function, principally by reestablishing the anterior mandibular contour, anterior tongue suspension, and supporting maximal tongue mobility. Skin grafts and pliable, thin free flaps provide the best opportunity to achieve these reconstructive goals.

Careful orientation of the primary specimen and neck dissection/nodal specimens is of critical importance. Margin-negative resection with greater than 18 lymph nodes in each selective neck dissection represents a quality resection that enhances the predictive value of pathologic prognostic information. Close or positive margins, multiple cancer-positive lymph nodes, perineural invasion, and lymphovascular invasion are indications for postoperative adjuvant radiotherapy. Chemotherapy should be added in the adjuvant setting if margins are positive and extracapsular spread is present in the positive lymph nodes.

Review Questions

1. Which of the following is an indication for rim mandibulectomy?

   a. Invasion of periosteum and cortex in an edentulous patient

   b. Invasion of cortex in a dentulous patient

   c. **Invasion of periosteum without invasion of cortex**

   d. Submental lymphadenopathy noted on CT

2. Which of the following is a reasonable method of treating the neck in

early stage (T1/T2) cancer of the floor of the mouth with a clinically negative neck cN0?

a. Ipsilateral elective neck dissection

b. Watchful waiting

c. Sentinel lymph node biopsy

d. **All of the above**

3. Appropriate preoperative workup for all patients includes all of the following, except

a. Assessment of malnutrition

b. **Swallowing study**

c. CT scan

d. Tissue biopsy

4. Which of the following describes an accurate location of the mental nerve?

a. In a vertical plane beneath the second incisor

b. In a vertical plane beneath the first molar

c. In a vertical plane beneath the central incisors

d. **Midway between the first molar and second incisor**

Operative Otolaryngology

Excision of Buccal Carcinoma

Donovan Eu, and Chwee M Lim

Introduction

The buccal mucosa is an uncommon site for oral cavity cancer (SCC) and comprises 5% to 10% of all intraoral squamous cell carcinoma (IOSCC) in North America and Europe. However, it is more commonly seen among Taiwanese Chinese and in India, where betel nut chewing is prevalent in these communities. Among the published reports, buccal SCC was found to comprise between 23% and 37% of all IOSCC in a Taiwanese cohort.[1] Most patients with buccal SCC are in the fifth to sixth decade of life, and other risk factors, such as smoking and alcohol consumption, are also commonly encountered in these patients.

Treatment of buccal SCC is primarily wide surgical excision with negative margins, followed by adjuvant radiation or chemoradiation, depending on adverse clinicopathologic features. In patients with gross local disease that is unresectable (e.g., involvement of internal carotid artery), treatment is usually palliative radiation. Complete excision of buccal SCC lies in the thorough understanding of the three-dimensional surgical anatomy of the buccal space and its relevant surrounding areas, so as to anticipate possible spread of the cancer and avoid leaving microscopic disease behind in the surgical field.

Key Operative Learning Points

1. Buccal SCC is in close proximity to the underlying buccal space, which can potentially lead to subclinical infiltration of the masticator space,

infratemporal fossa, and pterygopalatine fossa.

2. Surgery for buccal SCC requires a thorough three-dimensional understanding of the related surgical anatomy so as to achieve complete surgical extirpation.

3. Due to the proximity of the buccal space to the retromolar trigone and the inferior and superior alveolar ridges marginal mandibulectomy and/or inferior maxillectomy may be necessary to achieve wide surgical margins. Similarly, excision of the skin of the cheek may be necessary for deep infiltration of the tumor to the dermis.

4. Reconstruction of the surgical defect is necessary to reconstitute both form and function of the oral cavity. Specifically, reconstitution of the oral commissure may be necessary to prevent drooling in the postoperative period.

Preoperative Period

History

1. History of presenting illness
   a. The duration and progression of the buccal primary should be ascertained.
   b. Local complications such as bleeding should be assessed. Speech and swallowing impairment may also occur due to fixation of the tongue by the cancer.
   c. Trismus should be assessed because it may signify posterior extension into the pterygoid muscles, or it may result from submucosal fibrosis from chronic betel nut chewing among these patients.
   d. Risk factors such as alcohol ingestion, smoking, and betel nut chewing should be sought.
2. Past medical history
   a. Previous history of cancer of the head and neck and previous treatment with either surgery or radiotherapy are important for management.

b. The patient's overall medical condition should be thoroughly evaluated for assessment of perioperative anesthetic risks.

c. Antiplatelet agents may increase perioperative bleeding and should be omitted before surgery. The decision to either stop or bridge the need of anticoagulation should be made with the patient's primary medical physician.

Physical Examination

1. Examination of the oral cavity

   a. All oral cavity subsites should be examined for possible synchronous cancers or premalignant lesions.

   b. The patient's ability to open his or her mouth should be evaluated for trismus and its severity. This may be a sign of medial pterygoid muscle involvement by the cancer. This may either represent unresectability or signify the need of a combined skull base approach to have complete tumor extirpation.

   c. Intraoral extension to the tongue, gingival, superior or inferior alveolar ridge, and retromolar trigone (Fig. 31.1) is evaluated.

   d. The mobility of the tongue is assessed for involvement of the extrinsic tongue muscles.

   e. The distance of the cancer from the oral commissure should be measured. This allows the surgeon to identify whether some form of oral competence reconstitution will be necessary following resection.

   f. Bimanual palpation should be also performed to identify possible fixation of the cancer to the overlying dermis. A peau d'orange appearance of the cheek skin, if present, is an accurate indicator of subdermal lymphatic infiltration by the cancer.

   g. Facial nerve function should be assessed, in particular the function of the buccal branch with regard to upper lip elevation and symmetry of the nasolabial fold.

2. Nasoendoscopy

   a. Nasoendoscopy is performed to evaluate for extension of the cancer to the nasal cavity in instances when the hard palate is involved.

b. The upper airway should be evaluated, especially in patients with trismus, so as to anticipate a possible difficult airway during induction of general anesthesia.

c. Possible second primary cancers of the head and neck should be excluded.

3. Head and neck examination

a. The neck is examined for possible cervical lymph node metastasis.

b. The sensation of the lower teeth is assessed as it may be affected due to involvement of the inferior alveolar nerve.

FIG. 31.1 Right buccal squamous cell carcinoma with involvement of retromolar trigone.

Imaging

Computed Tomography (CT) Scan

CT gives reliable information on extension into bone, especially if involvement of the mandible is suspected. CT has been shown to achieve 100% sensitivity and 88% specificity for assessment of invasion of the mandibular cortex.

Magnetic Resonance Imaging (MRI)

MRI is frequently used to evaluate the deep extension of the buccal SCC because it gives excellent visualization of the masticator space, infratemporal fossa, and pterygopalatine fossa. Features of masticator space involvement include extension of soft tissue mass to the masticator space, effacement of the masticator adipose tissue, infiltration of the muscles of mastication, such as the pterygoid muscles, and destruction of the ramus of the mandible. Displacement of adipose tissue by cancer within the pterygopalatine fossa on noncontrasted T1-weighted imaging is a sign of posterior extension into the pterygopalatine fossa.

MRI imaging also carries a higher sensitivity in detecting perineural spread as compared with CT.[2] MRI features of perineural invasion include enhancement of the nerve, nerve enlargement, and widening of the respective neural foramina.

Angiography

Angiography is seldom required unless there is suspicion of encasement of the internal carotid artery.

Indications

1. T1-T4a buccal SCC

2. Select T4b cancer (masticator space involvement that is inferior to the mandibular notch)

Involvement of the masticator space is classified as T4b disease by the American joint consensus committee (AJCC) 2002 staging system. This classification is defined as such because any involvement of the masticator space will imply incomplete surgical eradication of cancer due to the free communications to the deeper infratemporal and pterygopalatine fossa. In this instance, a compartmentalized resection of cancer will be unachievable.

However, clinical studies suggest that selected cancers with limited invasion of the masticator space might benefit from surgical extirpation. In a retrospective study performed by Liao et al., 45 patients with T4b

oral cavity SCC (majority buccal SCC) underwent surgical resection. Patients with involvement of the masticator space that was inferior to the mandibular notch achieved improved disease-free survival than did patients with extension beyond the mandibular notch.[3]

3. Surgery is rarely performed for palliation, although it may be necessary to palliate a fungating cancer that is bleeding.

Contraindications

1. Involvement of the masticator space that is superior to the mandibular notch

2. Involvement of the infratemporal fossa, pterygopalatine fossa, and encasement of internal carotid artery by cancer

3. Preexisting medical conditions that carry significant perioperative anesthetic risks

Preoperative Preparation

1. Three-dimensional perception of the buccal SCC should be appreciated with clinical examination and radiologic assessment

2. The defect following surgery should be anticipated and communicated with the reconstructive surgeon.

Operative Period

Surgery is the mainstay of treating buccal SCC, and it aims to completely resect the tumor with negative margins. A wide 2-cm margin surrounding the tumor is mapped out prior to resection.

Anesthesia

General Anesthesia

General anesthesia is typically used in order to control the upper airway during surgery. An orotracheal tube is typically used and with the tube

positioned opposite to the side to be resected. Alternatively, a nasotracheal tube may be used, and the advantage is that it allows a fuller visualization of the oral cavity. In locally advanced cancers, a planned tracheostomy is often created for the purpose of airway control postoperatively. This is often performed when a bulky flap is anticipated for reconstruction of the buccal space defect.

Positioning

Supine

The patient is placed supine, and a shoulder roll is placed for mild neck extension. When a free microvascular flap or a pedicled muscle flap is required, the donor site is exposed to allow for concurrent surgery.

Preoperative Antibiotic Prophylaxis

Antibiotics with appropriate anaerobic coverage are ideally chosen for perioperative antibiotic prophylaxis. A broad-spectrum antibiotic, such as amoxicillin with clavulanate, may be used. In patients with penicillin allergy, clindamycin is a good alternative.

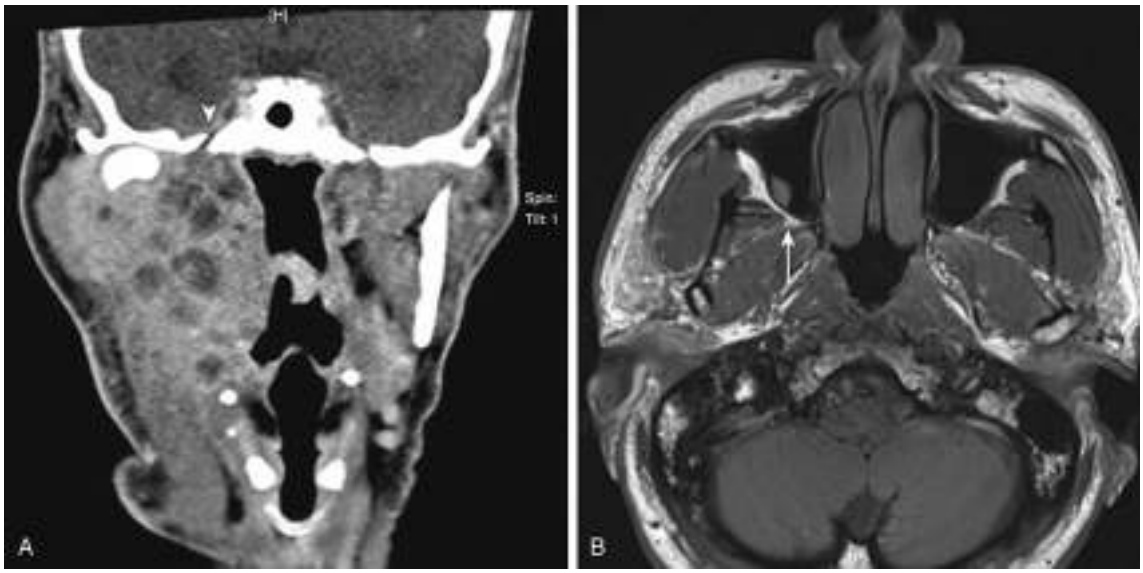

FIG. 31.2 **A,** Coronal computed tomography of buccal tumor with extension to masticator space and

infratemporal fossa. *White arrowhead* demonstrating foramen ovale. [H] is a radiological marking representing the position of the head. **B,** T1 magnetic resonance imaging of buccal space with *white arrow* demonstrating extension to pterygomaxillary fissure. [P] is a radiological marking that indicates posterior direction on the axial plane.

Instruments and Equipment to Have Available

1. A mouth gag (e.g., Jennings gag) is useful to expose the entire buccal mucosa.

2. An oscillating saw should be available when a mandibulectomy is anticipated.

Key Surgical Anatomy and Clinical Implications

Buccal Space

The buccal mucosa is composed of nonkeratinizing squamous epithelium, which is where SCC arises. Deeper to this mucosal layer lies the buccinator muscle, which forms the medial boundary of the buccal space. The buccal space and adjacent masticator space are important anatomic spaces because they communicate with the infratemporal fossa and pterygopalatine fossa via the foramen ovale and pterygomaxillary fissure, respectively (Fig. 31.2). Therefore involvement of these spaces by the cancer may be associated with extension into these deeper anatomic spaces.

The contents of the buccal space includes the buccal adipose tissue pad, parotid duct, minor salivary glands, the facial artery and its branches, and lymphatic channels and branches of the facial and mandibular division of the trigeminal nerve (V3) (Fig. 31.3). Cancer infiltration of this space should alert the surgeon to possible perineural spread along V3, either proximally into the foramen ovale or distally

along the inferior alveolar nerve through the mandibular foramen. In this regard, sacrifice of V3 may be necessary in locally advanced buccal SCC involving the buccal space. Frozen section evaluation of V3 may allow the surgeon to trace the resection margins within the surgical limits and allow adjuvant radiation to be delivered postoperatively.

Anterolateral to the buccal space lies the superficial layer of the deep cervical fascia and the muscles of facial expression. The superficial musculoaponeurotic system (SMAS) is just superficial to this, and the superficial adipose tissue compartment lies between the SMAS and the external skin. Because the distance from the cheek skin to the buccal space is often small, clinical evaluation of "dimpling" of the subdermis may suggest early involvement of the skin of the cheek and requires a wide excision of the cheek skin in order to avoid a close surgical margin.

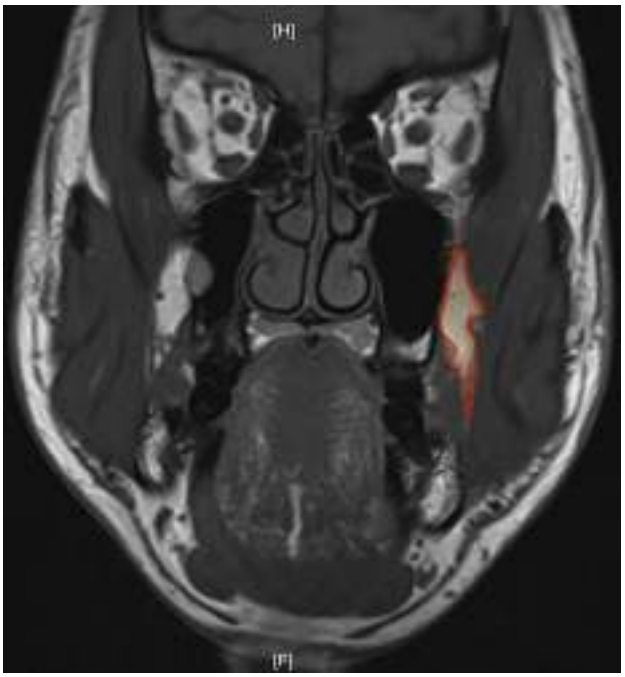

FIG. 31.3 Left buccal space highlighted in *red*. [H] is a radiological marking that represents the direction of the head, while [F] represents the direction of the feet.

Masticator Space

Posterolateral to the buccal space lies the masticator space and the deep lobe of the parotid gland. The masticator space is contiguous with the

buccal space, and it lies in the potential space between the lower border of the mandible and the medial pterygoids. The medial aspect of the masticator space communicates freely with the infratemporal fossa and the pterygopalatine fossa, as described earlier (Fig. 31.4).

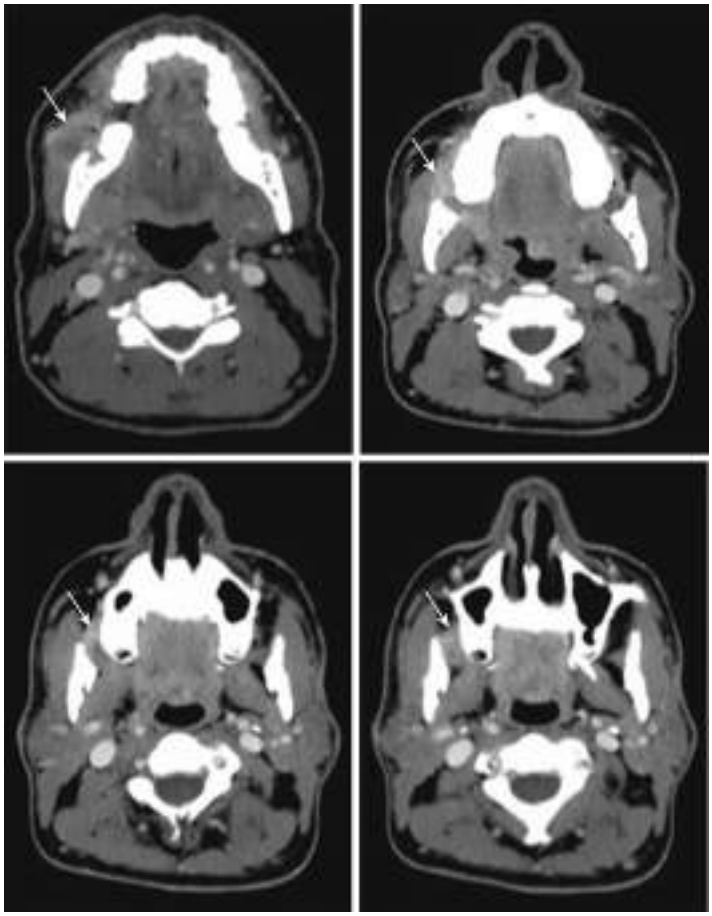

FIG. 31.4 Carcinoma of the right buccal space *(white arrows)* extending from masticator space to infratemporal fossa.

Cancer of the buccal mucosa may extend contiguously within the oral cavity to involve the other subsites, as follows (Table 31.1).

Depending on the local extent, surgery will need to encompass these subsites so as to achieve a wide en bloc resection. Specifically, considerations for inferior maxillectomy and/or marginal mandibulectomy must be anticipated if the tumor encroaches onto the superior alveolar ridge and retromolar trigone, respectively. Correspondingly, the resultant defect needs to be addressed

appropriately with a suitable flap reconstruction. Specifically, achieving a good oral competence to avoid drooling, as well as sealing off the oronasal communication (in the instance of partial inferior maxillectomy), is an important consideration for a good functional outcome.

TABLE 31.1

Extension Into Other Oral Cavity Subsites

Direction of Extension	Oral Cavity Subsites Involved
Anteriorly	Oral commissure
Posteriorly	Retromolar trigone
Posterosuperiorly	Maxillary alveolus Hard palate
Caudally	Mandibular cortex Alveolus Floor of mouth

Prerequisite Skills

Sound knowledge and understanding of the anatomy of the buccal space, masticator space, and the pterygopalatine fossa are necessary.

Surgical Technique

Airway Control

Methods of securing the airway before induction depend largely on patient and disease factors. The size of the oral cavity tumor, presence of teeth, neck stiffness, retrognathia, and the modified Mallampati scores are important considerations to predict a difficult airway. Disease factors such as the size of the tumor, its extension into the oral cavity, and the infiltration of the pterygoid muscles leading to trismus further contribute to difficulties with intubation. In patients with an anticipated difficult airway, an awake fiberoptic intubation can be performed by an experienced anesthesiologist. Nasal intubation, whenever feasible, should be performed so as to allow for greater visualization and maneuverability in the surgical field.

A tracheostomy under local anesthesia is another option if awake fiberoptic intubation is not feasible due to patient or physician factors. It is our practice to perform a temporary tracheostomy in patients with locally advanced disease where a bulky flap reconstruction is planned. This will facilitate airway protection in the immediate postoperative period.

Surgical Approach

Transoral

Transoral resection is an ideal approach in patients with T1 and most T2 cancers. Resection can be safely accomplished when the tumor is anteriorly based and minimally infiltrative and when there is no associated trismus. The oral cavity is widely exposed using a Jennings mouth gag, and the lesion is excised with a 2-cm margin. The depth of excision is typically at the plane before the buccal adipose tissue pad. Frozen sections are used to ensure negative surgical margins upon completion of resection.

Cheek Flap

A lower cheek flap is usually performed in patients with more extensive cancer because this approach affords a greater exposure for wide excision of the cancer. This is particularly so for cancers that extend posteriorly toward the retromolar trigone. When the cheek skin is clinically involved (indicated by induration or dimpling of the skin or on MRI evaluation demonstrating dermal infiltration), the cheek skin will be sacrificed for oncologic purpose and an inferior cheek flap is not indicated.

In elevating a cheek flap, the lip is split in the midline down to the cortex of the mandible and continued laterally along the submandibular skin crease on the medial aspect. The mandibular periosteum is elevated up to the mental foramen so as to preserve the mental nerve. This foramen is usually directly inferior to the mandibular second premolar. If a mandibulectomy is planned due to cortical involvement of the mandible, sacrifice of the mental nerve is often necessary in order to rule out perineural involvement along the proximal inferior alveolar nerve. Frozen section of both proximal inferior alveolar nerve and distal mental

nerve margins is required in this setting.

In instances in which the mental nerve is preserved, the inferior cheek flap is retracted laterally by incising the alveolar mucosa with an adequate cuff (at least 5 mm) to facilitate primary closure. With the flap elevated to the mental foramen, a good exposure of the posterior aspect of the oral cavity is usually obtained.

Mandibulotomy

A mandibulotomy approach may be necessary in more extensive T4 cancers that encroach medially onto the floor of the mouth or ventral tongue or when posterior extension to the base of the tongue along the glossotonsillar sulcus is encountered. In these instances, en bloc resection of these cancers may be difficult with an cheek flap approach, and greater exposure may be necessary through a mandibulotomy.

FIG. 31.5 Right inferior maxillectomy, marginal manidbulectomy, and excision of overlying skin with the oral commissure.

If mandibulectomy is necessary as part of the resection, the surgeon should plan the site of the mandible split so as to avoid two separate osteotomies, which may result in devascularization of the intervening

mandibular segment. For example, if a posterior marginal mandibulectomy is planned, the surgeon should perform the mandibulotomy at the body of the mandible where the intended bone margin is anticipated and plate the osteotomy sites after resection. In patients with thin mandibular cortices, a segmental mandibulectomy may be a more appropriate option.

Extension to the Inferior Maxilla/Masticator Space

Buccal SCC that extends posterosuperiorly to the maxillary gingiva will require a partial inferior maxillectomy (Fig. 31.5). This resection can be achieved transorally, especially in a small cancer. In this instance, the upper gingival incision is incised onto the premaxilla and a maxillotomy is performed to ensure that there is no extension of the cancer into the maxillary sinus. An osteotomy is made over the lateral maxillary buttress to release the lateral attachment. Similarly, the hard palate is partially resected depending on the extent of the cancer to release the medial attachment.

When a subtotal maxillectomy is planned, a lateral rhinotomy approach is added to improve the exposure for complete surgical extirpation. Care is taken as one performs the posterior osteotomy on the pterygoid plate so as to ensure that there is no spillage of cancer through the posterior maxillary wall. Furthermore, brisk bleeding from the internal maxillary artery and the pterygoid plexus may be encountered. Suture ligation using a figure-of-eight silk suture is often effective in securing hemostasis in this setting.

In a select group of patients with masticator space involvement (T4b cancer), surgical resection can be undertaken with equivalent oncologic outcome as T4a tumors.[4] This form of resection should be undertaken by experienced head and neck surgeons in high-volume centers. In addition, a thorough evaluation for resectability using preoperative MRI assessment is mandatory. A key feature on MRI evaluation is to ascertain if a 1-cm margin from the masticator space is achievable during resection. This level corresponds approximately at the level of the mandibular notch. Therefore extension of the cancer beyond the mandibular notch is not resectable, as it represents extension beyond the masticator space.[3] Care needs to be exercised as one proceeds to dissect more medially at the level of the mandibular condyle as the internal carotid artery lies

medial to this mandible at this level.

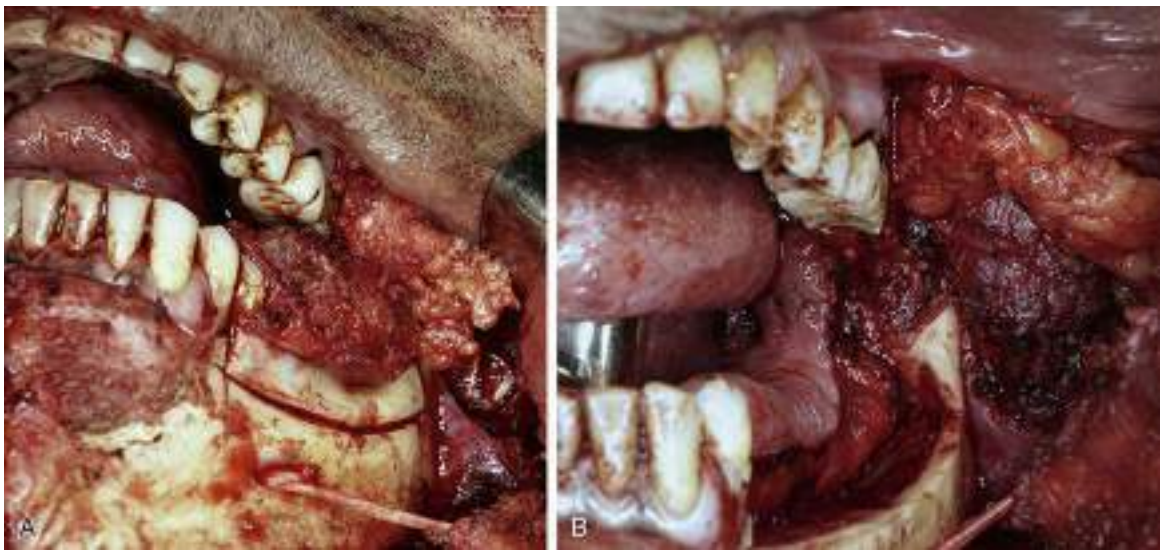

FIG. 31.6 **A,** Left marginal mandibulectomy. **B,** Defect following left marginal mandibulectomy.

Extension to the Retromolar Trigone/Ascending Ramus

Posterior extension toward the retromolar trigone is of particular concern because it is separated from the mandibular cortex by the thin pterygomandibular raphe. Thus it is not surprising that cancers extending to the retromolar trigone have a high predilection for invading the cortex of the ascending ramus. Therefore, depending on the extent of mandibular involvement, a marginal mandibulectomy (Fig. 31.6) or segmental mandibulectomy of the ascending ramus is necessary. In addition, cancers that extend to the retromolar trigone may also spread via the pterygomandibular raphe superiorly to involve the maxilla.[5] As such, careful preoperative evaluation of the maxilla is critical, and a maxillectomy may be required to achieve adequate margins.

Neck Dissection

Elective neck dissection (END) is usually performed on patients with early T1-T2 oral SCC with a clinically N0 neck. This is based on the results of a prospective clinical trial published in 2015,in which superior

clinical outcomes were reported in patients who had undergone END compared with those who were observed clinically.[6] However, most of these patients had oral tongue SCC and only a small subset (13.7%) had primary SCC of the buccal mucosa.

In other published retrospective reports, the overall rate of occult metastasis for early buccal cancers (T1 and T2) was 7.3%. Occult metastasis was present in 1.8% of cT1 lesions and 10.6% of cT2 lesions.[7] This same study also demonstrated improved 5-year disease-free survival (82.09% vs. 59.09%) and 5-year neck control rates (92.6% vs. 68.2%) in patients who received END. We typically perform selective neck dissection encompassing level I to III for clinically T1/T2 buccal SCC because the nodal basins harboring occult disease are usually located in level I and II. The risk of skip nodal metastasis in buccal SCC, unlike oral tongue SCC, is uncommon.

TABLE 31.2

Reconstructive Options for Buccal Space Defects

Reconstruction Method	
Primary closure	Primary closure may be performed in small defects.
Skin grafts	A full-thickness skin graft may be used to cover a superficial buccal defect.
Buccal adipose tissue pad	Local flaps, such as the buccal fat pad flap, have been reported to fill the surgical defect following resection.
Pedicled flaps	Reconstruction of larger defects may require the use of rotational pedicled flaps. The pectoralis major or a submental island flap may be used in this setting.
Microvascular free flaps	Depending on the extent of the defect, various free flaps may be used. Defects of the buccal space and retromolar trigone may be covered by free radial forearm flaps. This is an ideal flap where large tissue bulk may impede patient's swallowing and speech functions. An anterolateral thigh flap may be used in cases where large bulk of tissue is required to reconstruct a large defect (e.g., when the external cheek skin is excised). Reconstruction following segmental mandibulectomy would necessitate an osseocutaneous flap, such as the free fibular flap.

Patients with clinically positive lymph nodes (N+) are treated with modified radical neck dissection. However, there are some data demonstrating the low risk of occult disease (approximately 1%) to level V, and hence level V may be omitted in patients with limited N+ disease (N1/N2a).[8]

Reconstruction

The multiple methods of reconstruction of the surgical defect are beyond the scope of this chapter. The principle of reconstruction ladder is helpful to determine the optimal reconstructive option (Table 31.2).

Postoperative Period

Postoperative Management

Management of Wound/Flap

After surgery, it is imperative to ensure good oral hygiene so as to promote healing of the oral wound. Regular mouth rinses using antiseptic mouth gargles is helpful in this regard. The patient may be placed on a short period (5 to 7 days) of nasogastric tube feeding before commencing on an oral diet.

When a flap is used for reconstruction, regular flap monitoring is important to identify early free compromise so that early flap salvage may be possible. This is achieved by regular examination of the flap's color, turgor, capillary refill, and presence of vascular congestion. When a microvascular free flap is deployed, vascular flow may be monitored using a transcutaneous ultrasound Doppler to ascertain patency of the microvascular anastomoses. The donor site is also examined for any possible donor site complications.

Complications

The main surgical complication following excision of buccal SCC is related to the wound healing of the buccal defect. Wound dehiscence, infection, and flap failure may occur and may be treated with approximate antibiotics and wound care. The key toward preventing these wound complications lies in tension-free closure of the defect and ensuring good oral hygiene in the postoperative period.

Alternative Management Plan

In patients who are not surgical candidates, radiotherapy or

chemoradiation may be considered. Radiation therapy for curative intent may be a viable alternative in patients with early cancer because the results of a retrospective study demonstrate a 3-year disease-free survival of 85% and 63% in patients with stage 1 and 2 cancer, respectively.[9] Nevertheless, superior 5-year overall survival and locoregional control were far superior in the surgical cohort compared with radiotherapy alone in a published result from a single center.[10]

Evidence-Based Medicine Question

Is buccal carcinoma associated with poorer survival/functional outcomes compared with cancers of the other subsites of the oral cavity?

Buccal carcinomas have been traditionally reported to have a significantly poorer outcome compared with the other subsites of the oral cavity. Previously published data from Memorial Sloan Kettering Cancer Center reported a 58% 5-year disease-specific survival for buccal carcinoma compared with 72% to 82% from the other subsites. However, this does not appear to be consistent throughout all centers. More recent publications demonstrated no differences in 5-year disease-specific survival of buccal cancers (70%) compared with that of other subsites of the oral cavity (75%). The 5-year overall survival of buccal carcinoma is reported to be 63% to 73%,[1] and locoregional recurrences are reported to occur in 26.5% to 57% of patients.[10] The higher propensity of locoregional recurrences compared with oral tongue cancer is possibly due to the increased risk of close to positive surgical margins resulting from the complex three-dimensional anatomy of the buccal space, which facilitates subclinical spread of cancer. In a large series of buccal cancers comprising 394 patients, poor prognostic factors for survival included positive surgical margins, positive nodal metastasis, and locally advanced tumor disease.[1]

The functional outcome after surgery for buccal cancer is dependent on the extent of resection and appropriate reconstruction efforts. In general, most patients achieved good swallowing and speech outcomes in cases of small T1-T2 tumors. Consideration of achieving good oral competence and sealing any oronasal communication are crucial even in small cancers. In larger cancers in which part of the ventral tongue, soft palate, or tongue base is resected, a period of swallowing and speech

rehabilitation is necessary to achieve good functional outcomes.

Editorial Comment

Cancers of the buccal mucosa have among the most aggressive behavior of any oral cavity malignancy. Early detection and early aggressive management offer the best opportunities for locoregional control and survival. The proximity of these cancers to the parotid, masticator, pterygomaxillary, and infratemporal fossa spaces provides complex opportunities for local cancer progression by either direct extension or perineural invasion. Appropriate imaging techniques such as CT and/or MRI scans are of paramount importance in surgical planning. Surgery is the preferred initial management for these cancers where resection is possible and distant metastatic cancer has been excluded. Surgical efforts may include transoral excision, infrastructure or total maxillectomy, skull base resections, parotidectomy, and neck dissection. Margin clearance should be a primary objective and confirmed with frozen sections where possible. Neck dissection should be performed for all N-positive cases, and elective neck management for the clinically N0 neck should be considered in cases that are T2 or greater. The reconstruction of smaller intraoral defects can be achieved with skin grafts or local flaps in select cases. More formidable defects are best reconstructed with microvascular free tissue transfer, in particular "through and through," defects of the cheek. In complex cases a combination of flaps, such as free flaps and cervicofacial rotation flaps, may be required to achieve acceptable closure to maximize postoperative function and cosmesis. Postoperative adjuvant radiation therapy is necessary in cases with close or positive margins (less than 5 mm), multiple positive lymph nodes, extracapsular extension in lymph nodes, perineural invasion, lymphovascular invasion, and advanced stage. Chemotherapy should be considered in cases in which margins are positive and in cases with extracapsular extension of lymph node metastases. Postoperative surveillance and survivorship include careful periodic examination, speech and swallowing rehabilitation, nutritional education and support, and psychosocial support, as required.

Review Questions

1. Buccal carcinomas that have invaded the masticator space may extend to the pterygopalatine fossa via the

   a. Formaen ovale

   b. Infraorbital nerve

   c. **Pterygomaxillary fissure**

   d. Greater palatine foramen

2. In the management of buccal carcinoma with limited invasion to the retromolar trigone the preferred approach would be

   a. Transoral resection

   b. **Inferior cheek flap and marginal mandibulectomy**

   c. Mandibulotomy and marginal mandibulectomy

   d. Segmental mandibulectomy

3. Patients with gross invasion of the masticator space are amendable to surgical resection with improved survival outcomes if the cancer lies

   a. **Inferior to the mandibular notch**

   b. Superior to the mandibular notch

   c. Anterior to the mandibular notch

   d. Posterior to the mandibular notch

4. The role of elective neck dissection in cN0 buccal carcinomas has been shown to

   a. Be unnecessary as there is usually submucosal fibrosis

   b. Significantly improve disease-free survival

   c. **Improve overall 5-year survival**

   d. Be beneficial for diagnosis of skip metastasis

5. Magnetic resonance imaging (MRI) is often the preferred imaging of

choice because it

a. Allows for accurate evaluation of the mandibular cortex

b. Is essential to determine invasion of the maxilla

c. **Allows excellent evaluation of the infratemporal fossa and pterygopalatine fossa**

d. Shows invasion of the maxillary sinus

6. The main cause of mortality in buccal carcinomas is secondary to

a. Malnutrition

b. Distal metastasis

c. **Locoregional failure**

d. Secondary malignancies

Transoral Inferior Maxillectomy

Peter S. Vosler, and Eugene N. Myers

Introduction

The hard palate is the site of origin of benign and malignant tumors.[1,2] The most common tumor of minor salivary gland origin in this site is pleomorphic adenoma, a benign tumor that appears as a smooth submucosal mass. Approximately 5% of cancers of the oral cavity involve the hard palate and maxillary alveolus.[3] Squamous cell carcinoma accounts for approximately 90% of malignancies of the hard palate and the upper alveolar ridge (Fig. 32.1).[4] Cancers arising in the minor salivary glands are the most prevalent non–squamous cell cancers of the hard palate. Adenoid cystic carcinoma is the most common of the cancers of minor salivary gland origin, followed by mucoepidermoid carcinoma, malignant mixed tumor, acinic cell carcinoma, and other adenocarcinomas.[2] Lymphoma and plasmacytoma also arise on the hard palate. Polymorphic reticulosis (formerly called lethal midline granuloma) commonly involves the hard palate and upper alveolus. Necrotizing sialometaplasia and pseudoepitheliomatous hyperplasia have an appearance similar to squamous cell carcinoma.[2] Malignant melanoma may also occur in the mucosa of the hard palate. Sarcomas of bone and soft tissue have likewise been reported in the hard palate and upper alveolus, more commonly in children.[4]

Evidence of a direct cause-and-effect relationship between tobacco, alcohol, and cancer of the hard palate is not as clear-cut from an epidemiologic point of view as it is with cancer in other upper aerodigestive tract sites. An exception is the high incidence of cancer of the hard palate in parts of India and the Philippines, where reverse smoking is practiced. Poor oral hygiene, mechanical irritation, ill-fitting dentures, syphilis, and even mouthwash have been suggested as other

possible causative relationships.[2]

Key Operative Learning Points

1. A thorough examination of the oral cavity, nasal endoscopy, examination of the neck, imaging with maxillofacial computed tomography (CT) scan, and biopsy are essential to fully characterize the lesion, devise a plan of management, and determine the extent of the resection.

2. Comprehensive understanding of the three-dimensional anatomy and surrounding structures will facilitate resection and help to avoid complications.

3. Reconstruction of smaller palatal defects with a prosthesis is sufficient, whereas larger defects will require a local, regional or even microvascular free tissue flap.

Preoperative Period

History

1. History of present illness:
   a. How was the mass discovered?
      1) Incidentally by a dentist or by the patient
   b. How long has the mass been present?
   c. Associated signs and symptoms
      1) Pain
      2) Numbness of the palate and face
      3) Bleeding from the mass
      4) Epistaxis
      5) Dental infections, tooth extraction/removal, loose teeth, poorly fitting dentures
      6) Trismus

7) Voice change

8) Neck mass

9) Weight loss

2. Past medical history:

a. Prior oral lesions removed?

b. History of periodontal disease

c. Medical history

1) Diabetes, immunosuppression, coronary artery disease, thrombosis, hypertension

d. Prior head and neck surgery or radiation

e. Social history

1) Smoking and alcohol consumption

f. Family history

1) History of cancer of the head and neck or other malignancies

g. Medications

1) Anticoagulation/antiplatelet therapy

2) Insulin

3) Homeopathic products

Physical Examination

1. Oral cavity: Using a bright light, tongue depressors, and suction; a thorough examination of the oral cavity is paramount in determining the extent and characteristics of the mass.

a. Location

1) Involvement of the hard or soft palate, involvement of lingual or buccal alveolus

b. Size of mass: Map the area of the tumor including areas of swelling suggestive of subepithelial spread of the tumor.

c. Characteristics of the mass:

1) Leukoplakia or erythroplakia lesion

2) Endo- or exophytic mass. Palpation of the mass is clinically the best way of evaluating thickness and depth of infiltration.

3) Submucosal lesion

d. Dentition: Evaluate for loose dentition, ill-fitting dentures, and gingivitis.

e. Examine loose dentition for the possibility of malignant involvement of the tooth sockets and underlying bone.

f. Sensation of palate: Numbness of the palate may indicate involvement of the palatal foramina and skull base.

2. Nasal endoscopy: Detailed inspection of the floor of the nasal cavity, inferior meatus, and lateral nasal wall is essential to determine the presence of intranasal extension of the cancer.

3. Neck: The neck should be examined for the presence of a mass because many patients will present with metastasis to the neck. Evidence of prior surgery should be noted.

4. Cranial nerve examination: Specifically evaluate the distributions of the trigeminal nerve to evaluate for neural involvement by the cancer.

FIG. 32.1 Squamous cell carcinoma is the most commonly encountered cancer of the hard palate.

5. Flexible fiberoptic laryngoscopy: Evaluation of the remainder of the upper aerodigestive tract is performed to exclude the possibility of a

second primary cancer, because second primaries may occur in 20% to 25% of patients with squamous cell carcinoma of the oral cavity and oropharynx.

Imaging

1. Maxillofacial, neck, and chest CT scan with and without contrast: Identify the size and extent of infiltration of the tumor, any areas of bone invasion, involvement of the nasal cavity and maxillary sinuses, and the presence of metastases to the lymph nodes. CT is also very helpful in diagnosing distant metastases, which occur most commonly in the lung.

2. Positron emission tomography (PET)/CT: This technique is not helpful in the evaluation of the primary cancer, but it may be very helpful in evaluating the neck for metastatic lymph nodes because they may be involved in up to 50% of patients with squamous cell carcinoma of the hard palate.[4] PET/CT scanning is also valuable in detecting the presence of distant metastasis.

Indications

1. Surgery is the first-line treatment of all benign and malignant tumors of the palate.

   a. Benign tumors may be removed without resecting bone and there is no requirement for reconstruction.

   b. Malignant tumors will require resection of part or all of the hard palate or maxillary alveolus (or both) to remove bone that is obviously involved along with at least a 1-cm margin. These defects will require some form of reconstruction.

   c. Adjuvant chemoradiation is beneficial when there is bone invasion, perineural invasion, two or more positive lymph nodes, or extracapsular spread.

2. Ipsilateral selective neck dissection, levels I to III, should be performed for tumors that do not involve the midline. Bilateral selective neck dissections should be performed for tumors involving the midline.

Contraindications

1. Presence of distant metastasis in the lung

2. Very advanced local disease (T4b) involving the masticator space, pterygoid plates, skull base, or encasement of the carotid artery

3. Severe medical comorbidities

Preoperative Preparation

1. Map out the extent of the tumor based on physical examination and imaging findings.

   a. Anticipate the extent of the defect to determine whether the patient will require restoration of oral-nasal separation with a dental prosthesis, local pedicle flap, or free flap reconstruction.

   b. If the dimensions and site of the tumor, whether benign or malignant, require resection of the maxillary alveolus or palatal bone, or both, a plan must be made to achieve oral-nasal separation. In most circumstances this can best be accomplished through the use of an obturator.[5,6] A prosthodontist should always be consulted preoperatively so that the appropriate dental records and impressions can be taken and a surgical splint fabricated for use following resection of the tumor.

2. Biopsy: A definitive biopsy is necessary to plan surgical management. Benign and malignant tumors of salivary gland origin may be covered by mucosa, and incisional biopsy is usually necessary in such cases for accurate diagnosis.

3. In the presence of a malignant tumor, determine the need for ipsilateral or bilateral neck dissection.

4. Preoperative medical clearance must be secured for patients with significant medical comorbidities.

5. Counsel the patient regarding the risks of the procedure. Informed consent should include: bleeding; infection; need for local, regional, or microvascular reconstruction; possible use of a dental prosthesis; evaluation by a prosthodontist; and potential cosmetic deformity.

6. Discontinue use of anticoagulation and antiplatelet therapies prior to surgery.

7. Early admission is recommended for detoxification in patients with known alcohol abuse.

Operative Period

Anesthesia

1. General anesthesia is indicated for most procedures involving the maxilla for airway protection and patient comfort.

Positioning

1. The patient is placed in the supine position with the head of the bed turned 90 or 180 degrees away from the anesthesiologist.

2. The use of a local or regional flap should not modify patient positioning. Microvascular free tissue transfer may require repositioning based on the donor site of the flap and will be governed by the reconstructive surgeon.

Perioperative Antibiotic Prophylaxis

1. Antibiotics covering for oral flora (gram positive, gram negative, and anaerobic bacteria) such as ampicillin-sulbactam or clindamycin for penicillin-allergic patients

Monitoring

1. No specific neural monitoring is necessary for this surgery. Monitoring of hemodynamics, body-fluid homeostasis, and oxygen saturation should be performed per the anesthesiologist's preferred protocol based on the patient's medical comorbidities.

Instruments and Equipment to Have

Available

1. Basic head and neck or plastic surgery set

2. Monopolar and bipolar cautery

3. Microtome for split-thickness skin graft (STSG)

4. Surgical splint made by a prosthodontist prior to surgery

5. Saw or drill (reticulating or sagittal saw or Midas Rex pneumatic drill), and osteotomes

6. Dental tray

Key Anatomic Landmarks

1. The hard palate and alveolar ridge form the superior boundary of the oral cavity.

2. The hard palate separates the oral cavity from the nasal cavity and maxillary sinuses.

3. The pterygopalatine and infratemporal fossae are located posterior to the maxilla.

Prerequisite Skills

1. Three-dimensional understanding of the anatomy of the maxilla

2. Neck dissection (see Chapter 87)

Operative Risks

1. Intraoperative hemorrhage from palatine and internal maxillary arteries

2. Neurovascular injury from the neck dissection (see Chapter 87)

3. Creation of defects larger than anticipated without proper preoperative preparation

Surgical Technique

1. Approaches to the surgical management of cancer limited to the hard palate and alveolar ridge include:

   a. Excision of benign tumors

   b. Partial lateral maxillectomy: Surgical approach for tumors of the hard palate that involve the maxillary sinus and nasal cavity

   c. Inferior maxillectomy: Surgical approach for tumors of the hard palate that do not involve the floor of the maxillary sinus and nasal cavity

   d. Complete maxillectomy (see Chapter 15)

2. **Approach to benign mucosal tumors of the palate** (Biopsy-confirmed benign tumors only involving the mucosa (i.e., pleomorphic adenoma, necrotizing sialometaplasia, etc.))

   a. Incise with electrocautery or scalpel with 0.5-cm margins of the lesion.

   b. The deep margin should be the periosteum of the hard palate.

      1) If there is concern for tumor involvement deep to the periosteum, the surface of the hard palate is drilled with a burr to remove the superficial layer of bone.

   c. Reconstruction

      1) A palatal island rotational flap or rotational flap based on either the greater palatine or ascending palatine arteries is used to cover the site of the defect.

3. Partial transoral lateral maxillectomy

   a. Hands-free cheek retractor, a bite block, or a side-biting mouth gag is placed to gain access to the oral cavity.

      1) Use of a sweetheart retractor aids in retracting the tongue.

   b. Mark the margins of the resection with a marking pen or electrocautery.

      1) Margins should be a minimum of 1 cm for any lesion suspicious for malignancy or biopsy-proven malignancy.

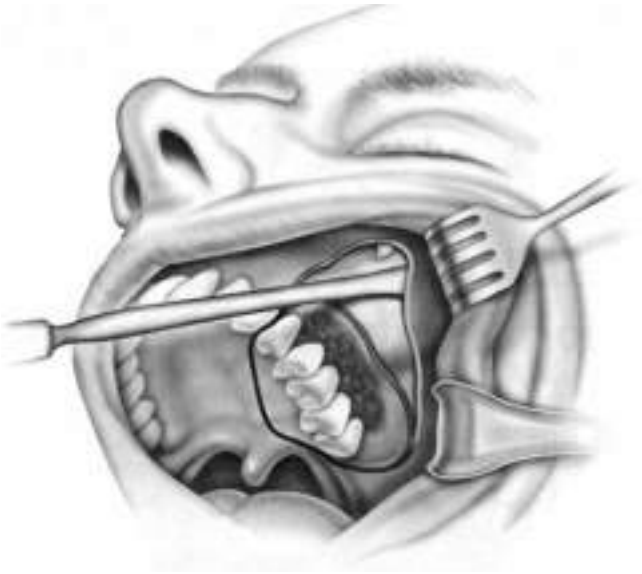

FIG. 32.2 Gingivobuccal incision and anterior maxillotomy with visualization of the maxillary sinus floor and infraorbital rim. Reprinted with permission from Simental AA Jr, Myers EN: Cancer of the hard palate and maxillary alveolar ridge: technique and applications. *Oper Tech Otolaryngol Head Neck Surg* 16:30, 2005.

c. Incise the mucosa with electrocautery for improved hemostasis.

d. Elevate the soft tissue in the subperiosteal plane of the front and lateral walls of the maxillary antrum to the level of the infraorbital nerve with a Freer elevator or a 9 Molt periosteal elevator.

    1) Identification of the infraorbital nerve helps prevent permanent anesthesia of the soft tissues of the face (Fig. 32.2).

e. Enter the maxillary antrum using a small osteotome and remove the anterior wall with a Kerrison rongeur sparing the infraorbital nerve.

    1) This allows for sufficient visualization of the maxillary antrum to evaluate the extent of resection.

f. A sagittal saw with reciprocating or sagittal blades is used to make osteotomies with at least 1-cm bony margins from the edge of the tumor along the frontal and lateral walls of the antrum.

g. Transect the palate into the maxillary sinus with care to avoid entering the nasal cavity if the tumor margins allow.

    1) If the nasal cavity is entered, the inferior turbinate is resected to facilitate fitting of the obturator made by the prosthodontist.

h. Place a large, curved osteotome posterior to the last molar at a 90-

degree angle to cut the hard palate in a superomedial direction (Fig. 32.3).

i. Once the pterygoid plates are fractured, brisk bleeding is expected from the pterygoid plexus and internal maxillary artery.

1) Use heavy curved Mayo scissors to complete transection of the soft tissues of the pterygopalatine fossa and soft palate and remove the tumor en bloc.

2) The posterior osteotomy is the final cut due to concern of hemorrhage from the internal maxillary artery and its branches in the pterygopalatine fossa. Performing this cut last allows for removal of the tumor, and hemorrhage from the pterygopalatine fossa cannot be adequately controlled until the tumor is removed.

FIG. 32.3 Posterior osteotomy created by aiming superomedially. Great care is taken not to violate the orbital floor. Reprinted with permission from Simental AA Jr, Myers EN: Cancer of the hard palate and maxillary alveolar ridge: technique and applications. Oper Tech Otolaryngol Head Neck Surg 16:31, 2005.

3) Control bleeding with clamp and ligature technique.

j. Obtain frozen section analysis from the left tissue margins of the specimen that are concerning for residual tumor or are too close to be oncologically sound.

1) Unfortunately, there is no way to evaluate bone margins by frozen section.

k. Remove the entire mucosa from the maxillary sinus to avoid contamination by oral cavity microorganisms and prevent resultant edema and inflammation that can interfere with the fit of the oral splint.

1) Remove any sharp edges of bone with a drill or file.

l. An STSG is harvested at a thickness of 0.018 inch and it is sutured into place to line the cheek defect (Fig. 32.4).

m. Pack the defect tightly with Xeroform gauze to close off dead space and compress the skin graft to the underlying tissue to ensure graft survival.

n. Place the previously formed surgical splint over the defect and secure it with a screw drilled into the remaining hard palate or suture it into place (Fig. 32.5).

1) In patients who have residual dentition, clips placed by the prosthodontist can also be used to further stabilize the splint. The presence of the surgical splint allows the patient to swallow and speak during the immediate postoperative period.

4. Inferior maxillectomy

a. Retract the lips with a hands-free cheek retractor, a bite block, or a side-biting mouth gag to gain access to the oral cavity.

b. Mark the margins of the resection with a marking pen or electrocautery.

1) Margins should be a minimum of 1 cm for any lesion suspicious of malignancy or biopsy-proven malignancy.

c. Incisions are made in a manner similar to that described for tumors of the alveolar ridge.

FIG. 32.4 A split-thickness skin graft is used to line the cheek flap. The maxillary sinus mucosa is removed entirely. Reprinted with permission from Simental AA Jr, Myers EN: Cancer of the hard palate and maxillary alveolar ridge: technique and applications. Oper Tech Otolaryngol Head Neck Surg 16:31, 2005.

d. The maxillary sinus is entered and the inferior aspect of the maxillary sinus is thoroughly evaluated (Fig. 32.6).

e. A sagittal saw is used to make precise osteotomies.

f. The osteotomy is usually completed with the osteotome at the level of the pterygoid plates.

g. The nasal cavity is entered and the septum is transected with heavy curved Mayo scissors 1 to 2 cm superior to the floor of the nose.

h. The soft palate is transected with electrocautery, and any residual soft tissue attachments are transected with scissors.

i. After the mucosa of the maxillary antrum is removed as previously described, the inferior turbinate is also removed to prevent infection and edema, which would interfere with the application of a palatal prosthesis.

j. More extensive tumors limited to the hard palate and alveolar ridge can be removed by simply extending the osteotomies.

k. Once the specimen is removed, it is sent to the pathology laboratory

for frozen section diagnosis and assurance of clear surgical margins.

5. Management of the neck in squamous cell carcinoma of the hard palate and alveolar ridge

a. A high incidence of cervical metastasis (30%) in the subsites of tongue and floor of the mouth cancer has been well documented.[7] Our observed data of squamous cell carcinoma originating in the maxillary alveolus suggest the rate of metastasis to the neck from squamous cell carcinoma of the hard palate and alveolar ridge to be 37%, which is similar to that in other sites in the oral cavity.[7]

b. Dissect the neck before the oral cavity because resection of the neck is considered clean.

c. If the primary tumor does not involve the midline, we perform a unilateral selective neck dissection. Midline lesions or lesions involving the entire hard palate require bilateral neck dissections.

d. If metastasis in the neck is present, N1 to N2, a selective neck dissection is performed. An N3 neck requires a modified or radical neck dissection. Once the neck dissection is completed, we re-drape and isolate the neck dissection wound from the oral cavity procedure.

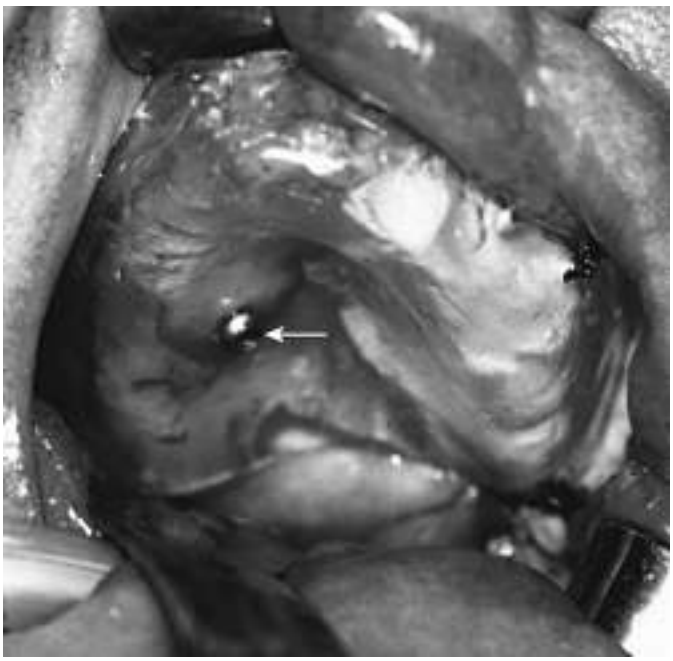

FIG. 32.5 A lag screw *(arrow)* facilitates fixation of the

acrylic splint.

Common Errors in Technique

1. Inadequate exposure
2. Positive margins

Postoperative Management

Rehabilitation of a Patient With Loss of Oral-Nasal Separation

Patients treated by inferior maxillectomy require a means of restoring the oral-nasal separation lost by removal of the palate and alveolar bone. Not doing so results in patients who can neither speak nor swallow, which gives rise to an unacceptable quality of life.

A comprehensive midface and maxilla classification system has been established incorporating both vertical and horizontal defects.[8] The defects are categorized into classes I to VI vertical defects based on involvement of the maxillary alveolus, nasal cavity, and orbit and horizontal defects based on the extent of the palatal defect (Fig. 32.7). Based on their experience, the use of obturation was reserved for class I to IIa-c defects, whereas free tissue transfer was preferred for more extensive defects of the maxillary alveolus (class IId) and defects with nasal and orbital involvement (classes III to VI).[8]

1. The four major means of rehabilitation include:
    a. Dental prosthetic management: A patient with a limited lesion of the alveolar ridge alone or the alveolar ridge and palate that does not involve more than half the hard palate can be rehabilitated relatively easily.[3]
        1) Preoperative dental impressions are made and a surgical splint is fashioned and inserted at the time of resection as described earlier.
        2) A lag screw is inserted through a hole in the prosthesis into the remaining palatal bone to hold the prosthesis in place (see Fig.

32.5).

3) On the fifth postoperative day the screw is removed and the prosthesis is taken out and the packing is removed. The skin graft is healed by that time and the sutures holding the skin graft are removed (Fig. 32.8).

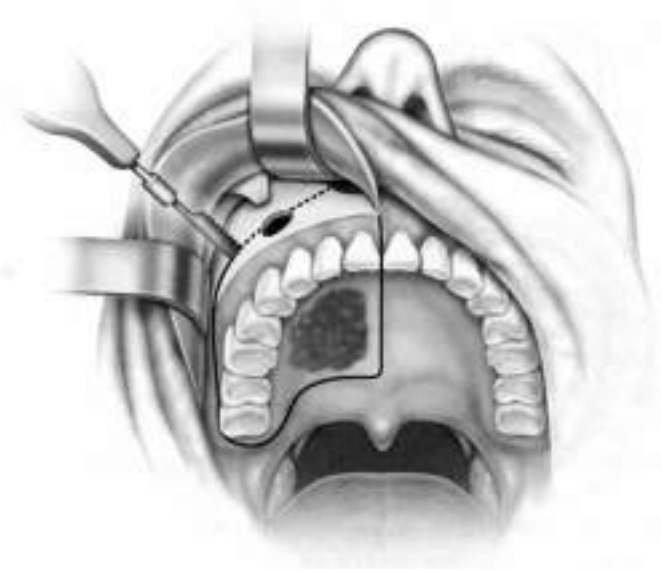

FIG. 32.6 An anterior maxillotomy is made to visualize the entire floor of the maxillary sinus. Reprinted with permission from Simental AA Jr, Myers EN: Cancer of the hard palate and maxillary alveolar ridge: technique and applications. Oper Tech Otolaryngol Head Neck Surg 16:32, 2005.

4) Prostheses are designed according to the Aramany classification.[6] The permanent prosthesis will have teeth similar to a denture; it can be removed and cleaned by the patient (Fig. 32.9). It is essential for the surgeon and prosthodontist to coordinate their efforts in restoring the patient's voice and ability for adequate oral intake.

b. Local flaps: The palatal island flap for reconstruction of palatal lesions is a single-stage mucoperiosteal flap that is a reliable source of regional vascularized soft tissue that obviates the need for prosthetic rehabilitation.

c. Regional flaps: The temporalis flap allows for immediate reconstruction with minimal morbidity for patients who have undergone total inferior maxillectomy (Fig. 32.10). The temporalis

muscle is an attractive option for reconstruction for the following reasons:

1) The donor site and the defect are within the same operative field and therefore the need for more complex free tissue transfers can be avoided.

2) Considerable tissue is available.

3) Well-vascularized flap

4) Negligible functional defect

5) The cosmetic deformity is limited to a mild concavity in the area of the temporalis fossa, which in women is covered by hair.

6) The flap can be used to correct unilateral and total defects.

7) Reconstruction can be carried out in less time than a free flap.

8) Limitations

a) No prosthetic rehabilitation with dental implants to improve cosmetic outcome

b) Lack of direct vision to tumor area to monitor for recurrent tumor. This has been largely overcome with the use of PET/CT scanning and nasal endoscopy.

d. Microvascular free tissue transfer: Reconstruction of defects after inferior maxillectomy are well summarized under the theme of functional palatomaxillary reconstruction.[9] Larger defects (classes III to VI) require reconstruction with composite free flap reconstruction to close off the defect and restore natural facial contour.

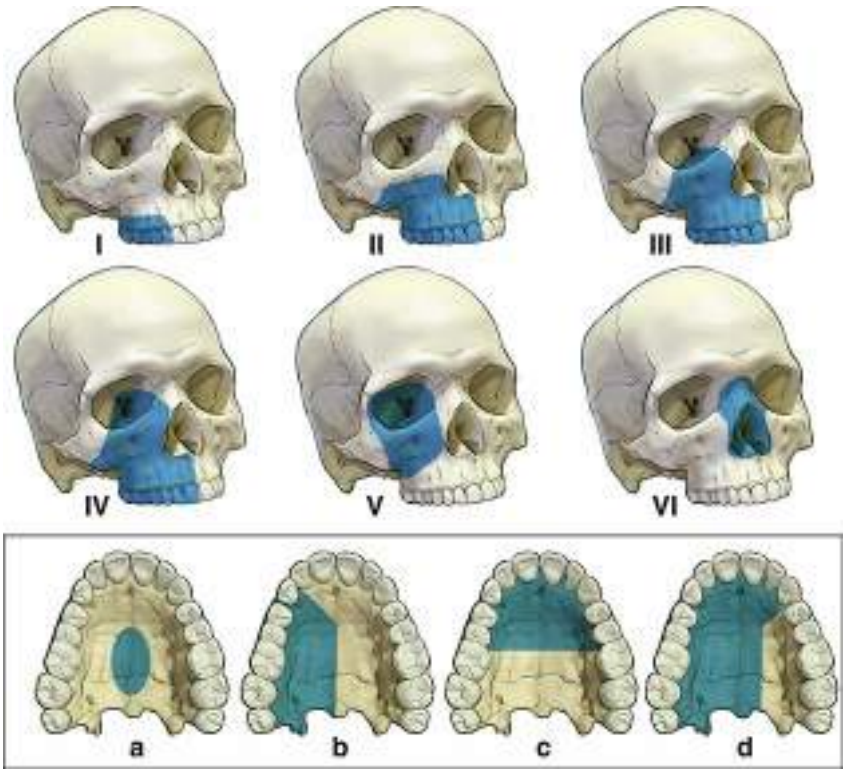

FIG. 32.7 Classification of vertical and horizontal maxillectomy and midface defect. Vertical classification: I—maxillectomy not causing an oronasal fistula; II—not involving the orbit; III—involving the orbital adnexa with orbital retention; IV—with orbital enucleation or exenteration; V—orbitomaxillary defect; VI—nasomaxillary defect. Horizontal classification: a—palatal defect only, not involving the dental alveolus; b—less than or equal to ½ unilateral; c—less than or equal to ½ bilateral or transverse anterior; d—greater than ½ maxillectomy. Letters refer to the increasing complexity of the dentoalveolar and palatal defect and qualify the vertical dimension. Reprinted with permission from Brown JS, Shaw RJ: Reconstruction of the maxilla and midface: introducing a new classification. Lancet Oncol 11:1002, 2010.

FIG. 32.8 **A,** This patient underwent resection of an adenocarcinoma of the hard palate. The defect is demonstrated. **B,** Retention of the prosthesis is facilitated by residual dentition. The final prosthesis achieves good oral-nasal separation.

1) The free flap must include vascularized bone and soft tissue from the radial forearm, fibula, iliac crest, or scapula.

2) Free tissue transfer is superior to prostheses in larger defects with regard to improved speech and swallowing; however, placement of dental implants may be delayed or impossible based on the type of flap used.

3) Prosthesis placement allows for immediate restoration of speech and swallowing but requires multiple revisions if the patient requires radiation therapy or surgical revision.[8]

4) Soft tissue free flap reconstruction[10]:

    a) Lateral upper arm flap

    b) Rectus abdominus

    c) Radial forearm

    d) Latissimus dorsi

5) Osseocutaneous free flap reconstruction[10]:

    a) Fibula

    b) Iliac crest

    c) Radial forearm

d) Thoracodorsal angular artery scapula tip

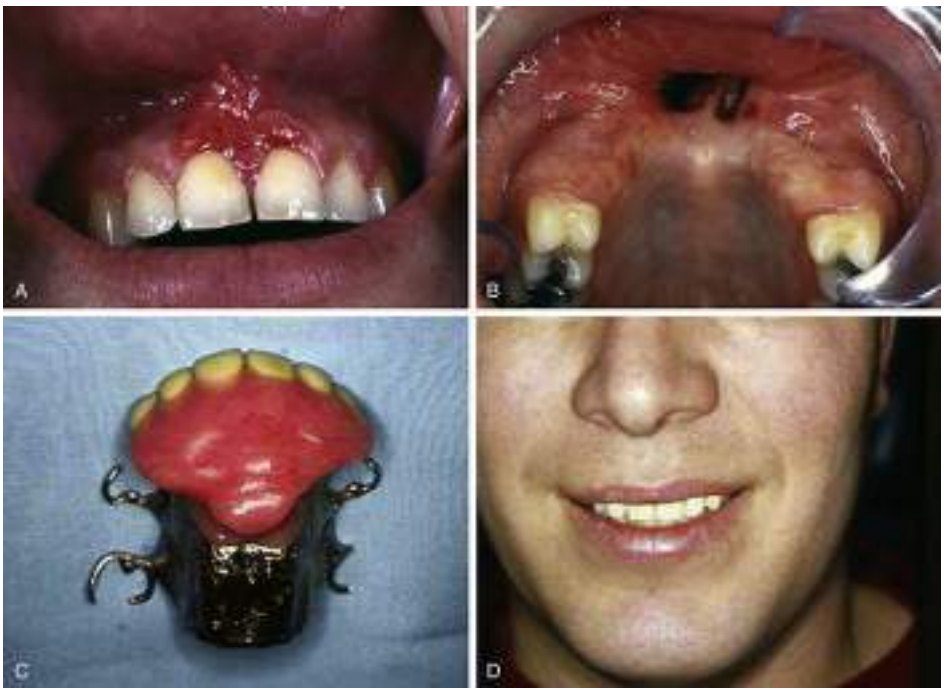

FIG. 32.9 Patient with a removable denture that restores good oral-nasal separation and provides for a good cosmetic appearance. **A,** Preoperative appearance. **B,** Surgical defect. **C,** Removable prosthesis with clasps. **D,** Good cosmetic result with restoration of oral-nasal separation.

6) Free flap reconstruction of the palate provides reliable permanent oronasal separation in one stage with restoration of masticatory function and normal phonation. In addition, the potential for dental rehabilitation exists. The choice of flap is tailored to specific palatal defects and patient needs.

Postoperative Period

Postoperative Management

1. Transfer to a dedicated head and neck cancer unit with nurses trained in the care of head and neck patients. There is usually no need for intensive care unit–level of care for this surgery unless microvascular reconstruction is employed. If microvascular reconstruction is

performed, the reconstructive surgeon dictates the level of care.

2. Check hematocrit in cases of large-volume intraoperative blood loss.

3. Pain medication: Opioid pain medication such as oxycodone 5 to 10 mg every 4 hours as needed should provide adequate analgesia in the perioperative period. Acetaminophen may suffice in elderly patients.

4. Meticulous oral hygiene with chlorhexidine mouthwash swish-and-spit after every meal is essential to help prevent infection.

5. Diet

a. Benign or low-grade malignant lesions where bone was preserved

1) Soft diet starting on postoperative day 1

b. Prosthetic rehabilitation and local or regional flap

1) Full liquid or pureed diet starting on postoperative day 1

c. Microvascular free flap

1) Based on reconstructive surgeon's postoperative protocol

6. Remove the prosthesis and bolster on postoperative day 5. Excess STSG is removed.

7. The temporary obturator is installed by the prosthodontist. This is used in the interim while the final prosthesis is delayed until the maxillectomy cavity matures. If there are plans for adjuvant radiation therapy, the final prosthesis may have to be delayed until after completion of radiation to ensure a proper fit.

8. Early ambulation with or without physical therapy is essential for postoperative rehabilitation.

9. Patients who have undergone neck dissection in conjunction with resection of the primary cancer will have the neck wound managed as described in the chapter on neck dissection (see Chapter 87).

10. Patients with bone invasion (T4 lesions) or with high-grade salivary gland cancers are referred for postoperative radiation therapy. Patients who have perineural involvement in their primary tumor or positive resection margins should always be referred for radiation therapy. Similarly, patients who have more than two positive nodes or extracapsular spread in one or more nodes will be referred for

chemoradiation therapy.

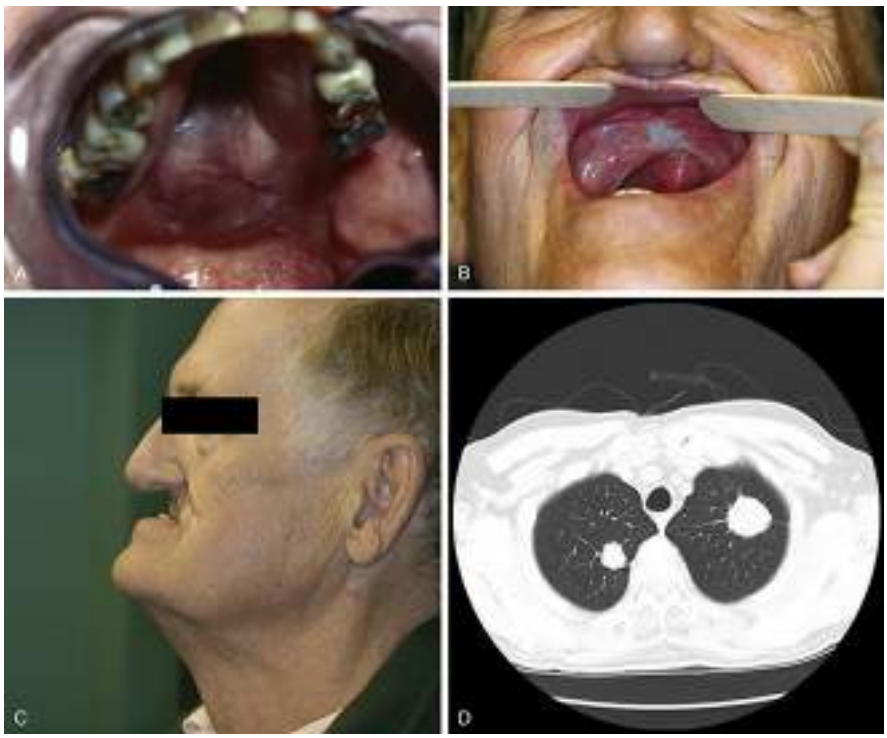

FIG. 32.10 **A,** Patient with adenoid cystic carcinoma of the palate. **B,** After total inferior maxillectomy, the defect was reconstructed with a temporalis muscle flap, which quickly became mucosalized. Complete healing was followed by a full course of radiation therapy. **C,** Removal of the maxilla resulted in recession of the upper lip. **D,** CT scan disclosing multiple metastatic nodules that were discovered 13 years after the surgery and radiation therapy and were treated with radiation therapy. It has now been 15 years since the patient completed his surgery, and he is asymptomatic despite the stable lung metastasis.

Complications

1. Creation of an oral-nasal fistula in removal of a benign tumor
    a. Perforation of soft tissue on the nasal side of the palate with removal of palatal bone as a deep margin

b. Repair intraoperatively with soft tissue via a prosthesis, local, regional, or microvascular free flap.

2. Contraction of buccal mucosa

a. Resurface the upper lip and buccal mucosa with an STSG to avoid contraction deformity.

b. Resurfacing of soft tissue defects with an STSG when the hard palate is intact is rarely necessary. The defect will heal by secondary intention.

3. Hemorrhage

a. Focal pressure will usually provide adequate hemostasis.

b. Return to the operating room (OR) for site control if focal pressure does not resolve the bleeding.

4. Infection

a. Meticulous oral hygiene and perioperative antibiotic prophylaxis will prevent most infections.

b. Local wound care

c. Treat with postoperative antibiotics covering for oral flora (gram-positive, gram-negative, and anaerobic bacteria) such as ampicillin-sulbactam or clindamycin for penicillin-allergic patients with pus and systemic signs of infection (fever or leukocytosis)

Alternative Management Plan

1. Nonsurgical management: The patient who is not a surgical candidate due to the site of the tumor or due to medical comorbidities can be referred for radiation therapy.

2. Palliative care: The option of palliation is offered to our patients based on the extent of tumor involvement, the patient's medical comorbidities, and the wishes of the patient and family. The palliative care physicians discuss issues such has symptom management (pain, hunger, thirst) and the details of hospice care.

Discussion

Evidence-Based Medicine Question

Is selective neck dissection indicated for squamous cell carcinoma of the maxilla?

Occult metastasis occurs at a rate of 34.6% in squamous cell carcinoma of the palate and alveolar ridge.[7] Selective neck dissection is indicated for T3 and T4 lesions. Lower stage lesions (T1 and T2) without concerning features such as perineural invasion (PNI) or extracapsular spread (ECS) can be observed, just as with other oral cavity sites.

Editorial Comment: Inferior Maxillectomy

The hard palate and alveolar ridge give rise to a wide variety of conditions ranging from necrotizing sialometaplasia, a benign condition, to squamous cell carcinoma, which is the most frequently encountered malignant tumor. Malignant tumors and most benign conditions are treated surgically because radiation applied to bone structures can result in osteoradionecrosis.

When I was first introduced to the inferior maxillectomy it was carried out through a lateral rhinotomy approach, which provides wide exposure but at the price to the patient of a conspicuous scar. I soon realized that most tumors arising in the area of the palate could be removed successfully through a transoral approach, and I abandoned the lateral rhinotomy incision.

Loss of oronasal separation, which is fundamental to both swallowing and speaking, was managed with a prosthesis except in cases of a total inferior maxillectomy, which was reconstructed with a temporalis muscle flap. Reconstruction of the palate with free tissue transfer introduced more recently was not embraced fearing that closing the defect would preclude cancer surveillance. This concern has been overcome with the introduction of the PET/CT scanner, which is used to detect recurrent cancer.

Another major step forward in the management of patients with squamous cell carcinoma is the management of the neck. It was believed that cancers of the hard palate and alveolar ridge, which occurred much less frequently than cancer in other sites such as the tongue and the floor

of the mouth, had a different pattern of metastasis. I became aware of a study done at the University of Virginia in which the members of the Department of Otolaryngology observed a rate of metastasis of approximately 35%, which is the same as in other sites in the oral cavity.

A subsequent study performed in our department[7] validated the findings of the aforementioned study. Based on this study, we adapted the use of the selective neck dissection, bilateral or unilateral based upon the location and extent of the primary. When combined with radiation or chemoradiation, depending on the presence or absence of extracapsular spread, we have been able to establish excellent local regional control in patients undergoing inferior maxillectomy.

Review Questions

1. Management of the neck in a patient with squamous cell carcinoma involving the left maxillary alveolus extending to midline includes which levels?

   a. Left level IA and B

   b. Left levels I to III

   c. Bilateral levels IA and B

   d. **Bilateral levels I to III**

2. According to the Brown and Shaw maxillary defect classification, a maxillary defect involving the orbital **rim,** but preserving the eye and involving greater than half of the palate falls into which of the following classes?

   a. Ia

   b. IIb

   c. **IIId**

   d. IVc

3. A maxillary defect not involving the orbit and less than half of the hard

palate is best reconstructed with which of the following?

a. Local flap

b. **Prosthesis**

c. Regional flap

d. Microvascular free flap

Transoral Excision of Oropharyngeal Malignancy

Sefik A. Hosal, and Canset Aydin

Introduction

The most favorable management of oropharyngeal cancer is still controversial. In the past, oropharyngeal cancers were treated with surgery followed by radiation. Surgical resection usually required mandibulectomy or mandibulotomy and removal of pharyngeal musculature, which resulted in significant morbidity. Because of the functional and cosmetic impairments and current development of organ preservation regimens, chemoradiation has become the treatment of choice in many patients with cancer of the oropharynx. Furthermore, studies have demonstrated an increased incidence of human papilloma virus (HPV)-related cancer of the oropharynx, particularly among young adults who have a better prognosis. There are emerging data that less aggressive treatment can be performed in this group of patients without sacrificing the good cure rate.

The oropharynx is the middle part of the throat that extends from the junction of the soft and hard palate superiorly to the superior edge of the epiglottis and the hyoid bone inferiorly, circumvallate papillae of the tongue anteriorly, and pharyngeal wall posteriorly. It includes the base of the tongue, the soft palate, the lateral and posterior pharyngeal walls, the tonsils, and tonsil pillars. The function of this region is crucial in swallowing, respiration, and speech. It is noteworthy that the swallowing function is adversely affected both by surgical resections and chemoradiation. Dysphagia and poor speaking may result in social problems, but aspiration may cause life-threatening complications. Therefore appropriate selection of the type of surgical approach is quite important in the management of cancer of the oropharynx.

The prognosis and treatment of cancer of the oropharynx are strongly related to the involvement of cervical lymph nodes. The incidence of lymphatic metastasis is relatively high, depending on the subsite. Even in patients with no adenopathy at the time of diagnosis, elective ipsilateral or bilateral neck treatment is required either through a neck dissection or by radiation therapy. In addition, the tonsillar fossa and base of the tongue are known as the most common potential mucosal sites in unknown primaries. There is also a risk for metastasis to the retropharyngeal lymph nodes in cancer of oropharynx, particularly in those patients in whom the posterior pharyngeal wall or the soft palate is involved. These nodes are beyond the classical neck dissection. The majority of those patients are required to have adjuvant radiotherapy. In such instances, radiation therapy is rational as a single treatment modality for primary and lymphatic metastasis, as well. Otherwise, transoral surgery is a feasible option in selected early limited cancer, in which the need for adequate exposure is fundamental.

Transoral resection of cancer of the oropharynx was first described by Huet in 1951.[1] This technique eliminates the morbidity created by the mandibular swing or composite resection. In addition, this minimally invasive surgery may avoid adverse consequences of chemoradiation with comparable outcome. Moreover, it provides pathologic staging for further adjuvant treatment.[2] Transoral surgery is generally indicated in early-stage cancer of the oropharynx. This can be done either via transoral robotic surgery or endoscopy-based transoral laser microsurgery. The transoral approach has been expanded with the development of transoral robotic surgery. This technological improvement provides three-dimensional visualization for precise dissection and safety of margins. There are some advantages of robotic surgery, including shorter hospitalization, rapid functional recovery, avoidance of tracheostomy, and reduced need for nasogastric tube feeding. We favor transoral robotic surgery in carefully selected patients.

Key Operative Learning Points

- Careful patient selection
- Accurate assessment of tumor extension and lymph node involvement
- Surgical anatomy of the carotid artery and association pharyngeal

structures

- Special training for robotic surgery if transoral robotic surgery is preferred
- Ipsilateral or bilateral neck dissection is necessary. It can be done either simultaneously or separately. We prefer concurrent neck dissection following transoral resection.

Preoperative Period

History

- History of present illness
  - Persistent sore throat, throat discomfort
  - Neck mass
  - Odynophagia, referred otalgia with swallowing, globus sensation
  - Trismus, dysphagia, bleeding, difficulty moving the tongue
- Past medical history
  - Tobacco use, alcohol consumption, betel quid chewing
  - HPV exposure
  - Radiation exposure
  - Comorbid diseases, including systemic diseases and hemorrhagic diatheses
  - Medications and herbal products being used

Physical Examination

- Oral cavity—oropharynx
  - Must include all mucosal surfaces to evaluate a second primary or extension of the primary tumor to surrounding structures
  - Any dentures should be removed during the inspection.
  - Palpation for size, deep fixation, and mobility of the lesion

    - Assessment of cranial nerves, particularly cranial nerve IX, X, and XII
- Endoscopy
    - Both flexible and rigid endoscopic evaluation
    - Endoscopy under general anesthesia. This is preferred before definitive treatment in order to evaluate for the adequate exposure and availability of the tumor for transoral approach.
- Neck
    - Palpation of the both necks
    - Recording of the levels of lymph node involvement

Imaging

- Computed tomography (CT), for bony invasion of the skull base, mandible, and status of the lymph nodes, particularly retropharyngeal lymph nodes
- Magnetic resonance imaging (MRI) for the depth of tumor invasion, perineural infiltration, and association with vital structures, particularly the carotid artery
- Positron emission tomography–computed tomography (PET-CT) to discover distant metastasis, especially in cases of advanced cancer. Not required in all cases

Indications

- Primary or recurrent cancer of the oropharynx, which can be excised transorally depending on the surgeons' experience and patients' condition and wishes
- Generally indicated in T1 and T2 cancers of the soft palate (Fig. 33.1), posterior pharyngeal wall, tonsil and anterior pillar, the base of the tongue, and uvula (Fig. 33.2)

Contraindications

- Trismus
- Inadequate exposure
- In robotic surgery, cancer requiring resection of more than 50% of the base of the tongue or more than 50% of the posterior pharyngeal wall (Fig. 33.3)[3]
- Close association of the tumor with carotid artery
- Invasion into the parapharyngeal space[4]
- Bone invasion
- Tumor fixation of prevertebral fascia
- Invasion of the vital structures by the primary cancer
- Unresectable lymph node metastasis regardless of the primary cancer

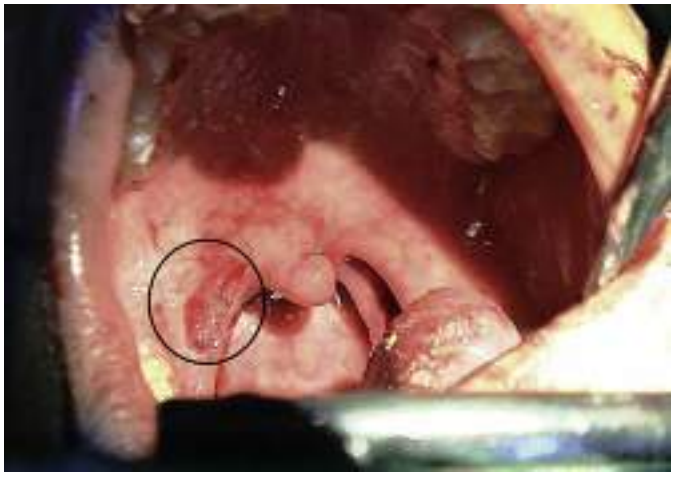

FIG. 33.1 Superficial carcinoma of the soft palate.

- Poor exposure due to patients anatomic situation, such as micrognathia, cervical spine injury, macroglossia
- Inability to convert to open surgery intraoperatively
- Patients preference for another treatment modality
- Comorbid diseases with increased risk for general anesthesia
- Distant metastasis. Adenoid cystic carcinoma with limited pulmonary metastasis may be an exception.

Preoperative Preparation

- Biopsy to confirm the diagnosis
- Review any biopsies or tissue from previous surgery
- Routine laboratory tests and preparation of red blood cell suspension for probability of transfusion during surgery

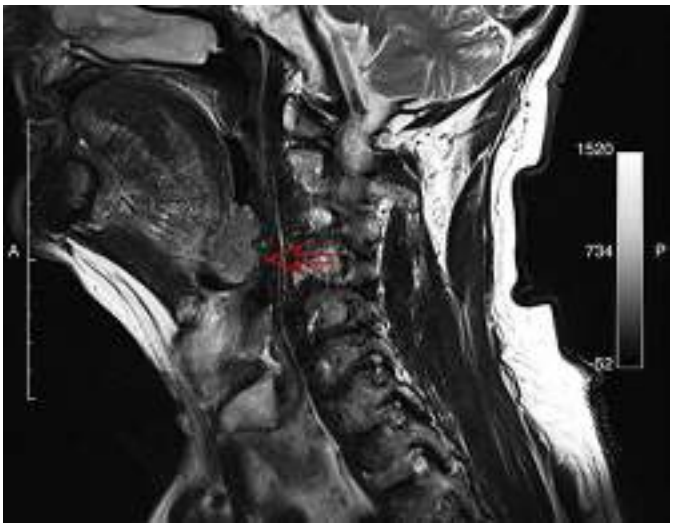

FIG. 33.2 T2 sagittal section of magnetic resonance imaging showing the tumor of the base of the tongue (arrow) accessible for transoral surgery.

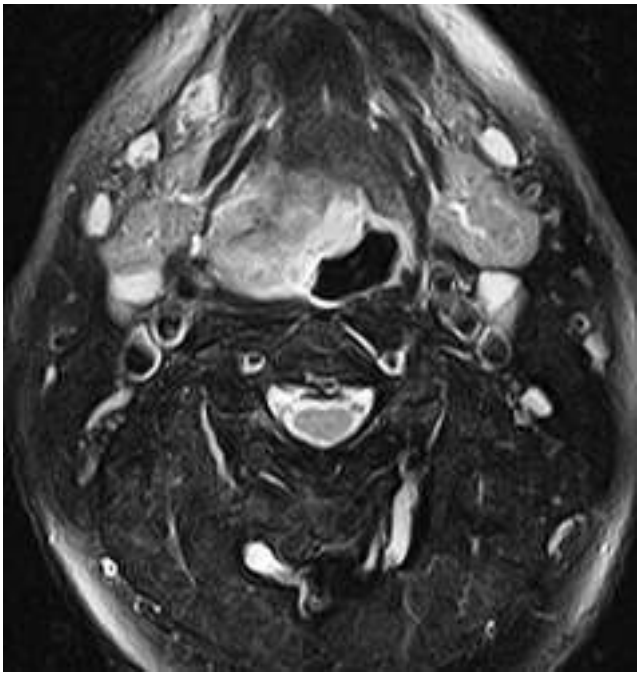

FIG. 33.3 Tumor invasion with more than 50% of the base of the tongue is a contraindication for transoral surgery.

- Cessation of antiplatelets/anticoagulant drugs
- Evaluation of the patient's dentition is essential to prevent osteoradionecrosis due to probable postoperative radiotherapy.
- Dental consultation with prosthodontist for temporary postoperative palatal prosthesis in patients who need partial resection of the palate
- Counseling of the patient about the probable needs for temporary tracheostomy and/or nasogastric tube
- Cervical lymph node dissection is a part of the treatment of cancer of the oropharynx even in N0 neck; thus the patient should be informed about neck dissection.

Operative Period

Anesthesia

- General anesthesia with orotracheal, nasotracheal intubation or a

tracheostomy

Positioning

- Supine position with neck extended with shoulder roll

Perioperative Antibiotic Prophylaxis

- Ampicillin sodium/sulbactam sodium

Monitoring

- Routine anesthesia monitoring

Instruments and Equipment to Have Available

- Standard tonsil surgery set
- Standard neck dissection set
- Mouth retractors (Crowe Davis or Feyh-Kastenbauer)
- Teeth-protecting molds
- Headlight
- Bipolar cautery
- Monopolar electrocautery
- A CO_2 laser device if transoral laser microsurgery is preferred
- A robotic system if transoral robotic surgery is preferred

Key Anatomic Landmarks

- Keep thin adipose tissue and fascia layer in the posterolateral parapharyngeal region to protect the carotid artery and to prevent communication into the neck (Fig. 33.4).

- Branches of the lingual artery

Prerequisite Skills

- Experience in locating and protecting the carotid artery
- Robotic surgery requires special training and a learning curve.
- The surgical team must set up for conversion to open surgery.

Operative Risks

- Intraoperative bleeding
- Injury of the nerves
- Injury to the teeth

Surgical Technique

- Provide sufficient exposure with mouth gag (Figs. 33.5 and 33.6).
- Palpate and confirm that the cancer is mobile, not fixed to the deep structures.
  - Posterior pharyngeal wall
    - Mark incisions by making dots with monopolar electrocautery (Fig. 33.7).
    - Keep at least 1-cm safety margin around the cancer.
    - Grasping and retraction of the cancer provide extending the incisions through the submucosal plane (Fig. 33.8).
  - Tonsillar region

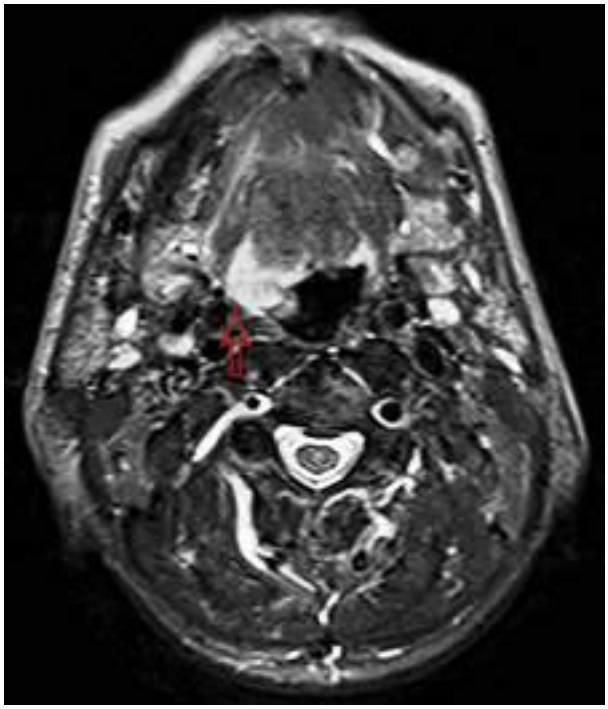

FIG. 33.4 T1 axial scan, arrow demonstrating thin adipose tissue and fascia layer in the posterolateral parapharyngeal region.

FIG. 33.5 Adequate exposure with standard mouth retractor for cancer of the right tonsil.

- Excision starts at the retromolar trigone extending to the pterygomandibular raphe that is the lateral and superior aspect of the cancer (Fig. 33.9).
- Dissection proceeds in the superior to inferior direction.

- Base of the tongue
  - Outline all incisions with dotted lines by cautery. This is particularly useful for the deep inferior margin. Starting incision may begin at the anterior aspect of the lesion to pull the cancer posteriorly. Alternatively, a deep horizontal incision may be done at first for the safety of the inferior margin.

- Bleeding from small veins and arteries is controlled by cautery. Branches of the lingual artery may require vascular clips (Fig. 33.10).
- Inspect for pulsation of the carotid artery posterolaterally, which is covered by fascia and adipose tissues.
- Palpate the depth of the lesion during excision that helps to obtain negative tumor margins; however, this is not likely with robotic surgery.
- Resect the cancer en block, and mark the specimen with a suture so the pathologist can orient the specimen.
- Frozen sections must be obtained from all sides and the deep aspect. Free margins are mandatory for local control and survival.
- The surgical field is left open for healing by second intention.
- The patient is prepared for unilateral or bilateral neck dissection.

FIG. 33.6 Exposure with FK retractor in robotic surgery.

Common Errors in Technique

- Inadequate exposure
- Starting with the anterior incision without marking the inferior margin may cause disorientation at the inferior or posterior part of the cancer, which may risk safe margins.
- Inaccurate preoperative evaluation for the extent of the cancer
- Inaccurate evaluation of the status of retropharyngeal lymph nodes
- Failure in assessment of surgical margins
- Poor positioning of robotic arms if robot is used

Postoperative Period

Postoperative Management

- Local wound care with mouth rinses and gargles
- Prophylactic broad-spectrum antibiotics for 5 to 7 days
- Oral feeding in the first postoperative day unless tracheostomy and nasogastric tube placement
- Elevation of the head to prevent edema
- Nonsteroidal anti-inflammatory drugs are usually used to control pain. If pain is not relieved with these drugs, narcotic analgesics can also be used in the early postoperative period.
- Proton pump inhibitors for antireflux treatment or stress ulcers
- If tracheostomy is present, decannulate as soon as there is an adequate airway.
- If a nasogastric tube is present, removal of the tube is delayed until decannulation of the tracheostomy.
- Rehabilitation for swallowing

Complications

- Airway edema

  Patients should be monitored and treated with intravenous steroids. The risk of swelling is usually in the first 24 hours. If there are significant edema and airway compromise, a temporary tracheotomy may be necessary.

- Unplanned tracheostomy

  Related to airway edema

- Tongue swelling and tongue numbness

  Related to the mouth retractors. Prolonged retraction in longer surgery may increase the risk. Tongue numbness is generally transient and resolves in time.

FIG. 33.7 Marking the incision by making dots with monopolar electrocautery. The portion of the mucosal incision that is most difficult to visualize should be made first.

- Bleeding

  Occurs mostly in the first 2 weeks. Minor bleedings require observation only. Major bleeding may be sometimes catastrophic.

Exploration of the neck and ligation of the external carotid system should be done under general anesthesia. Alternatively, the bleeding vessel can be identified by angiography, and endovascular embolization can be performed.

- Aspiration and aspiration pneumonia

  There may be some degree of aspiration due to swallowing dysfunction. Swallowing therapy is recommended. Significant aspiration requires nasogastric tube placement.

- Fistula formation between neck and pharynx

  Some surgeons prefer to delay the neck dissection for a few weeks after the transoral surgery for avoidance of this problem. The probability increases with previous radiation therapy. Daily wound dressing in the neck, stopping oral feeding, or placing a drain to divert the saliva away from vascular structures can be done. This may heal on its own, or sometimes additional surgical procedures may be necessary to close the fistula.

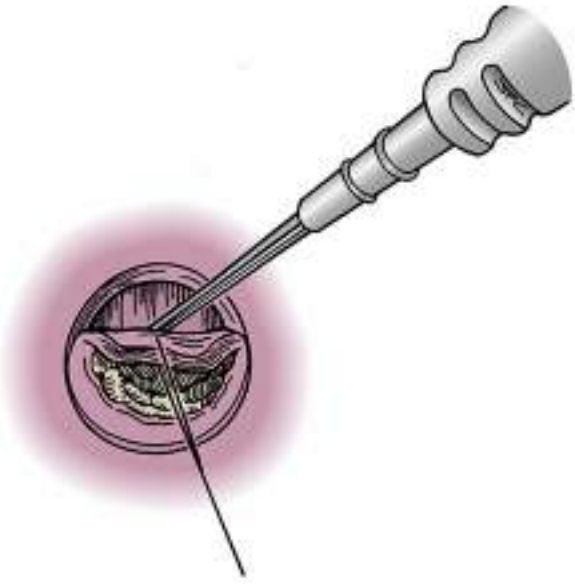

FIG. 33.8 Grasping and retraction of the tumor provide extending the incisions through submucosal plane. A suture is placed for retraction, as well as orientation of the specimen for the pathologist.

FIG. 33.9 Marking incisions in robotic surgery for carcinoma of the tonsil.

- Nerve injuries

  Neuropraxia may occur, mostly in the hypoglossal nerve. Usually transient and secondary to retractor pressure

- Wound breakdown

  Associated with concurrent neck dissection in previously radiated necks. Treated with antibiotics and wound dressing

- Rhinolalia

  Results from excessive resection of the soft palate. Pharyngoplasty with suturing pillars is recommended.

Alternative Management Plan

- Nonsurgical treatment with chemoradiation
- Open surgical approaches
  - Transmandibular
    - Mandibulotomy
    - Mandibular swing
  - Transcervical transpharyngeal

- Transhyoid pharyngotomy
- Lateral pharyngotomy

Discussion

Evidence-Based Medicine Question

Does transoral surgery for cancer of the oropharynx provide better outcome than open conventional surgery or chemoradiation?

There is no randomized controlled trial of surgical or nonsurgical management of oropharyngeal cancer. Furthermore, there are no randomized studies comparing transoral surgery with open surgery. However, recently there is increasing evidence suggesting the efficacy of transoral robotic surgery for oropharyngeal cancer. A prospective analysis of small case studies and few larger studies indicates encouraging results on safe marginal control, few complications, short hospital stay, less swallowing dysfunction, and fewer tracheotomies.[4-6] Better quality of life scores have also been reported in nonrandomized clinical studies.[2] Current data on robotic surgery support promising favorable outcome in selected cases of cancer of the oropharynx. However, oncologic results have not been validated with controlled studies yet.

FIG. 33.10 Vascular clips on the lingual artery during

robotic surgery for the base of the tongue cancer.

Editorial Comment

This is a nicely written and concise chapter that provides an overview of transoral surgery for cancer of the oropharynx. Although chemoradiation remains a viable alternative to surgical approaches for oropharyngeal cancer, the immediate and late side effects are real and affect patients for their lifetime. Despite these significant consequences, there has been a prevailing practice to avoid the destructive effects of classic open mandibulotomy approaches in favor of chemoradiation. However, this paradigm is shifting with the resurgence of transoral laser microsurgery (TLM) and the advent of transoral robotic surgery (TORS). Although current data as to the value of transoral surgery versus chemotherapy come from only published cohort studies, there are large controlled national studies that are ongoing and that may eventually provide the definitive support for primary surgery instead of chemoradiation for cancer of the oropharynx.

Review Questions

1. Which of the following is NOT a contraindication for transoral resection of oropharyngeal cancer?

   a. Trismus

   b. **Recurrent tumor of the base of the tongue**

   c. Involvement of the parapharyngeal space

   d. Bone invasion

2. Which of one the following is FALSE for transoral robotic surgery for oropharyngeal cancer?

   a. Short hospitalization

   b. Less swallowing dysfunction

   c. **Indicated in advanced stage**

d. Less tracheostomy

3. All of the following statements for transoral resection in oropharyngeal cancers are TRUE, except

   a. **Frozen section is not necessary**

   b. Neck dissection can be done simultaneously or staged

   c. Experience is needed to locate and protect the carotid artery

   d. Adequate exposure is required

Transoral Laser Microsurgery of the Base of the Tongue

Guy Petruzzelli

Introduction

The base of the tongue (BOT) is the most anterior-superior portion of the oropharynx bounded anteriorly by the circumvallate papillae, laterally by the paired glosso-palatine sulci, and inferiorly by the vallecula. The BOT is formed from the medial fusion of elements from the first and second and is composed of both the endoderm and ectoderm. The branchial arch hypobranchial prominence, a specialized region of second branchial pouch mesoderm, is located posteriorly on the rudimentary tongue. This structure will eventually differentiate into the thyroid primordium and descent via the foramen cecum into the neck. Embryology provides the basis for the development of the benign tumors (lingual thyroid, hemangioma, dermoid) that are observed in this region. The BOT is histologically complex, with nonkeratinizing stratified squamous epithelium covering lymphoid aggregates (lingual tonsils), minor salivary glands, and striated muscle accounting for the multiple epithelial (squamous cell carcinoma, lymphoepithelioma) and nonepithelial (lymphoma, sarcoma, minor salivary gland) malignancies in this location. Transoral resection of the BOT can be used for definitive excision of low-grade and benign neoplasms, definitive resection of high-grade malignancies prior to adjuvant treatment, assessing the BOT in the survey for the occult primary, and volume reduction of the BOT in cases of obstructive sleep apnea.

Specialized retractor systems provide improved transoral exposure and access to tumors of the BOT, and the development of laser fibers and enhanced optics have provided greater surgical visualization and operative ability in this region. These elements have contributed to a

renewed interest in primary surgical treatment for selected malignancies of the BOT. Since transoral laser microsurgery resections heal by re-epithelization reconstruction, flaps are not used, thereby eliminating donor site morbidity. Transoral resection of tumors obviates the need for a pharyngotomy, thus significantly reducing the likelihood of salivary contamination of the neck and wound infection. In selected patients, tracheostomy can also be avoided, thus providing an earlier return of speech and deglutition. Finally, data obtained from histologic analysis of surgical specimens can more precisely identify patients for appropriate adjuvant treatment. Clinical trials are currently being carried out that, based on human papilloma virus status, are looking to "deintensify" adjuvant chemotherapy and radiation, thus decreasing late toxicity and improving return of function and overall quality of life.

It is important that the head and neck surgeon understand that TLM resection of the tongue base is one technique in the armamentarium of surgical exposures to the oropharynx. The surgeon must consider not just the anatomic location but the biology of the tumor, the risks to surrounding structures, vascular control, airway protection, reconstructive options, and most critically the goals and wishes of the patient in making treatment recommendations.

Key Operative Learning Points

1. TLM procedures are tedious and require extreme patience.

2. Formal staging endoscopy and examination under anesthesia may be necessary to determine if transoral resection is feasible.

3. Multiple oral retractor systems and/or fixed bore and bivalve laryngoscopes may all be needed to provide safe and complete resection of the tumor.

4. Retractors may need to be repositioned several times during the resection.

5. Multiple frozen sections may be needed.

6. Suction cautery to supplement the laser for hemostasis

7. The line of sight laser micromanipulator is not adequate in all cases. Laser fibers are needed to work on an upward angle into the BOT.

8. Standard tonsillectomy instruments are too short to reach deep into the vallecula. Modified 22-cm working distance specialized insulated instruments are necessary.

Preoperative Period

History

1. Medical and surgical history including active medical problems and comorbidities, current medications, allergies, and complete review of systems

2. Otalgia in the normal appearing ear

3. Social history should include a history tobacco and alcohol use and risk factors for exposure to the human papilloma virus.

4. Prior environmental, history occupation of therapeutic exposure to low-dose ionizing radiation, particularly as a child

5. Chief complaint and review of systems positive for otalgia, dysphagia, dysarthria, foreign body sensation, oral of pharyngeal pain, voice changes, worsening snoring or exacerbation of sleep apnea syndrome, foul breath (from necrotic tumor)

6. Other factors that should be considered include history of obstructive sleep apnea, morbid obesity, prior head and neck surgery, and/or radiation therapy to the head and neck.

7. Treatment with oral antibiotics for cervical lymph adenopathy without a history of symptoms of infection (no fever, malaise, pain)

8. Asymptomatic mass in the neck

9. “Hot potato” voice

Physical Examination

1. Assessment of comorbidities with appropriate cardiac and pulmonary risk stratification

2. Evaluate tongue motion, protrusion, fixation, and fasiculations.

3. Fiberoptic naso-pharyngoscopy, inspection, and palpation of the base of the tongue

4. Examination of the base of the tongue with a magnified angled Hopkins telescope

5. Careful attention to the epiglottis should be performed as well. Cancer of the BOT may involve the supraglottis either by superficial extension or deep infiltration.

6. Detailed palpation and office ultrasound of the neck. In our own experience approximately 85% of patients treated for cancer of the BOT will present with a mass in the neck on initial physical examination.

Imaging

1. Initial imaging with contrast enhanced computed tomographic (CT) scanning

- Imaging cervical metastases is best performed with contrast-enhanced CT scan.
- Diameter greater than 15 mm, central necrosis, round shape, and loss of a clear margin of the node borders and obscured adipose tissue planes indicating extracapsular extension all indicate metastatic adenopathy.

2. Contrast-enhanced magnetic resonance imaging (MRI)

- MRI acquires data in a multiplanar fashion and better visualization of subtle soft tissue details.
- Visualization of local extension of the cancer into the intrinsic muscles of the tongue, perineural spread, submucosal extension of the tumor, inferior extension into the preepiglottic space, and lateral extension into the parapharyngeal and carotid spaces

3. PET-CT scan

- Patients with stage IV disease or those at increased risk of harboring metastatic cancer
- Patients with unknown primary carcinomas
- Restaging patients prior to aggressive salvage treatment

Indications

1. Lingual tonsillectomy for chronic lingual tonsillitis or hypertrophy or biopsy of suspected lymphoma arising in Waldeyer ring

2. Volume reduction of the tongue base for obstructive sleep apnea

3. Management of obstructing lingual thyroid or other benign neoplasm of the base of the tongue

4. Staging the patient with an occult primary of the head and neck—excisional biopsy of the lingual tonsils and base of the tongue

5. Definitive resection of oropharyngeal (base of the tongue, tonsil, soft palate uvula, posterior pharyngeal wall) squamous cell carcinoma

6. Definitive resection of minor salivary gland neoplasms of the base of the tongue

Contraindications

1. Trismus—Reduced mandible-maxilla excursion with inability to place appropriate retractors

2. Teeth—Visualization obscured by dentition

3. Tumor—Bulky, friable, and/or hemorrhagic tumor obscuring visualization or a tumor with a depth of infiltration into the tongue base that precluded obtaining a satisfactory deep oncologic margin

4 Tori—Large obstruction maxillary or mandibular tori

5. Tongue—Relative macroglossia and redundant tongue tissue that cannot be satisfactorily retracted by the blades of the operating oropharyngoscope, thus collapsing into lumen

6. Tummy—Morbid obesity is frequently associated with a narrow oropharyngeal passage and poor visualization of the cancer.

7. Tonsils (lingual)—Lingual tonsillar hypertrophy obscuring the view of the tumor and making differentiation from tumor challenging

8. Throat—Elongated thin neck with narrow mandibular arch

9. Tilt—Limitations in neck extension from fibrosis from prior radiotherapy, degenerative disease of the cervical spine, or morbid obesity with unfavorable body habitus

10. Therapy—Prior surgical or nonsurgical therapy can limit exposure and make differentiation of normal from abnormal tissue difficult.

Preoperative Preparation

1. Complete history and physical examination as noted above

2. Fiberoptic laryngoscopy with careful assessment of airway anatomy, neck extension, intubation risks

3. Review of imaging studies

4. Pretreatment biopsy prior to TLM is essential in patients with a lesion of the base of the tongue to rule out lymphoreticular or other tumors not treated with primary surgery.

5. Discussion at multidisciplinary tumor planning conference as indicated

6. Careful informed consent included discussion of emergency airway management, including tracheostomy, postoperative hemorrhage requiring operative or angiographic control, dental injury, tongue numbness or paralysis, taste disturbance, and need for delayed extubation.

7. Panendoscopy and biopsy as needed prior to TLM resection definitive resection

- Fine-needle aspiration of suspicious cervical masses
- Transoral biopsies of the tongue base when feasible
- Obtain definitive histopathologic biopsy material prior to definitive resection.
- Assess for synchronous primary head and neck malignancies.
- Determine anatomic constraints for access to the tumor.
- Evaluate the transoral exposure of the tongue base, microscopic visualization of the tumor, and ultimate suitability for transoral laser

microsurgery.

Operative Period

Anesthesia

Close frequent communication between the head and neck surgeon and the anesthesia teams is imperative in safely managing patients undergoing TLM. Postprocedure airway management (extubation, overnight intubation, or tracheostomy) must be discussed with the anesthesia team prior to the conclusion of the operation. Information gleaned from the preoperative endoscopy and ease of initial intubation should all be considered in formulating the plan for postprocedure airway management.

1. TLM is performed under general anesthesia.

2. Orotracheal intubation using laser-approved endotracheal tubes

- T1 or T2 lateral cancer undergoing
- Unilateral neck dissection

3. Indications for tracheostomy

- Exophytic friable lesion or obstruction of true vocal folds
- Bilateral neck dissections in the event of venous or lymph edema of the larynx
- Resection involves portion of supraglottis, thereby reducing the patients' ability to protect the airway
- Higher risk for secondary hemorrhages (significant operative hemorrhage or large exposed surface area)

Positioning

TLM is performed with the patient in the supine position with the head placed in extension. A shoulder roll may not always be needed to facilitate exposure of the oropharynx and the base of the tongue.

Preoperative Antibiotic Prophylaxis

One of the principal advantages of the TLM approach is obviating the need for a pharyngotomy or mandibulotomy approach. Therefore TLM with a neck dissection can be classified as clean uncontaminated surgery, requiring only one dose of parenteral antibiotics with a first-generation cephalosporin. However, in many cases the neck can be contaminated from the following:

1. Inadvertent pharyngotomy during tumor resection

2. Micropharyngotomy (which can be unrecognized) at the time of tumor resection

3. Planned pharyngotomy to facilitate resection and margin control for a larger tumor

For those reasons, we treat all TLKM cases as clean contaminated procedures and use ampicillin-sulbactam 3 g IV every 6 hours intraoperatively and for 48 hours postoperatively. In penicillin-sensitive patients we use clindamycin 600 mg IV every 8 hours intraoperatively and for 48 hours postoperatively. Patients requiring either a pedicle or free flap reconstruction have their antibiotic coverage extended to 5 days postoperatively.

Monitoring

Routine anesthesia monitoring, appropriate for the patients comorbidities and expected length of the procedure, are all that are required for TLM. Cranial nerves are not routinely monitored.

Instruments to Have Available

1. Carbon dioxide laser with capability for micromanipulator and fiber delivery systems as needed

2. Microscope

3. Retractor systems—Bivalve oropharyngeal retractors (Karl Storz), modified FK oropharyngeal retractor, Davis retractor blades with

integrated suction ports (Fig. 34.1)

4. Laser plume and cautery smoke evacuation systems

5. Insulated suction cautery

6. Large caliber laryngeal suction

7. Endoscopic clip appliers curved and straight working length 22 cm

8. Insulated grasping forceps working length 22 cm

9. Large oval grasping forceps with integrated suction working length 22 cm

10. Cotton pledgets with topic hemostatic agent

11. Suspension system for bivalve laryngoscopes and oral retractors

12. Standard head and neck surgical instruments for neck dissection and conversion to transcervical pharyngotomy for complete tumor resection

Key Anatomic Landmarks

Transoral laser microsurgery requires a paradigm shift in understanding the anatomy of the head and neck from the traditional superficial to deep ("outside-in") orientation learned in the anatomy laboratory to an "inside-out" approach. Critical landmarks are:

FIG. 34.1 Instrumentation for TLM. **A,** FK retractor system with notched blades. **B,** Davis blades with integrated suction for Crowe-Davis retractor. **C,** Steiner self-retaining oropharyngoscope with integrated suction. **D,** Steiner instrumentation with graspers, clip appliers, and suction cautery.

1. Identification of the circumvallate papillae defining the junction of the base of the tongue and the oral tongue

2. Dorsal lingual branch of the lingual artery

   a. Originates deep to the hyoglossus muscle

   b. Courses superior to the lateral surface of the genioglossus muscle

   c. Tortuous vessel with convoluted course

   d. Will be encountered deep to hyoid bone with deep and inferior resections

3. Hypoglossal nerve courses lateral to the carotid artery and can be encountered in the anterior aspect of tongue base

Prerequisite Skills

Carcinomas of the base of the tongue represent one of the greatest challenges for the transoral laser microsurgeon. According to Steiner, "the base of the tongue is the most unfavorable area for endoscopic surgery, especially if the exposure through the distending laryngoscope is not optimum." Transoral laser surgery should not be attempted without prior experience with:

1. Careful office assessment of the base of the tongue and ability to perform staging endoscopy if needed

2. Transoral laser laryngeal microsurgery

3. Laser or cautery palatine and lingual tonsillectomy

4. Ability to control intraoperative and postoperative hemorrhage

5. Neck dissection

6. Ability to convert to open resection of the tongue base by transcervical (suprahyoid or lateral) pharyngotomy

7. Close working relationship with pathologists

8. Patience

Operative Risks

1. Airway or operative field fire

2. Dental injury

3. Lingual or hypoglossal neuropraxia due to pressure from the retractor with resulting anesthesia of the tongue, paralysis, and disturbance of taste

4. Lingual, facial, or ascending pharyngeal artery hemorrhage

5. Inadvertent and unrecognized pharyngotomy

6. Failure of visualization and incomplete tumor resection

7. Facial burn

8. Laser injury to the operative team or the surgeon

Description of the Technique

1. Set the CO_2 laser at 10 to 15 watts continuous super pulse mode for dissection.

2. If a tracheostomy is anticipated, perform it now to maximize visualization.

3. Place dental protectors—Dental injury can be prevented by carefully placing any one of a number of commercially available plastic tooth protectors. Custom thermoplastic teeth guards can be fabricated from sheaths of Aquaplast external nasal splint.

4. An appropriately sized retractor is placed just anterior to the foramen cecum, the microscope is positioned, and the initial curvilinear incision is made at the level of the circumvallate papillae. A temporary retention suture placed in the anterior tongue is helpful in establishing and maintaining optimum tongue position.

5. If the cancer is centrally located, this anterior incision is carried across the entire base of the tongue; for more laterally located cancers the incision is terminated at the midline and extends posteriorly. Frozen sections are obtained as the margins are established.

6. Deep resection margins are established by changing the trajectory of the laser into the base of the tongue. The surgeon must reposition or continually adjust *both* the microscope and the retractor system to maintain appropriate visualization and control depth of dissection.

7. Insulated grasping forceps are used to manipulate the surgical specimen as it is developed, to maintain tension between the specimen and the residual tissue to allow for the most efficient cutting of the laser and to cauterize bleeding within the tongue base.

8. Segmental tumor resection may be necessary—that is, larger cancers are can split into several segments with perpendicular laser cuts to facilitate resection.

9. Control posterior margins in the vallecula with the epiglottis retracted inferiorly. Frozen sections of the base of the laryngeal surface of the epiglottis can be obtained at this point.

10. Multiple frozen sections are required during TLM tongue base

resection; therefore close cooperation with the frozen section surgical pathologist is necessary. In our own experience an average of 6 to 7 frozen sections are required for the typical resection of the base of the tongue.

11. Definitive hemostasis. Suction cautery, defocused laser. Clip any pulsatile branches of lingual artery; use thrombin-gelfoam hemostatic material or topical fibrin-based spray. Angled rigid Hopkins telescopes can be placed into the mouth both during and at the conclusion of the procedure to inspect the defect for bleeding and sites of residual cancer

12. Neck dissection as indicated:

a. Opportunity to convert to open procedure (lateral or transhyoid pharyngotomy) to complete cancer resection if necessary

b. Ligation of the at-risk branches of the lingual artery

c. Bilateral neck dissections are performed for centrally located or any T3

d. Pharyngeal perforations or intention pharyngotomy is closed and oversewn and bolstered with local tissue such as the strap muscles or the platysma. Carefully placed suction drains are then used to facilitate coaptation of the neck flap to the neck wound.

Common Errors in Technique

1. Attempting to proceed with TLM without detailed preoperative anatomic assessment of the patient and review of imaging data

2. Using existing instrumentation possibly ill-suited for correct exposure

3. Assuming cancer of the tongue base can be excised without repositioning microscope or changing retractors

4. Inadequate frozen sections to control margins

5. Failure to realize that TLM of the base of the tongue is technically very challenging and requires an extreme amount of patience

Postoperative Period

Postoperative Management

1. Observed overnight in the surgical intensive care unit to monitor airway

2. Monitor for postoperative hemorrhage.

3. Continue IV antibiotics for 24 hours if there was no pharyngotomy.

4. Continue antibiotics for 3 days if pharyngotomy was closed primarily or with local flap and 5 days if reconstruction was more extensive (pedicle flap or microvascular free tissue transfer).

5. Begin enteral feeding via NG tube or gastrostomy as soon as possible.

6. If resection was extensive, speech and swallowing evaluation may be needed prior to resuming oral alimentation.

7. Topical cyclohhexidine gluconate 0.12% mouth rinses are begun as soon as possible.

8. Wound and suction drain care are used for patients undergoing neck dissection.

9. Patients requiring a tracheostomy can usually be decannulated prior to discharge.

Complications

1. Retractor related due to excessive extension of retractor blades and prolonged pressure on the tongue

   a. Edema and hematoma of the tongue, laceration of the dorsum and lateral tongue, and delayed airway obstruction

   b. Compression of the lingual nerve between the retractor blade and the inferior border of the mandible, resulting in permanent or temporary disturbance of taste and anesthesia of the tongue

   c. Compression of the hypoglossal nerve between the retractor blade and the hyoid bone, resulting in paralysis of the tongue

   d. Other retractor-related complications include dental injury and lip lacerations.

2. Complications related to the resection include:

a. Laser thermal injury

b. Endotracheal tube fire and operative field fire

c. Hemorrhage and aspiration of blood

d. Airway obstruction

e. Delayed recovery of speech and swallowing

f. Life-threatening and potentially fatal hemorrhage following TLM is rare (<2%).

g. Careful attention to hemostasis by judicious use of the suction cautery, transoral clip hemostasis of identified bleeding vessels, and elective transcervical ligation of at-risk branches of the lingual, facial, and ascending pharyngeal arteries have been advocated.

3. Infectious complications—Micro- or intentional pharyngotomy in the neck can result in salivary contamination of the neck with subsequent infection, abscess, or pharyngocutaneous fistula. Delaying neck dissection after transoral laser resection can avoid this complication (Fig. 34.2).

FIG. 34.2 Case example. **A,** Patient prepared for TLM of

carcinoma of the base of the tongue. **B,** Patient in surgical position prior to TLM excision of squamous cell carcinoma of the left base of the tongue. **C,** Surgical defect in the same patient following TLM resection. **D,** Oriented surgical specimen.

Alternative Management Plans

1. Primary nonsurgical therapy with definitive concurrent chemoradiation protocols

2. Planned transhyoid or lateral pharyngotomy

3. Midline or parasymphyseal mandibulotomy

Evidence-Based Medicine Question

Which of the follow statements is *false?*

1. TLM resection of the tongue base increases identification of the primary site in patients with occult primary head and neck malignancies.

2. TLM is only suited for early-stage T1 or low-volume T2 tumors.

3. Following TLM resection of p16 positive tongue base tumors, dose reduction of external beam radiation therapy is possible without compromising oncologic outcomes.

4. In certain patients, staging panendoscopy may be necessary to ensure adequate exposure prior to TLM resection.

5. TLM resection of tongue base minor salivary gland tumors of the BOT is an oncologically sound approach.

Editorial Comment

As the section editor would like to comment on a few of the many important points and concepts presented in this chapter. One key issue in TLM or any other technique for transoral surgery of the base of the tongue is the risk of postoperative bleeding. The author notes the principal source of intraoperative bleeding in TLM of the tongue base to

be the dorsal lingual branch of the lingual artery. While I fully agree with this comment across the collective spectrum of small to larger tongue base procedures, there are more components to the lingual artery that come into play with larger resections. For resection of cancer of the base of the tongue with endophytic cancer or those that have some endophytic component, it is not uncommon to encounter both the dorsal lingual branches as well as the actual main lingual artery trunk as it courses over the hyoid into the intrinsic tongue musculature. This is a much larger diameter artery with significant anterograde and retrograde blood flow. Ideally this vessel would be identified and dissected proximally and distally with clip ligature prior to inadvertent transection. In addition, there is a suprahyoid branch of the lingual artery that can also course through the vallecula as it supplies to suprahyoid musculature. This vessel has anastomoses with the contralateral suprahyoid artery and can prove to be a significant source of postoperative bleed if it was not adequately controlled during the resection of the base of the tongue.

It is also important to emphasize the risk of traction or compression injury to either or both the hypoglossal and lingual nerves from using the various options of transoral retractors for base of tongue resections, regardless of the technique. Release of the retractor for short periods of time may be considered as an option to reduce this risk during prolonged base of tongue resections.

Ryan Soose

Review Questions

1. What is the principal source of intraoperative arterial bleeding in TLM of the tongue base?

   Dorsal lingual branch of the lingual artery

2. What are the complications associated with prolonged retractor time and excess pressure?

   Lingual and hypoglossal nerve paresis or paralysis

3. What are the three most important technical factors associated with successful visualization during TLM surgery?

Meticulous hemostasis, retractor and microscope repositioning, patience

4. What are the three important benefits of TLM resection?

Reduced rate of infection due to reduced need for pharyngotomy

Superior functional results due to mucosal re-epithelization, maintained sensory and motor function, and reduced need for flap reconstruction

5. What is the principal oncologic benefit of the TLM approach?

Earlier initiation of adjuvant treatment because of more rapid recovery

Transoral and Robotic Tonsil Surgery for Cancers of the Base of the Tongue and Pharynx

Alexandra Kejner, and Jason G. Newman

Introduction

Almost 50,000 people develop oral and oropharyngeal cancers each year with almost 9000 deaths annually. When diagnosed and treated in its early stages, 5-year survival rates can exceed 83%.[1]

Oropharyngeal cancer is on the rise, and in particular, human papilloma virus (HPV)–related cancers have increased in the United States by 225% since 1998.[2] Historically, open surgery of the oropharynx was fairly morbid and invasive and was noted to have comparable outcomes to primary chemoradiotherapy.[1] In the mid 2000s, with the advent of the surgical robot and its use by Drs. Weinstein and O'Malley, oropharyngeal surgery was revolutionized, making it less morbid and allowing for the potential of de-escalation therapy.[3,4]

Having a standardized set of techniques (similar to laryngectomy) allows for consistent margin control in a safe and effective manner and follows Halstedian principles of en bloc resection.

Patient selection is of the utmost importance because margin-negative resection is highly predictive of overall survival in head and neck cancers.[5-7]

Key Operative Learning Points

1. Knowledge of inside-out anatomy is key to a safe and effective operation, particularly when approaching the oropharynx transorally.

2. Halstedian principles of oncologic surgery must be maintained when removing tumors, allowing for adequate margins and decreased tumor spillage.

3. Ligating feeding vessels to the oropharynx during the neck dissection can aid in prevention of postoperative hemorrhage.

4. In cases of the unknown primary with HPV+ squamous cell carcinoma, the most commonly affected site is the oropharynx and can be easily sampled en bloc for pathologic analysis.

5. Reconstruction is important when addressing this area because it is vital in the functions of speech, breathing, and deglutition.

Preoperative Period

History

1. History of present illness

   a. Many patients will present initially with a mass in the neck; in these cases, questions regarding onset, location, duration, exacerbation, and any treatments may give insight into the underlying etiology of the mass (vascular, infectious, autoimmune, neoplastic).

   b. The patient should be questioned regarding dysphagia, odynophagia, otalgia, weight loss, hemoptysis, hoarseness, dysgeusia, and dyspnea, because these are most likely to be seen in patients with underlying malignancy.

   c. Current treatment with antibiotics or other medications.

2. Past medical history

   a. Prior treatment: Any antibiotics or recent viral illnesses

   b. Medical illness: History of other head and neck cancers (which can be seen in more than 36% of patients who smoke),[8,9] history of lung cancer, history of cervical cancer,[10] previous surgery in the oropharynx

      1) Any illnesses that would be contraindications for surgical intervention including significant cardiovascular, pulmonary, or

other end-stage cancers

2) Hypercoagulable disorders requiring chronic anticoagulation

3) Coagulopathy including von Willebrand disease or other

4) Stents requiring antiplatelet therapy

5) Significant sleep apnea (to understand postoperative risk of flash pulmonary edema and/or need for tracheostomy)

6) History of aspiration events

7) History of autoimmune disorders or transplantation requiring long-term antirejection therapy

c. History of radiation to the head or neck area (including for Hodgkin, treatment of acne)

d. Surgery

1) Previous tonsillectomy or sleep apnea surgery

2) Any neck surgery

3) Arm and leg surgery (in case the patient may require free flap reconstruction)

e. Family history

1) History of head and neck cancers

2) Autoimmune disorders

3) Cervical cancer in significant other (Data from the Swedish Cancer Registry (1958–1996) showed that spouses of patients with cervical cancer had a significantly elevated risk of development of tongue or tonsil cancer.)[10]

f. Medications

1) Antiplatelet drugs or anticoagulant medications

2) Immunosuppressive medications

3) Herbal products (fish oil, valerian root)

g. Social History

1) Alcohol

2) Smoking tobacco

3) Illicit or recreational drugs

4) Support system at home

5) Current occupation

Physical Examination

1. Overall appearance and breathing

   a. Note quality of breathing—mouth breathing or stridor; signs of obstruction, drooling or dry mouth

   b. Examine for cachexia, temporal wasting

   c. Some patients will have a characteristic foul odor of the breath, particularly those with larger cancers.

2. Examination of the cranial nerves

   a. In particular, lower cranial nerves (IX, X, XI, XII), because involvement indicates a significant disease process

3. Oral cavity/oropharynx

   a. Examine lips, gums, teeth, floor of mouth, tongue, and visible oropharynx with two tongue blades.

   b. Bimanual palpation of lips, floor of mouth, tongue, base of the tongue, cheeks, and hard palate

   c. Mirror examination if patient tolerates; flexible endoscopy if not

4. Nasal cavity

   a. Anterior rhinoscopy can be performed to evaluate for intranasal growths. Topical anesthetic and decongestant can also be applied at this time in preparation for nasal endoscopy.

5. Neck

   a. Palpation of the lymph node basins of the neck from level Ia to level V

      1) Any lymph nodes need to be assessed for fixation, mobility in certain directions

   b. Palpation of the thyroid gland

Imaging

Computed tomography (CT): CT with contrast should be done to better characterize the remaining neck for occult disease that is not felt on physical examination. It can also provide information regarding involvement of vessels or local structures. Special attention should be paid to the location of the carotid artery to ensure that it does not have a retropharyngeal course **as this is a contraindication for radical tonsillectomy.**

Magnetic resonance imaging (MRI): MRI is particularly useful for lesions of the base of the tongue or unknown primaries, because it can detect subtle changes in soft tissue.

Staging scans: Positron emission tomography (PET) CT can evaluate from the brain to the upper thighs for metastatic cancer. At the least, a chest CT should be performed to evaluate for metastatic cancer to the lungs.

Indications

1. Patients with primary T1, T2, T3, and select T4 lesions of the oropharynx with possible reconstruction

2. Patients with recurrent cancer of the oropharynx; to be performed in conjunction with a reconstructive surgeon

3. Metastatic cancer to the neck from an unknown primary as a part of the evaluation and treatment

Contraindications

1. Medical comorbidities with increased risk for general anesthesia: End-stage cardiac disease (Preoperative risk assessment by a cardiologist is necessary.)

2. End-stage cancer

3. Involvement of the carotid artery

4. Retropharyngeal carotid

5. Relative contraindication: Prevertebral fascia involvement

6. Relative contraindication: Pterygoid involvement (will require extensive reconstruction as part of planning)

Preoperative Preparation

Procedures

1. Nasopharyngolaryngoscopy
   a. Allows examination of the mucosa from the nasal cavity to the larynx
      1) This is often helpful for assessing the extent of palate involvement and the status of the airway in anticipation of a visit to the operating room (OR).
      2) Predicting possibly problematic airways is very important. Often, pictures or video can be shared with the anesthesia team.
2. Fine-needle aspiration (FNA) biopsy
   a. FNA can be performed on easily palpated cervical lymph nodes with or without ultrasound guidance as long as there is no evidence of involvement of the carotid artery.
   b. Some patients will tolerate biopsy of the oropharynx in the office.
   c. HPV typing should be done on the specimens.
   d. In patients for whom transoral robotic surgery (TORS) is to be considered, staging endoscopy is often necessary to determine the resectability of the tumor. Mobility of the tumor, involvement of adjacent structures, and exposure are all evaluated at the time of this endoscopy. If the tumor cannot be reached in the office setting, pan endoscopy with biopsy should be performed in the OR. This also gives the surgeon an idea of how well the cancer can be exposed, particularly if transoral resection is being planned or if the patient will require extensive reconstruction (in which case, a mandible split or a robotic approach may be necessary).
3. Preoperative imaging

4. Preoperative clearance

5. Panendoscopy results with HPV testing

6. Airway assessment

7. Staged or concomitant neck dissection with ligation of vessels

Operative Period

Anesthesia

General anesthesia with full paralysis. Relaxation is of the utmost performance during transoral surgery because this aids in visualization, dissection, and in reducing the risk of the patient moving during surgery.

Positioning

Supine: The patient is positioned supine, without a shoulder bump. The eyes and teeth are protected. This allows for full range of motion by the surgeon. Additionally, if the surgical robot will be used, this allows maximization of the robotic camera and instrument mobility.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin and metronidazole: Due to the typical flora of the oral cavity, dual coverage with a cephalosporin and metronidazole are warranted.

Clindamycin: Can be used as an alternative in patients with penicillin allergy because it covers the majority of oral flora. The caveat with this medication is its association with *Clostridium difficile* as a complication.

Monitoring

Monitoring for continued neuromuscular paralysis

Instruments and Equipment to Have Available

For a nonrobotic procedure:

1. Loupe magnification and surgical headlight

2. Cautery unit (set at 15 to 20 W for COAG) with Bovie pedal and bipolar pedal—one pedal next to the assistant for suction cautery

3. Two Bovie pads (one for standard monopolar cautery and one for suction cautery)

4. Reusable bipolar cord

5. Crowe-Davis mouth gag

6. Extended tip Bovie

7. Extra-long DeBakey or Blue Burner forceps

8. Weder retractor or Minnesota retractor

9. Pediatric Yankauer suction

10. Tonsil sponges soaked with Afrin

11. Herd retractor

12. Fine dissector (Krile, Schnidt)

13. Surgical clip applier

14. Medications/pharmacologicals:

    a. Methylene blue for marking margins on specimen

    b. Topical phenylephrine for topical application transorally

    c. Topical hemostatic agent

15. Optional: Can use a 30-degree endoscope to evaluate the base of the tongue if not well visualized transorally. Alternatively, this area may be visualized with a laryngeal mirror.

If using the surgical robot:

16. Intuitive Surgical high-magnification camera head (45-degree field of

view [FOV])

17. Intuitive Surgical wide-angle camera head (60-degree FOV)

18. Ikegami high-definition 3D imaging system (da Vinci S only)

19. 30-degree Intuitive Surgical endoscope

20. 0-degree Intuitive Surgical endoscope

21. Three chairs that have a foot pedal for adjusting up and down, two at the bedside (for the nurse and the bedside surgical assistant) and one at the surgeon console

22. Three rectangular OR instrument carts and one small square OR instrument cart

a. Recommended 5-mm EndoWrist Instrumentation:

1) Monopolar cautery

2) Maryland forceps

Key Anatomic Landmarks

1. Laterally: Carotid artery, glossotonsillar sulcus

2. Posteriorly: Prevertebral fascia

3. Anteriorly: Base of the tongue

4. Medially: Uvula

Prerequisite Skills

1. Knowledge of inside-out anatomy

2. **If using robot:** Transoral robotic training

Operative Risks

1. Intraoperative hemorrhage from lingual artery, branches of facial artery, veins. Best prevented by preoperative or intraoperative transneck ligation of branches of the external carotid system, including superior

laryngeal, facial, and lingual

a. The blood supply to the tonsil is the dorsal lingual branch (of the lingual artery), ascending palatine artery (of the facial artery), tonsillar branch (of the facial artery), ascending pharyngeal artery (of the external carotid artery), and the lesser palatine artery (of the descending palatine artery).

2. Fistula: Communication between the oropharynx and the neck. This can be prevented by leaving the submandibular gland intact, resecting only a portion of it, and/or rotating an anterior digastric flap to bolster this area. Staging surgery to allow for the region to granulate may also reduce this risk.

3. Injury to the carotid artery: Rare but possible if the surgeon dissects too far laterally. If the adipose tissue surrounding the carotid is not involved, this can be safely retracted laterally after identifying the pterygoids.

Surgical Technique: [include narrated videos online]

General anesthesia with paralysis is necessary when approaching from a transoral technique. This allows for maximal mouth opening and minimizes muscular contraction when using monopolar cautery. After induction, the patient is intubated orally with a reinforced tube, which is sutured into position in the nasolabial fold. The eyes are protected using a plastic shield or thick towels. The bed should be lowered completely and the patient should not be placed on a shoulder roll. Preoperative steroids are given for a total of three doses.

Transoral Technique

Pearl

A key point to understand prior to beginning surgery is that the overall oncologic goal of radical tonsillectomy is to complete an en bloc resection approach to ensure widely negative margins (as is feasible based on the anatomy, i.e., base of the tongue, soft palate, medial and lateral mucosal

margins) and to minimize positive or close margins at the level of the constrictor muscles.

- A mattress suture is placed through the tongue using a silk suture. This is used to displace the tongue anteriorly.
- The Crowe-Davis retractor is placed using the appropriately sized tongue blade and opened as wide as is feasible for the patient.
- The Crowe-Davis retractor is placed so that 1 cm of the base of the tongue can be resected en bloc to minimize the likelihood of a close margin at the inferior aspect of the tonsil. All of this area is exposed at one time to decrease the need for replacing the mouth gag.
- The Crowe-Davis retractor can then be further stabilized using a Mayo stand or using a Storz scope-holder stabilizing arm.
- The endotracheal tube is positioned laterally and sutured between the oral tongue and the retromolar trigone (Fig. 35.1).
- This positions the tube out of the operative field and reduces the need for the assistant to reposition the tube throughout the case.

If using the robot: The robot is brought into position with the camera positioned directly in the mouth between two arms at 30-degree angles to the tumor. The spatula tip Bovie cautery is positioned ipsilateral to the tumor. The assistant, using two pediatric Yankauer suctions, retracts the cheek laterally and suctions smoke and blood. The assistant is extremely important during this case, not only for suctioning blood, smoke, and mucus but also for retraction to accomplish a four-handed surgical technique. The assistant is also charged with applying surgical clips as directed by the console surgeon.

- The assistant surgeon retracts the ipsilateral cheek laterally.
- The surgeon, using the extended tip **(or in the case of the robot, the spatula tip)** monopolar cautery, designs an index incision of the palate in the shape of a question mark (Fig. 35.2): superiorly at the level of the soft palate, laterally at the mucosa overlying the pterygomandibular raphe and extending inferiorly to the tongue base.

FIG. 35.1 Exposure is achieved using a Crowe-Davis mouth gag. Note that the tube is secured with silk suture to the melolabial crease and the tube is lateralized with a suture through the tongue to the retromolar trigone on the side contralateral to the tumor. This positions the tube out of the operative field and reduces the need for the assistant to reposition the tube throughout the case.

FIG. 35.2 The surgeon, using the extended tip (**or in the case of the robot, the spatula tip**) monopolar cautery, designs an index incision of the palate in the shape of a question mark: superiorly at the level of the soft palate, laterally at the mucosa overlying the pterygomandibular

raphe, and extending inferiorly to the tongue base.

- The incision is deepened to the level of the medial pterygoid muscle, which can be identified as a white band (Fig. 35.3).
- A dissector or a DeBakey, (**or in the case of the robot),** the Maryland forcep attachment, is then used as a hook retractor to hold the mucosal edge medially while the spatula tip Bovie is used as a dissector to push the lateral pharyngeal adipose tissue pad laterally and away from the constrictors.

Establishing the correct plane is vital because the carotid artery is just lateral to this adipose tissue pad and dissecting too laterally can cause bleeding or stroke.

- An index incision is made medially to ensure that excessive posterior pharyngeal mucosa is not removed and to define the medial-most aspect of the resection (Fig. 35.4).

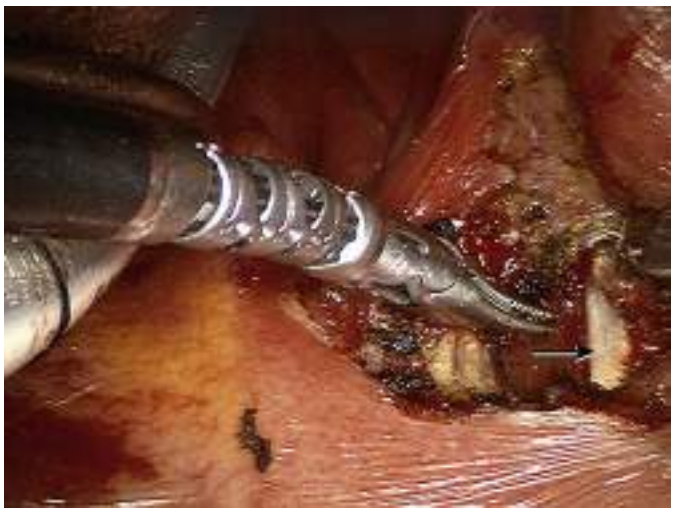

FIG. 35.3 The incision is deepened to the level of the medial pterygoid muscle, which can be identified as a white band *(black arrow)*.

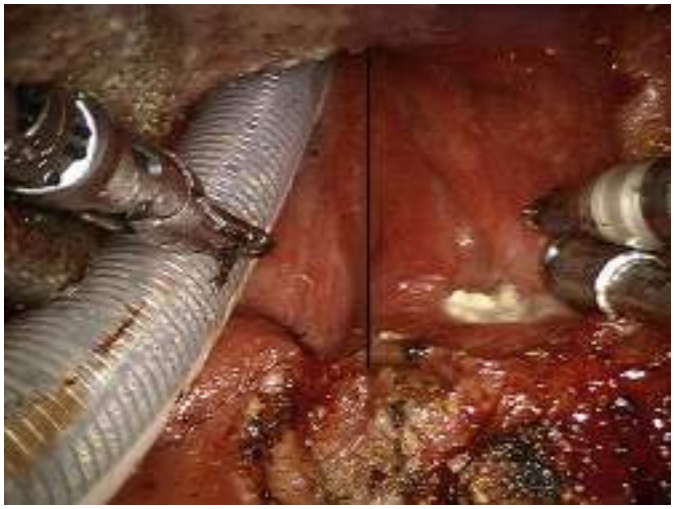

FIG. 35.4 An index incision is made medially *(solid black line)* to ensure that excessive posterior pharyngeal mucosa is not removed and to define the medial-most aspect of the resection.

- Once the incision is deepened to the level of the constrictor muscles, it is continued inferiorly toward the base of the tongue.
- The superior soft palate margin is outlined and joined to the previous incision at the level of the pterygoids (Fig. 35.5).
- The styloglossus and stylopharyngeus muscles are identified and the inferior dissection is temporarily halted (Fig. 35.6).
- "Connect the dots" between the medial mucosal incision and the lateral pterygomandibular raphe incision. This is extended posteriorly to the level of the shiny, avascular plane of the prevertebral fascia overlying the longus coli muscle (Fig. 35.7).
- The specimen is elevated and then blunt dissection sweeps the specimen anteriorly, sweeping the medial constrictors off of the prevertebral fascia.
- The constrictors can then be grasped with the Maryland (in the case of the robot) or with a Schnidt in a plane parallel to the spine. The constrictors are divided along the edge of the instrument, taking care to avoid clamping perpendicularly or too far laterally because this can cause inadvertent injury to the internal carotid artery.

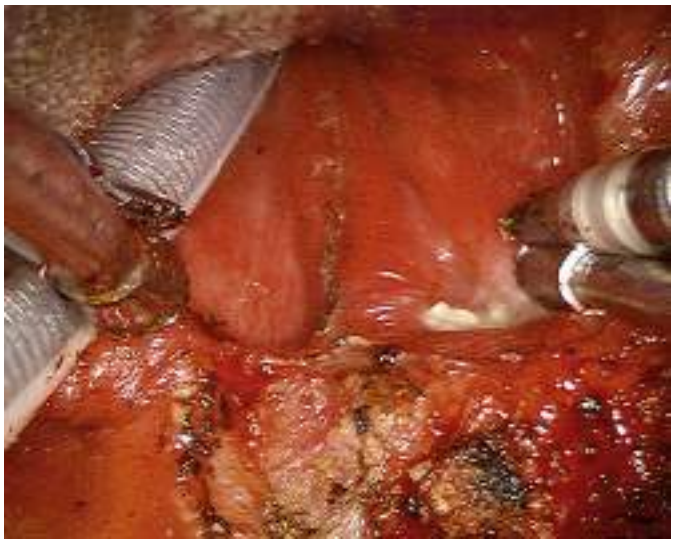

FIG. 35.5 The superior soft palate margin is outlined and joined to the previous incision at the level of the pterygoids.

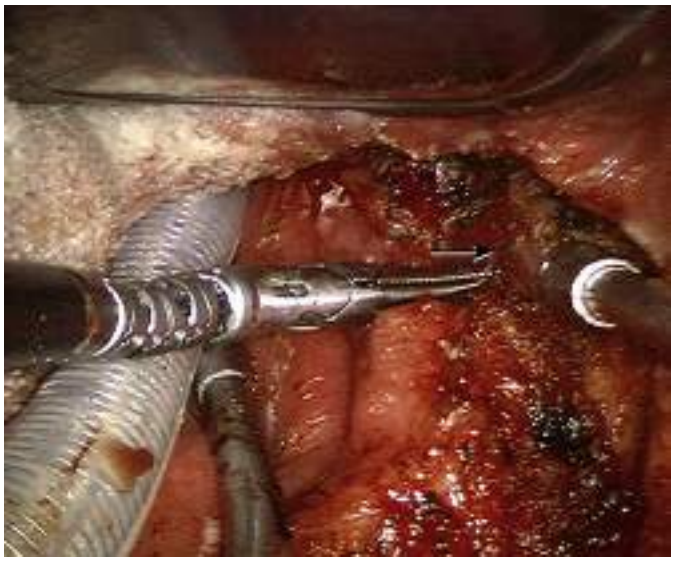

FIG. 35.6 The styloglossus and stylopharyngeus muscles are identified and the inferior dissection is temporarily halted *(black arrow)*.

FIG. 35.7 Demonstration of the prevertebral fascia, a relatively avascular plane under which the robotic surgeon places the spatula tip Bovie to bluntly dissect it off *(black arrow)*.

FIG. 35.8 Final posterior pharyngeal and tongue base incisions.

Tongue Base Incisions

- Outline the tongue base incision to the area of the glossotonsillar sulcus as well as a small portion of the mucosa of the floor of mouth.
- Blunt dissection can be undertaken in this area to isolate and control smaller contributory arteries and veins in this area (this may be

assisted by the assistant holding an endoscope or laryngeal mirror to better visualize this area) (Fig. 35.8).

- Alternatively, the surgeon may switch to a Lindholm laryngoscope to visualize this area and complete the incisions in the tongue base this way. Small vessels can be controlled with surgical clips or laparoscopic coagulation instruments (Dolphin).
- A 1-cm margin is advised for cancers with no obvious invasion of the base of the tongue.
- If there is invasion of the base of the tongue, more base of the tongue should be resected to ensure widely negative margins. This can include one-half of the base of the tongue if necessary. This has not been shown to have significant adverse effects on swallowing.

- Identify and clip the proximal and distal aspects of the artery when in close proximity to it, to achieve wide surgical margins.
- After completing the incisions into the base of the tongue and main dissection, attention returns to the styloglossus and stylopharyngeus muscles, which are dissected and Bovie transected leaving a margin of muscle around the junction of the tongue and constrictors.
  - In this region, there are multiple veins and arteries that are encountered and can be controlled using bipolar cautery or clipped.
  - In addition, the glossopharyngeal nerve may be encountered deep to the styloglossus. It may be necessary to resect this nerve if significant dissection and exposure are required to achieve wide margins around the cancer.
- The parapharyngeal adipose tissue plane is preserved to protect the great vessels.
  - If frozen section analysis identifies penetration of the cancer through the constrictor muscle, these planes may be further resected to achieve clear surgical margins.
- The resection is then completed by bringing the base of the tongue incisions and dissection to the lateral oropharyngeal wall just inferior to the stylopharyngeus muscle.
- The specimen can be removed en bloc upon the final through-and-through incisions into the constrictor muscle along the remaining

course of the medial pharyngeal index incision.

FIG. 35.9 The wound is inspected to assess the extent of soft palate resection and the risk of nasopharyngeal regurgitation and incompetence postoperatively.

- The surgical specimen is then taken to the surgical pathology suite for inking and orientation is performed with both the surgeon and pathologist present.
- Frozen sections of mucosal or muscular margins are performed where the margins are deemed clinically close as determined by sectioning into the tumor and by palpation.
- The wound is inspected to assess the extent of soft palate resection and thus the risk of nasopharyngeal regurgitation and incompetence postoperatively (Fig. 35.9).
- In general, no or minimal reconstruction is needed if the lateral mucosa at the junction of the soft palate and the posterior pharyngeal wall remains intact.
- For buccal adipose pad reconstruction, the same exposure may be used without changing the retractor.
  - The pad is mobilized by dissecting superior and lateral to the medial pterygoid muscle into the buccal space.
  - The adipose tissue is then gently mobilized medially and sutured to both exposed musculomucosal surfaces of the pharynx and soft palate. If a neck dissection is planned, reinforcement from below may be created using the posterior belly of the digastric muscle or a

sternocleidomastoid rotational flap.

- The wound is inspected for bleeding and mild oozing can be controlled with bipolar cautery.
- Have the anesthesiologist perform a Valsalva maneuver with the bag to confirm that there is no active bleeding.
- Apply a thin layer of Tisseel Fibrin Sealant (Baxter Healthcare) or other hemostatic agent to the surgical site.
- A nasogastric feeding tube should be inserted under direct visualization and secured with a nasal sill suture to optimize nutrition during postoperative healing.
- The patient is extubated in the OR if the airway is considered safe.

Common Errors in Technique

1. Patient selection: At the time of panendoscopy, prior to definitive surgery, examination of the mobility of the tumor (especially with regard to the carotid artery) should be noted. Additionally, issues with mouth opening should be noted at this time because they may preclude the use of the mouth gag/visualization.

2. Poor exposure: Placing the mouth gag in the best configuration for exposure of the palate, the tonsil, and about 1 cm of the base of the tongue. This involves pulling the oral tongue toward the contralateral side and using a tongue blade long enough to expose the base of the tongue. Failure to do this can result in the need for repositioning midway through the case or increasing the risk of positive margins.

3. Excessive resection of the soft palate without reconstruction can result in nasopharyngeal insufficiency with nasal regurgitation and rhinolalia. This can be prevented by performing a local pharyngoplasty or buccal adipose tissue pad flap placement.

4. Resecting tissue to the level of the contralateral lingual artery or through the hyoid. This can lead to dysphagia postoperatively that can be persistent and can result in the need for a feeding tube.

5. Control of the lingual artery: To prevent postoperative bleeding, we advise clipping the lingual artery both where it comes over the hyoid

bone and its distal extension. Clipping the lingual and facial branches of the external carotid artery during the neck dissection can also help to prevent postoperative hemorrhage.

6. Failure to resect the tumor en bloc: Data have shown that having to re-resect margins can lead to worse local control than if the margins are sampled from the specimen (i.e., sufficient tissue taken at the time of resection to allow for adequate margin sampling).

Postoperative Period

Postoperative Management

1. The patients should be monitored in a step-down unit with monitoring including pulse oximetry and readily available nursing in case of postoperative hemorrhage, which can lead to devastating airway complications if not addressed immediately.

2. Postoperatively, pain management is very important. We have used standard opioids, typically with a patient-controlled device as well as scheduled gabapentin and a short course of steroids (three doses are recommended).

3. Nasogastric feeds can be started on postoperative day 1. Oral feeding can be attempted on postoperative day 1 and can be advanced as tolerated. A speech-language pathology consultation may be necessary in certain situations.

4. Ambulation is encouraged to prevent pulmonary thromboembolism and pneumonia.

5. Incentive spirometry is an extremely important adjunct.

6. Patients can usually be discharged on postoperative day 3 or 4 on a soft diet.

Complications

1. Hemorrhage: The most common and typically the one complication that results in rehospitalizations and need for reoperation

2. Dehydration

3. Injury to the teeth

4. Injury to the lingual nerve

5. Injury to the hypoglossal nerve

6. Death

Alternative Management Plan

1. Chemoradiation

2. Open surgery

Discussion

Evidence-Based Medicine Question

What is the role of TORS for HPV-related cancers?

For small tumors (T1 and T2) with resectable neck metastases, there is a functional benefit from a margin-negative resection that may not require radiation or a postoperative dose alone. With the Eastern cooperative oncology group (ECOG) 3311 surgical trial, de-escalation may possibly become the standard of care.

Editorial Comment

It is important to pay attention to the position of the endotracheal tube while dissecting medially with the pharynx and the base of the tongue, so as to prevent the risk of contact and potential for an airway fire. We use a wire reinforced endotracheal tube for all of these procedures. The surgical assistant provides retraction of the endotracheal tube to the contralateral side as needed during the operation. The bedside assistant plays a key role in providing countertraction that will facilitate the safe and effective dissection and en bloc resection. For cancers that invade the base of the tongue, the lingual artery is typically encountered while performing resection of the lateral base of the tongue. It lies lateral to the

intrinsic muscles of the tongue and medial to the hyoglossus muscle, coursing superior to the hyoid bone. Should the surgeon inadvertently enter the lingual artery, control is aided by suctioning from the bedside assistant as well as external pressure being applied to the neck by the assistant above the ipsilateral greater cornu of the hyoid. The artery can then be ligated from below during the neck dissection if planned. In cases where there is a soft tissue defect and gap, then a pharyngoplasty is performed by suturing the posterior lateral aspect of the soft palate mucosa to the side of the superior pharyngeal muscle and mucosal incision. It is important to include some palate and constrictor musculature in the horizontal mattress suturing or the mucosal approximation will likely tear and the lateral tissue gap may reopen. In cases where there remains a lateral tissue gap and communication with the nasopharynx after the pharyngoplasty, the recommendation is to use a pedicled pad of buccal adipose tissue for final closure.

Special thanks to Dr. Kyle Hatten, MD for compiling video footage.

Transoral Robotic Surgery for Neoplasms of the Base of Tongue

Raymond Chai, Bert O'Malley Jr. , and Jason G. Newman

Introduction

Carcinoma of the base of the tongue can be managed with either surgical or nonsurgical approaches. Historically, most surgical resections in this region have involved open approaches, such as suprahyoid pharyngotomy or lip-split mandibulotomy. Given the morbidity of these approaches, organ preservation protocols initially developed for cancer of the larynx were adapted to the oropharynx.[1] However, primary chemoradiation is not without serious toxicity. Long-term treatment-related sequelae from chemoradiation, particularly pertaining to swallowing dysfunction, have become increasingly recognized over time.[2] Transoral robotic surgery (TORS) was developed as a minimally invasive approach through a natural orifice to allow for precision oncologic resections while preserving function.[3–5]

A major advantage of a primary surgical approach to neoplasms of the base of the tongue is that it provides a pathologic specimen. Accurate staging and assessment of histologic risk factors can thus be definitively determined, rather than relying on imaging alone. With comprehensive pathologic staging, patients can then be risk stratified to receive appropriate adjuvant therapy, if indicated.

Two of the most challenging aspects of the procedure are appropriate patient selection and maximizing exposure during the resection.

Key Operative Learning Points

1. Appropriate docking and setup of the surgical robot, along with

proper selection and then positioning of the retractor, are the keys to optimizing exposure.

2. The dorsal lingual branch of the lingual artery is typically encountered in the lateral aspect of the resection and must be managed appropriately to prevent postoperative hemorrhage.

3. The bedside assistant plays a crucial role in the success of the procedure. Appropriate suctioning, traction, and countertraction greatly facilitate surgical access and visualization.

Preoperative Period

History

1. History of present illness

   a. Age of the patient

   b. Elicitation of symptoms including dysphagia, otalgia, odynophagia, aspiration, weight loss, and dyspnea. Symptoms can help to guide whether or not a patient is a candidate for TORS.

      1) Pre-existing dysphagia and/or gross aspiration may indicate the need for prolonged enteral feeding. In addition, these symptoms may suggest deep submucosal infiltration of the cancer that may not be clinically apparent.

      2) Referred pain such as otalgia may suggest extensive perineural invasion or involvement of the epiglottis.

2. Past medical history

   a. History of prior radiation therapy. Although salvage TORS has been described in the literature, the normal interface between tissue and tumor is often obliterated in these patients and may preclude a minimally invasive resection. In addition, wound healing and vascularity are compromised, and these patients may take many months to heal by secondary intention.

   b. Cardiopulmonary fitness and bleeding disorders need to be assessed. Patients with severe cardiac or pulmonary disease may not be able to tolerate major surgery and postoperative rehabilitation.

These patients may be better suited for primary chemoradiation. Likewise, patients with known hereditary coagulopathies are predisposed to postoperative bleeding. Given the open wound and healing by secondary intention inherent to TORS, these patients may not be appropriate surgical candidates.

3. Past surgical history

   a. Prior surgical intervention or biopsies for cancer

   b. Prior surgery on cervical spine or temporomandibular joint

4. Family history

   a. Bleeding disorders or adverse reaction to anesthesia

5. Social history

   a. Smoking and extensive use of alcohol

6. Medications

   a. Anticoagulants including Coumadin, Plavix, and aspirin should be discontinued preoperatively and ideally for at least 2 weeks after surgery. It should be recognized that the use of supplements such as Ginkgo biloba, fish oil, and vitamin E may pose an increased risk for postoperative bleeding.

   b. Long-term use of steroids may inhibit wound healing by secondary intention.

Physical Examination

1. Evaluation of the base of the tongue is performed by both direct examination and flexible laryngoscopy. The glossotonsillar sulcus, vallecula, and epiglottis are assessed for grossly visible cancer. Extension of the cancer to the midline is also assessed. Palpation, if tolerated, is critical to estimate depth of invasion into the tongue.

2. Palpation of the neck is performed. Care is taken to note the number of lymph node metastases and whether obvious contralateral metastasis is present. Lack of mobility of the lymph nodes may imply extracapsular extension.

3. Oral aperture along with mandibular dimensions and positioning,

tongue size and shape, and dentition are evaluated to determine if sufficient transoral exposure is possible.

Imaging

1. Magnetic resonance imaging (MRI) or computed tomography (CT) is performed to evaluate lymph node status, presence or absence of gross extracapsular extension, and extent of tumor invasion. Obvious involvement of deep parapharyngeal space structures, extrinsic tongue musculature, and the hyoid bone may preclude transoral resection. Sagittal sections are helpful in defining anterior extension of the cancer. From our evolving experience with imaging and TORS, it appears that MRI may be the best imaging study to provide more detail with respect to depth of invasion into both intrinsic and extrinsic tongue musculature.

2. Positron emission tomography–CT–computed tomography (PET-CT) is typically performed for initial staging and metastatic evaluation.

Indications

1. TORS can be performed for all tumors of the base of the tongue that are deemed resectable from a transoral approach. However, the ideal candidates are those who are anticipated from preoperative evaluation to be able to avoid either adjuvant chemotherapy or concurrent chemoradiation, as well as maintaining articulation and swallowing function.

Contraindications

1. Deep involvement of more than one-half of the base of the tongue. These patients are at risk for significant functional deficits after resection or risk of devascularizing the tongue from bilateral lingual artery sacrifice.

2. Invasion of the skull base, hyoid bone, great vessels, or mandible

3. Deep involvement of the extrinsic tongue musculature

4. Large cancers of the glossotonsillar sulcus that risk exposure of the

carotid artery

Preoperative Preparation

1. If exposure or resectability is indeterminate, patients should be brought to the operating room for an initial staging direct laryngoscopy with examination under anesthesia. The FK-WO retractor can be used at this time to determine if adequate exposure can be obtained.

2. Neck dissection can be performed either concurrently or in a staged fashion. Our protocol is to perform a staged surgery with the neck dissections done before the TORS resection. The lingual artery, facial artery, and the superior laryngeal artery are ligated during the neck dissection as a prophylaxis against potential catastrophic postoperative hemorrhage. This staged neck dissection approach also minimizes edema of the tongue and airway and prevents potential pharyngocutaneous fistula if extensive resection of the glossotonsillar sulcus is anticipated.

Operative Period

Anesthesia

1. Communication with the anesthesiologist needs to be thorough and may be aided by reviewing imaging or providing a video of preoperative fiberoptic laryngoscopy. Our preference is for transoral intubation with GlideScope assistance (Verathon, Bothell, WA) to maximize visualization of the airway. Awake fiberoptic intubation is occasionally necessary if there are concerns for a difficult airway. A wire-reinforced endotracheal tube is used to prevent kinking and allows for appropriate mobility of the tube with retraction. The endotracheal tube is then secured contralateral to the tumor side with a suture through the nasolabial fold.

2. Airway fire is a potentially life-threatening complication of oropharyngeal surgery. Fraction of inspired oxygen should be kept less than 30%, and an appropriate sized endotracheal tube must be placed to prevent leakage around the cuff.

3. All patients require full neuromuscular paralysis to facilitate placement of the retractor and allow for maximum exposure.

4. Protective goggles are placed over the patient's eyes to prevent injury.

Positioning

1. The operating table is rotated 180 degrees and lowered to the maximum extent to accommodate placement of the robotic arms. The patient is positioned so that the crown of the patient's head is at the very edge of the operating table.

2. The surgical robot (Intuitive Surgical da Vinci Si) is docked to the right and positioned at a 30-degree angle to the operating table, making sure that the robotic foot is touching the base of the table. The robot is positioned so that the pivot point of the camera arm is approximately at the level of the oral commissure.

3. Collisions are minimized if the instrument's arms are placed as high as possible. The pivot point of the central scope arm is rotated inwards and then lifted up to its maximum height. The scope is then lowered as far as it will go into the oral cavity. At this point, the scope arm is moved down until the camera touches the posterior pharyngeal wall. The scope is then adjusted upwards as needed for an optimum view. This ensures that the scope arm is positioned at a maximum height.

4. The instrument's arms are then positioned in a "V" configuration and lowered until the tip of the instrument cannula is approximately at the level of the frame of the retractor. The instruments are then advanced until they are in the field of view of the scope (Fig. 36.1).

5. A shoulder roll is not necessary for this procedure.

FIG. 36.1 FK-WO retractor with curved retractor blade.

FIG. 36.2 Proper orientation of robotic arms with usage of laryngeal clip applier.

Perioperative Antibiotic Prophylaxis

Our antibiotics of choice are intravenous cefazolin and metronidazole. Clindamycin is given to patients who are penicillin allergic. Antibiotics are typically given intravenously 1 hour before the incision.

Instruments and Equipment to Have Available

1. Feyh-Kastenbauer laryngopharyngoscope retractor (FK-WO) (Fig. 36.2)

2. Curved laryngeal clip appliers

3. Pediatric Yankauer suctions

4. Robotic 5-mm spatula electrocautery tip and robotic Maryland dissector

5. 0- and 30-degree 12-mm robotic endoscope. Although use of the 8.5-mm endoscope has been described, it is shorter than the 12-mm endoscope and will tend to collide with the other robotic arms outside the oral cavity.

Key Anatomic Landmarks

1. Glossotonsillar sulcus

2. Vallecula

3. Epiglottis

4. Hyoid bone

5. Dorsal lingual branch of the lingual artery

6. Lingual artery

Prerequisite Skills

1. Completion of a formal training program along with appropriate hospital credentialing and proctoring for robotic surgery is critical before

performing TORS resection of the base of the tongue.

Operative Risks

1. Intraoperative hemorrhage, particularly from the lingual artery or its dorsal lingual branch

2. Close or positive margins on the resection specimen

FIG. 36.3 Lateralization of the endotracheal tube after placement of the retraction suture.

3. Pharyngocutaneous fistula with concurrent neck dissection if extensive glossotonsillar resection is performed

4. Airway compromise due to edema of the tongue from prolonged retraction

Surgical Technique

A thorough examination under general anesthesia is performed, including digital palpation to confirm the location, size, and mobility of the tumor. For endophytic cancers, it can be helpful to paint the surface with methylene blue because these lesions may become obscured when retraction is applied.

The procedure is typically started with a 0-degree scope, with the 30-degree scope reserved if needed for visualization.

For this procedure, 5-mm instruments are optimal. The monopolar spatula cautery is placed ipsilateral to the tumor, and the Maryland

dissector is initially positioned contralateral.

A suture is then placed in the midline of the tongue to allow for retraction. A tooth guard is used to protect the maxillary dentition. While maintaining gentle anterior traction on the tongue, the FK-WO retractor is placed. The lateral tongue is slid under the straight edge of the retractor blade, and the slotted edge is kept medial. The retractor is opened, and the cancer is exposed. A small cuff of normal tongue is maintained between the tip of the retractor blade and the tumor to provide room to obtain an adequate anterior margin of resection. The retractor is suspended with both chest support suspension and laterally with an endoscope holder.

The endotracheal tube is positioned contralateral to the tumor and is secured in place with a suture placed between the lateral tongue and the retromolar trigone (Fig. 36.3).

With the primary surgeon at the console, the assisting surgeon sits at the head of the bed using two baby Yankauer suctions to retract, suction smoke, and help to achieve hemostasis.

If there is no significant invasion of the cancer into the glossotonsillar sulcus, the initial incision is made in the tonsillar fossa and extended to the lateral aspect of the base of the tongue to incorporate mucosa for a lateral margin (Fig. 36.4). If cancer is present at the glossotonsillar sulcus, the constrictor muscles and the styloglossus should be resected with the specimen.

A horizontal anterior incision is then made immediately below the tip of the retractor to allow the cancer to fall posteriorly into the operative field. This initial incision is performed to a depth of approximately 1 cm (Fig. 36.5).

The instrument's arms are then switched, with the monopolar cautery now placed contralateral to the cancer. A midline vertical incision is then made from the medial aspect of the horizontal incision to the level of the vallecula to establish the depth of the resection (Fig. 36.6). To facilitate this, the bedside assistant must provide strong lateral and medial retraction with the Yankauer suctions in the depths of the incision as it is made. Typically, there is no significant bleeding encountered in this location. The epiglottis should now be completely in view.

FIG. 36.4 Initial incision through the glossotonsillar sulcus to establish lateral margin.

FIG. 36.5 Horizontal incision at the anterior margin to allow the tumor to drop into the operative field.

FIG. 36.6 Midline vertical incision to establish the depth of resection.

The resection is then performed from medial to lateral following the previously made horizontal incision. It is important to angle the instruments anteriorly in an imaginary line from the plane of the retractor blade to the hyoid because the tendency is to prematurely truncate the specimen here. Angling the vector of the resection appropriately facilitates a wide anterior margin of muscle.

At the lateral aspect of the base of the tongue, the lingual artery and its dorsal lingual branch will be encountered at a depth of approximately 1 to 2 cm. When the artery is encountered, it should be isolated, and a string of hemoclips are placed along the exposed portion of the vessel to prevent postoperative hemorrhage (Fig. 36.7). If significant bleeding is encountered here from an inadvertently transected artery, external neck pressure at the greater cornu of the hyoid applied by the bedside assistant can be helpful.

FIG. 36.7 Exposure and control of the lingual artery and its dorsal lingual branches.

The specimen is removed and brought to the pathology department for orientation and margin analysis. Equivocal margins are assessed with frozen sections. If the margins are deemed close or positive, methylene blue is used to ink the region of concern on the patient, and re-resection is performed.

Multiple Valsalva maneuvers are performed, and meticulous hemostasis is obtained with electrocautery and hemoclips, as needed. Arista absorbable hemostatic powder (Davol, Providence, Rhode Island) is applied to the resection bed.

A nasogastric tube is placed under direct visualization and secured contralateral to the operative field for enteric access. If significant edema of the tongue is anticipated, patients may be kept intubated. In this situation, the wire-reinforced endotracheal tube is exchanged for a Hi-Lo Evac Endotracheal Tube with evacuation lumen (Covidien, Mansfield, MA). This is important because irreversible compression and potential airway compromise may occur if the patient inadvertently bites a wire-reinforced tube while intubated.

Common Errors in Technique

1. Poor exposure from inadequate positioning of the robot and/or retractor

2. Undercutting the cancer at the horizontal anterior resection line instead of angling the instruments forward toward the hyoid bone

3. Mismanagement of the lingual artery or its dorsal lingual branch. These arteries are usually exposed during the resection and should be ligated at multiple positions to prevent potential major postoperative hemorrhage. In addition, ligating the lingual artery in the neck at the time of staged or concurrent neck dissection should be performed.

Postoperative Period

Postoperative Management

1. If the patient is felt to be at risk for postoperative airway compromise based on the extent of cancer resection or notable residual edema of the tongue or pharynx, he or she is typically kept intubated for 24 to 48 hours; otherwise he or she may be extubated. We had previously administered intravenous dexamethasone 6 mg every 6 to 8 hours until discharge followed by a Medrol Dose Pack upon discharge. However, we are shifting our protocol toward a single dose of intraoperative intravenous dexamethasone of 10 mg with subsequent steroids only if edema of the airway or tongue is noted.

2. A prophylactic nasogastric feeding tube (Dobhoff) is placed while the patient is in the operating room for enteral access. Patients are evaluated

by a speech language pathologist, and a bedside swallow evaluation is performed. Most patients are then started on a diet of clear liquids and advanced to a mechanical soft diet as tolerated. If caloric intake is adequate, the feeding tube is removed prior to discharge. If swallowing assessment demonstrates significant dysphagia and/or aspiration, patients are discharged with tube feeds at home. A repeat swallowing evaluation is then repeated as an outpatient in 1 to 2 weeks.

3. If there is concern for malnutrition, a consultation with a nutritionist is obtained to guide appropriate caloric supplementation.

4. Significant postoperative pain is expected after resection of the base of the tongue. Patients are started on a patient controlled analgesia pump and transitioned to oral narcotics as tolerated. Nonsteroidal anti-inflammatory drugs are typically avoided within the first 2 weeks post operative given the risk for bleeding.

5. Patients are instructed to swish and spit with Peridex at least 4 times/day to maintain oral hygiene and increase comfort.

Complications

1. Postoperative bleeding occurs in 3% to 8% of patients.[6] This can range from minor oozing to potentially life-threatening hemorrhage. We routinely ligate the lingual, facial, and superior thyroid arteries preoperatively during the neck dissection. In our experience, this maneuver not only decreases intraoperative bleeding that can obscure visualization but also minimizes the risk for catastrophic bleeding. All vessels greater than 2 mm that are encountered during the resection are clipped in multiple locations. The lingual artery or its dorsal lingual branch is typically encountered at the lateral aspect of the resection. When identified, multiple clips are placed along the exposed portion of the artery.

The danger with postoperative bleeding is the risk of aspiration and subsequent airway compromise rather than exsanguination. In the event of major hemorrhage, care is taken to place the patient's head in the dependent position to prevent aspiration. External pressure is held near the greater cornu of the hyoid bone. The patient is then intubated, and the oropharynx is packed with a gauze roll. The patient is then brought

to the operating room immediately to explore the wound and control the bleeding. If transoral intubation is unsuccessful, a cricothyrotomy should be performed.

2. Inadvertent injury to the teeth can occur from retractor manipulation during surgery. Care is taken to place a tooth guard to protect the maxillary dentition prior to transoral exposure. If teeth are loosened during the procedure, they are removed to prevent aspiration. In the event of chipped or avulsed teeth, the patient is referred for dental care.

Alternative Management Plan

1. Primary chemoradiation

2. Open surgical approaches such as lip-split mandibulotomy or transhyoid pharyngotomy

Discussion

Evidence-Based Medicine Question

Do oncologic outcomes differ between traditional open approaches versus TORS?

In 2014 Ford et al. performed a retrospective review of 130 cases comparing TORS with open surgical approaches. Cases were matched with respect to TNM staging and adjuvant therapy. No difference in Human papillomavirus status was seen between the two groups. The authors demonstrated a statistically significant improvement in recurrence-free survival (RFS) favoring TORS (89% RFS vs. 73% at 3 years).[7]

Editorial Comment

Until the advent of TORS in 2004, surgery of the base of the tongue required either complex open approaches that had associated significant morbidity or transoral laser microsurgery that has its own set of challenges. Although these approaches were used by some, the majority

of cancers of the base of the tongue were treated with combined chemotherapy and radiation. The application of robotic surgery and TORS has changed this paradigm dramatically. Current estimates place transoral surgery, and in particular TORS, as the most common approach to T1 and T2 cancers of the base of the tongue. In addition to making this a more feasible and widely used technique, there is growing support in the literature for both the quality of life and cost benefit of including TORS in the treatment paradigm for cancer of the base of the tongue.

Another major benefit of using robotic technology and the development of defined TORS procedural steps has been in the realm of teaching. The use of dual or teaching robot consoles allows experienced surgeons to train residents and fellows the defined steps of TORS procedure in a safe and effective manner. Overall, TORS and its national and now global acceptance and application have changed the way head and neck surgeons treat cancer of the base of the tongue.

Bert O'Malley, Jr.

- Access the review questions online at http://www.expertconsult.com

Review Questions

1. In the event of major postoperative hemorrhage, all of the following should be performed, except

   a. Immediate transoral intubation or cricothyrotomy

   b. Packing the oropharynx once an airway is established

   c. Placing external pressure over the neck

   d. **Placing the patient supine**

2. Tumor contraindications to transoral robotic surgery (TORS) tongue base resection include

   a. Major invasion of the genioglossus muscle

   b. Tumor encasement of the internal carotid artery

   c. Deep involvement of more than half of the tongue base

   d. **All of the above**

3. Intraoperative robotic collisions can be minimized with

a. Elevating the camera arm to its maximum height

b. Placing the instruments arms in a "V" configuration

c. Positioning the pivot point of the camera arm at the level of the oral commissure

d. **All of the above**

Surgery of the Soft Palate

Jeffrey Hotaling, and David M. Cognetti

Introduction

The soft palate is a subsite of the oropharynx. Its axial plane defines the superior boundary of the oropharynx, incompletely separating it from the nasopharynx above. The soft palate comprises approximately one-third of the palate, with the more anteriorly positioned hard palate making up the remainder; the junction between the hard and soft palates also separates the oral cavity from the more posteriorly located oropharynx. In contrast to the hard palate, the soft palate is a mobile structure that is suspended from the posterior aspect of the hard palate via the palatine aponeurosis. This aponeurosis is formed by the expanded tendon of the tensor veli palatini. The thicker, anterior portion of this tendon constitutes the majority of the anterior soft palate, whereas the posterior aspect of the soft palate is mainly comprised of muscle (levator veli palatine, tensor veli palatini, palatoglossus, palatopharyngeus). At its most posteroinferior extent, the free margin of the soft palate contains a conical muscular projection, the uvula. Functionally, the soft palate is a dynamic structure that is critical for velopharyngeal competence. Elevation of the soft palate puts it into contact with the posterior pharyngeal wall, sealing it off from the nasopharynx (e.g., when swallowing), and its depression puts it in contact with the tongue base, sealing the oral cavity from the nasal passage (e.g., when breathing exclusively through the nose). In this way, function of the soft palate is critical to velopharyngeal competence.[1]

Neoplasms of the soft palate may arise from any of the individual, constituent parts of the soft palate (muscle, lymphatics, mucosa, connective tissue), encompassing a broad variety of benign and malignant tumors (Table 37.1). Importantly, benign tumors of the soft palate are extremely rare, and any soft palate lesion should be considered

malignant until proven otherwise. Squamous cell carcinoma is the most common neoplasm of the soft palate, and the oropharynx in general, accounting for more than 90% of all malignant tumors in the oropharynx (Fig. 37.1). Etiologic factors contributing to squamous cell carcinoma are alcohol and tobacco.[2] Although the human papillomavirus (HPV) has more recently been established as an etiologic and positive prognostic factor for oropharyngeal squamous cell carcinoma, a recent review has suggested that significantly less soft palate squamous cell carcinomas are HPV positive than other subsites (22% vs. 70%).[3]

A tumor of salivary gland origin represents the next most commonly encountered tumor of the soft palate, originating in the many minor salivary glands distributed throughout the soft palate. Although the most common benign salivary gland tumor of the soft palate is pleomorphic adenoma, it is estimated that nearly 50% of minor salivary gland tumors in the oropharynx are malignant. The most common of these malignancies are adenoid cystic carcinoma and mucoepidermoid carcinoma.[4] In contrast to the mucosal disruption caused by typical squamous cell carcinomas, minor salivary gland tumors are frequently submucosal.

Lymphatic drainage of the soft palate is primarily to the superior jugulodigastric chain (level II) with subsequent drainage inferiorly to levels III and IV.[5] Importantly the retropharyngeal lymph nodes also receive significant drainage from the soft palate, with one study demonstrating retropharyngeal node involvement of carcinoma in 56% of cancers of the soft palate.[6] Cancers of the soft palate also have a high incidence of metastases to the cervical lymph nodes, with one study demonstrating that 48% of patients with cancer of the soft palate present with metastases to the neck and another 40% who initially presented with an N0 neck who eventually went on to develop cervical lymph node metastases.[7] Because of this, all patients with clinically negative necks still require treatment with either an elective neck dissection or radiation, with bilateral neck dissection required for lesions involving or approaching the midline.

Key Operative Learning Points

1. The soft palate is a dynamic structure whose function is critical for

velopharyngeal competence.

2. There is a high incidence of cervical lymph node metastasis associated with cancer of the soft palate (particularly with squamous cell carcinoma). Treatment of both necks is recommended for squamous cell cancers involving or approaching the midline.

3. Reconstruction of the soft palate is complex, and reconstitution of a functional velopharyngeal sphincter is key.

Preoperative Period

History

1. History of present illness

   a. Symptoms range widely from asymptomatic to odynophagia, dysphagia, otalgia, airway compromise, oral bleeding, weight loss, changes in speech, and a mass in the neck.

   b. Early lesions are often found incidentally due to dental examinations, ill-fitting dentures, and office physical examinations but also may present at more advanced stages.

   c. Patients may have hearing loss due to middle ear effusion secondary to Eustachian tube dysfunction.

2. Past medical history

   a. Prior history of malignancies and treatment

   b. Anticoagulant medications

3. Social history

   a. Tobacco use history (all types)

   b. Alcohol use history

Physical Examination

1. All patients should undergo a comprehensive examination of the head and neck.

a. Thorough inspection and palpation of the oral cavity and oropharynx

b. Neck: assessment for cervical lymph node metastases

c. Laryngoscopy/pharyngoscopy: assessment posterior/inferior extent of lesion, evaluation of larynx/hypopharynx, evaluation for second primary malignancy, evaluation of airway patency

d. Cranial nerve examination: evaluation of palatal elevation (CN X)

2. The primary tumor should be evaluated with respect to location and extension into surrounding structures.

TABLE 37.1

Common Tumors of the Soft Palate

Benign	Malignant
Fibroma	Adenocarcinoma
Hemangioma	Adenoid cystic carcinoma
Lipoma	Lymphoma
Papilloma	Mucoepidermoid carcinoma
Pleomorphic adenoma	Mucosal melanoma
Schwannoma	Squamous cell carcinoma

FIG. 37.1 Advanced-stage squamous cell carcinoma of the soft palate.

a. Size of the lesion, local extent (e.g., involvement of adjacent subsites), firmness to palpation, mobility, endophytic versus

exophytic, oral airway obstruction

b. A neoplasm isolated to the posterior/nasopharyngeal surface of the soft palate is exceedingly rare.

c. Mouth opening should be evaluated because trismus and oral airway obstruction by tumor may preclude a transoral resection or intubation.

Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are frequently used for delineation of local extent of tumor (T-stage) and evaluation for cervical metastases; (Fluorodoxyglucose-Positon Emission Tomography/Computerized Tomography FDG PET/C) is used to evaluate for distant metastases.

1. CT with contrast: primary imaging modality for head and neck cancer; gives excellent delineation of involvement of adjacent bony structures (palate, mandible)

2. MRI with contrast: enhanced soft tissue resolution allowing better delineation of depth of invasion and evaluation of perineural invasion. Although MRI has a greater potential for motion artifact, dental artifact is usually significantly less than with CT.[8]

3. FDG PET/CT: improved sensitivity over CT or MRI alone in detecting metastases greater than 5 mm. The negative predictive value of PET/CT is nearly 100% for second primary tumors and metastatic disease.[9]

Indications

1. Early-stage (T1-T2) squamous cell carcinoma with minimal involvement of soft palate musculature

2. Advanced (T3-T4) cancer of salivary gland origin

3. Salvage surgery for persistent/recurrent cancers (salvage is typically successful in only ⅓ of patients)[10]

Contraindications

1. Advanced (T3-T4) lesions requiring resection of a significant portion of the soft palate musculature (exception: patients who are not candidates for or who have already received definitive radiation)

2. Patients with distant metastases or large/unresectable cervical lymph node metastases

3. Proximity to large vessels to or involvement of primary tumor (i.e., medialized course of carotid artery or tumor adjacent to carotid artery)

4. Patients with significant trismus or oral contractures limiting access for a transoral resection (transcervical resection may still be possible)

5. Patients medically unfit to undergo general anesthesia (rare)

Preoperative Preparation

1. Biopsy of the lesion should be performed for adequate diagnosis prior to any definitive resection.

2. Evaluation for metastasis should be completed preoperatively.

3. Discussion of surgery with a complete explanation of risks/benefits/alternatives

   a. Risks: bleeding, infection, need for additional surgery and/or adjunctive treatments, velopharyngeal incompetence

   b. Benefits: tumor excision, pathologic staging, possibility of avoiding radiation therapy and/or chemotherapy in some cases

   c. Alternatives: Radiation ± chemotherapy depending on tumor stage. Not effective in tumors of salivary gland origin.

4. Patients should be aware of the possibility and expected duration of a tracheostomy and/or placement of a feeding tube.

5. Patient should be seen in consultation with a Maxillofacial Prosthodontist with possible fabrication of a prosthesis.

Operative Period

Anesthesia

General anesthesia is typically required for patient comfort and airway protection.

Positioning

Supine with shoulder roll placement reserved for concurrent neck dissection or the rare transcervical approach

Perioperative Antibiotic Prophylaxis

Clean-contaminated surgery with recommendation for ampicillin/sulbactam or clindamycin, cefazolin which should be given prior to skin incision and then continued for no more than 24 hours[11]

Monitoring

Although muscle relaxant (i.e., paralysis) is often required for transoral resections, some surgeons prefer the patient nonparalyzed during concurrent neck dissection or the rare transcervical approach to enable nerve assessment.

Instruments and Equipment to Have Available

1. Mouth retractor: Crowe-Davis, McIvor, Dingman, and Feyh-Kastenbauer can all be used depending on patient factors (mouth opening, dentition, tumor location) and surgeon's preference.

2. Standard head and neck and oral surgery set

3. Cautery: Bovie electrocautery may be used for excision with suction cautery, and/or bipolar cautery is often required for hemostasis.

4. Adjunctive equipment:

   a. Robotic platform (da Vinci System) for transoral robotic surgery (TORS)

   b. CO_2laser (±microscope) for transoral laser microsurgery (TLM)

Key Anatomic Landmarks

1. Tonsillar pillars: Formed by the paired palatoglossus (anterior) and palatopharyngeus (posterior) muscles, these muscles form lateral connections of the soft palate to the tongue base and pharynx, respectively. These also serve as routes of extension of tumor onto the pharyngeal wall, tonsil, and base of tongue, which is important in surgical planning.

2. Hard/soft palate junction: defines the anterior boundary of the oropharynx and serves as the attachment point for the palatine aponeurosis, into which all four paired muscles of the soft palate insert (palatoglossus, palatopharyngeus laterally; levator veli palatini and tensor veli palatini centrally)

3. Lesser palatine artery: paired arteries arising from the lesser palatine foramina in the posterior hard palate that supply the soft palate

4. Uvula: conical, muscular projection from the free margin of the posteroinferior extent of the midline soft palate

Prerequisite Skills

If undertaking TLM or TORS, the surgeon must be experienced with these modalities.

Operative Risks

1. Bleeding

2. Infection

3. Dysphagia

4. Velopharyngeal incompetence

5. Need for additional procedures or treatment modalities

Surgical Technique

1. Ablation: Transoral resection is the rule for most isolated cancers of the

soft palate. Extended, transcervical approaches to the oropharynx (i.e., cheek flap, mandibulotomy with lip split) are rarely required for isolated cancer of the soft palate but may be necessary for larger/composite resections or in patients with severe trismus limiting transoral exposure. It is critical to have a three-dimensional (3D) understanding of the tumor, and larger tumors require margins to be achieved in both the oropharynx and the nasopharynx. Ideally, the posterior nasopharyngeal margins are directly visualized. Resection of the cancer should be performed with at least 1-cm margins of normal tissue with margins verified by frozen section. The incisions in the oropharyngeal mucosa are made first with any deeper, muscular or nasopharyngeal mucosal resection dictated by the extent of the tumor. Larger cancers will often require a through-and-through defect, whereas in more superficial lesions, the posterior soft palate can be preserved. Given the high prevalence of regional metastasis, all patients with squamous cell carcinoma should undergo unilateral neck dissection (levels II to IV), with bilateral neck dissection performed for patients with larger cancers in or approaching the midline. The transoral resection may be performed with multiple modalities according to patient factors and surgeon's preference:

FIG. 37.2 Well-healed pharyngeal flap reconstruction of the soft palate defect.

a. Transoral electrocautery: traditional method using handheld electrocautery; access and visualization may be limited by short working distance of the instruments

b. TLM: improved visualization enabled by the use of a microscope and longer working distance of the laser. This modality has been shown to be effective in both primary and salvage resections.[12]

c. TORS: affords 3D visualization with 10-fold magnification and an operation using two fully articulated instruments; outcomes are reliant on surgeon experience, but the modality has been proven effective with high local control and low morbidity[13,14]

d. Transcervical/transmandibular approaches: rarely used for isolated defects of the soft palate; may be required for larger, composite defects of the oropharynx or in salvage situations in patients with significant trismus

2. Reconstruction: Functional reconstruction of the soft palate is complex, owing to its important role in speech and swallowing. The best results are obtained with small defects wherein the musculature of the soft palate is minimally resected and can be reapproximated. If the defect extends beyond the midline of the soft palate, reconstruction typically involves reducing the cross-sectional area of the velopharynx.[15]

a. *Primary closure:* best for smaller, superficial defects (commonly submucosal cancer of minor salivary gland origin). Accomplished by approximating oropharyngeal mucosa to posterior/nasopharyngeal mucosa on either side of the defect (similar to a uvulopalatopharyngoplasty). Healing by secondary intention is also possible for small defects but may result in wound contraction and velopharyngeal insufficiency (VPI).

b. *Obturation:* best suited to smaller defects of the central palate. Adequate remaining dentition is necessary to anchor the prosthesis. It is also an option for patients who are not candidates for large reconstructive efforts. The prosthesis allows nasal breathing at rest but contacts the posterior pharyngeal wall to enable velopharyngeal closure during swallowing. Studies have shown equivalent speech outcomes between obturation and free flap reconstruction for extensive soft palate defects.[16,17]

c. *Local flaps:* The uvulopalatal flap, pharyngeal flap (Fig. 37.2), palatal island flap, and the superior constrictor flap have all been described and are best for defects of less than 50% of the lateral palate.

FIG. 37.3 Well-healed radial forearm reconstruction of the soft palate defect.

d. *Regional flaps:* Although the pectoralis major flap remains the most frequently used pedicled flap for large/composite oropharyngeal defects, the temporalis muscle flap is another option for larger, isolated defects of the soft palate.[18]

e. *Microvascular free flaps:* Often necessary for defects encompassing greater than 50% of the soft palate and composite defects of the oropharynx, both the radial forearm free flap (Fig. 37.3) and anterolateral thigh free flap have been successfully used.[19] These are often combined with a muscular velopharyngoplasty, which entails suturing the cut edges of the soft palate and posterior pharyngeal wall musculature together to reconstitute a functional velopharyngeal sphincter.[17]

Common Errors in Technique

1. Inadequate transoral exposure with resulting poor surgical outcome

2. Inability to appreciate 3D nature of the cancer/soft palate with resulting positive margins (Fig. 37.4)

3. Failure to ensure hemostasis along the posterior/nasopharyngeal edge of the soft palate, leading to postoperative hemorrhage

Postoperative Period

Postoperative Management

1. Intensive care unit (ICU)/stepdown with continuous pulse oximetry recommended following larger resections requiring reconstruction given the potential for edema of the airway

2. Larger resections may require feeding tube given high potential for dysphagia and pain limiting oral intake; percutaneous endoscopic gastrostomy PEG tube placement should be considered for patients undergoing more extensive resections in which long-term dysphagia and adjuvant therapy are anticipated.

3. Pain medication is often necessary for 7 to 14 days postoperatively.

4. Prosthetic rehabilitation (obturation) may enable improved velopharyngeal closure, and placement of an obturator at the time of resection may enable early oral feeding.

Complications

1. Bleeding: Any significant postoperative bleeding requires a return to the operating room to achieve complete hemostasis.

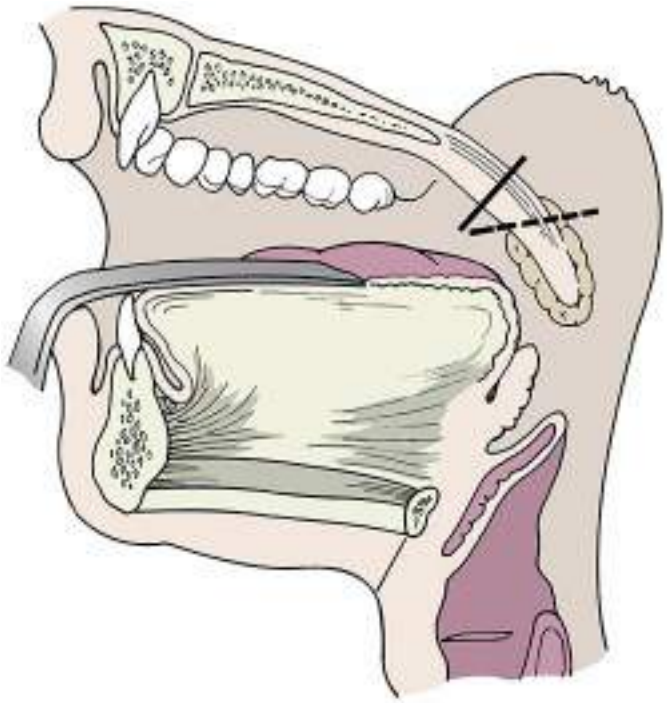

FIG. 37.4 In resecting tumors involving the soft palate, the surgeon must be careful to achieve clear surgical

margins in both the oropharynx and the nasopharynx.

2. Airway obstruction/compromise: typically due to postoperative edema or bulky flap reconstruction; prophylactic tracheostomy for patients requiring flap reconstruction

3. Velopharyngeal incompetence: often improves with time after small/moderate resections, but may require obturation or secondary procedure (pharyngeal flaps) if severe or persistent

Alternative Management Plan

1. Radiation versus chemoradiation depending on the stage with possible surgical salvage

2. Palliation

Discussion

Evidence-Based Medicine Question

What is the evidence for primary transoral surgical resection of early-stage squamous cell carcinoma of the soft palate (Fig. 37.5)?

Early-stage oropharyngeal cancers can be treated with either surgery or radiation therapy. A large review by Iyer et al. from Memorial Sloan Kettering in 2011 demonstrated no difference in outcomes in treatment of early-stage (T1-T2) soft palate squamous cell carcinoma with surgical or nonsurgical modalities.[20] Recently, there has been an increased interest in primary surgical management in patients with cancer of the oropharynx. The reason for this lies mainly in the advent of new transoral resection technique, including TORS and TLM, which are less morbid and may allow improved functional results when compared with previous open surgical resection.

Another argument in favor of primary surgical management for early-stage cancer of the soft palate lies in the ability to more accurately stage tumors, thereby more appropriately selecting adjuvant radiation or chemoradiation. A recent article by Smith et al. evaluated adjuvant therapy in patients with oropharyngeal squamous cell carcinoma

undergoing TORS and neck dissection. This study found that in 43% of the patients, TORS and neck dissection resulted in a change in the patient's stage, with 50% of these stage changes resulting in alterations in the treatment plan.[13] This improved staging enabled by primary surgery may enable deintensification or even elimination of adjuvant therapy in patients with early-stage soft palate lesions with limited neck metastasis.

FIG. 37.5 Early-stage squamous cell carcinoma of the soft palate.

Lastly, there has traditionally been concern that patients with soft palate resection suffered from suboptimal reconstruction resulting in poor functional outcomes with respect to speech and swallowing. However, recent studies have demonstrated that the size of the defect is the most important determinant of postoperative function. In fact, a recent study by Lv et al. studied at postoperative speech and swallowing function in 45 consecutive patients undergoing soft palate resections with immediate flap reconstruction. They obtained normal to near-normal function in patients with defects consisting of less than 50% of the soft palate, regardless of the particular type of flap used for reconstruction.[15] As most early-stage lesions of the soft palate require less than 50% resection of the soft palate, it follows that resection of these lesions does not result in poor postoperative function.

Surgical resection of early-stage lesions of the soft palate has results at least on par with nonsurgical treatment, enables more accurate staging and the possibility of deintensification or avoidance of adjuvant therapy

with its attendant side effects, and does not preclude good postoperative speech and swallowing function given our current reconstructive armamentarium.

Editorial Comment

Although radiation is a very acceptable primary therapy for T1 and T2 cancers[20] there is a movement toward primary surgery given the popularization of TORS and TLM over the past 5 years. This is occurring for multiple reasons, one of which is that the use of advanced imaging technology coupled with less invasive surgical techniques and improved local reconstruction has allowed head and neck surgeons to perform transoral palatal surgery with low morbidity. In addition, the authors make a very important point about the advantages of having both primary cancer and lymph node pathology results to guide the decision making and targeting of adjuvant therapy. Smith et al.[13] demonstrated that almost half of all patients treated with TORS and neck dissection had a change in staging after the postsurgical pathology results were known. Of these 50% of patients with revised staging, half received subsequent alterations in their overall treatment plan. The authors state that the ability to have surgical pathology and thus truly accurate staging may enable deintensification or even elimination of adjuvant therapy in patients with early-stage cancer of the soft palate with limited metastasis in the neck. This is a very important concept and one that is aligned with the broader interest and evolution of personalized medicine and therapy.

Review Questions

1. Velopharyngeal competence can be defined as:

   a. **Dynamic separation of the oropharynx from the nasopharynx**

   b. Patent nasal airway

   c. A lack of communication between the nasal cavity and the oropharynx

d. A patent oropharynx

2. The most common minor salivary gland malignancy of the soft palate is:

   a. Polymorphous low-grade adenocarcinoma

   b. Mucoepidermoid carcinoma

   c. **Adenoid cystic carcinoma**

   d. Acinic cell carcinoma

3. True or false: Most soft palate tumors are benign.

   a. True

   b. **False**

4. Indications for treatment of the neck in patients with cancers of the soft palate are based primarily on:

   a. Lesion T-stage

   b. Clinical or radiographic evidence of neck disease

   c. **Tumor type (pathology)**

   d. Lesion location

Transoral Removal of Elongated Styloid Process

Carl H. Snyderman

Introduction

The association of an elongated styloid process with pharyngeal and cervical pain is known as Eagle syndrome and was first described in 1937.[1] Eagle syndrome is characterized as a dull, aching pain localized to one or both sides of the throat with referred otalgia.[2] Some pain may occur on swallowing or protrusion of the tongue or on rotating the head, and some patients complain of a foreign body sensation in their throat.

The etiology of styloid elongation and ossification of the stylohyoid ligament complex is unclear.[2] Elongation of the styloid process occurs in approximately 4% of the population, but only a small percentage of patients with this finding are symptomatic (<10%). Eagle syndrome occurs more frequently in women than in men and is usually found in patients older than 30 years. Symptoms are often unilateral despite bilateral elongation.

The pathophysiology of Eagle syndrome is generally thought to be secondary to compression by the abnormal styloid of vascular and nervous structures, in particular the glossopharyngeal nerve and carotid artery.[2] "Classic Eagle syndrome" is associated with tonsillectomy or pharyngeal trauma. "Stylocarotid syndrome" is characterized by compression of the carotid artery by an elongated styloid process that deviates medially.

The differential diagnosis of this condition includes cranial nerve neuralgias (e.g., trigeminal, glossopharyngeal, sphenopalatine, superior laryngeal, and primary geniculate neuralgias), temporomandibular joint disease, chronic pharyngotonsillitis, unerupted or impacted molar teeth,

cervical osteoarthritis, and tumors in the oropharynx.

Key Operative Learning Points

- The diagnosis of Eagle syndrome is a diagnosis of exclusion.
- A transoral approach is preferred if the styloid process is palpable intraorally.
- A transcervical approach is preferred if there is complete calcification of the stylohyoid ligament.
- Intraoral visualization can be enhanced with endoscopy (nasal endoscope).
- Injury to the carotid artery and facial nerve can be avoided by maintaining the plane of dissection on the styloid process.
- A bone rongeur is used to resect the styloid process close to its origin at the skull base.

Preoperative Period

History

- Unilateral (or bilateral) pain in the throat or neck
- Dull, nagging pain that may be exacerbated by swallowing or turning the head
- Lack of other symptoms associated with cranial nerve deficits

Physical Examination

- Inspection of the oral cavity and pharynx (including nasopharynx and hypopharynx) is normal with no mucosal lesions.
- Palpation of the tonsillar fossa reveals a hard thin mass in the area of the tonsillar fossa and reproduces the patient's symptoms.
- Cranial nerve function is intact.

- Infiltration of lidocaine in the region of the tonsillar fossa may abolish the symptoms.

Imaging

- Plain film radiograph. Individual styloid processes can be difficult to view due to superimposition of the surrounding structures.
- Panorex. Both styloid processes can be seen in detail.
- Computed tomography (CT) scan. CT provides excellent visualization of bony detail. If performed with contrast, CT also screens for other pathology in the differential diagnosis. A CT angiogram demonstrates the relationship of the carotid artery to the styloid process.
- Three-dimensional (3D) reconstruction of CT scan (Fig. 38.1). Superb visualization of the styloid processes and calcified stylohyoid ligaments and their relationship to other structures is provided by a 3D reconstruction. This study is helpful in planning the surgical approach.

Indications

- Unilateral or bilateral throat or neck pain that does not respond to conservative measures (analgesics)
- Palpable styloid process with reproduction of symptoms
- Infiltration of lidocaine abolishes symptoms
- Absence of other pathology
- Radiographic evidence of enlarged or angulated styloid process

Contraindications

- Limited opening of the mouth
- Complete calcification of the stylohyoid ligament

Preoperative Preparation

- Preoperative imaging with CT scan
- Discussion with the patient that removal of the elongated styloid process does not always abolish the pain. There are other causes of these symptoms.

Operative Period

Anesthesia

- General anesthesia with muscle relaxants.
- Oral RAE tube to prevent kinking; positioned in the midline to accommodate retractors.

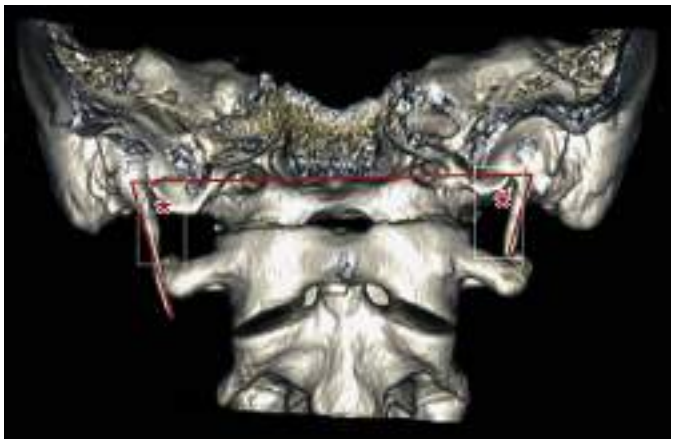

FIG. 38.1 Three-dimensional computed tomography of patient with Eagle syndrome demonstrates elongated styloid processes (right greater than left). Medial angulation *(asterisks)* may also be associated with Eagle syndrome. Reprinted with permission from: Kent DT, Rath TJ, Snyderman CH. Conventional and 3-dimensional computerized tomography in Eagle's syndrome, glossopharyngeal neuralgia, and asymptomatic controls. Otolaryngol Head Neck Surg 2015;153(1):41–47.

- Nasotracheal intubation through the contralateral nasal cavity is an excellent alternative to keep the tube out of the surgical field.

Positioning

- Supine with head and neck extended (Rose position)
- Reverse Trendelenburg position (15 degrees) to decrease bleeding

Perioperative Antibiotic Prophylaxis

- Penicillin
- If the patient is allergic to penicillins, use clindamycin.

Monitoring

- Facial nerve monitoring is optional.
- Navigation system. Image-based navigation (CT angiogram) can be helpful to localize the styloid process and the adjacent internal carotid artery.

Instruments and Equipment to Have Available

- McIvor or Dingman mouth retractor
- Zero-degree Hopkins rod endoscope (optional)
- Extended needle tip electrocautery
- Bipolar electrocautery
- Yankauer tonsil suction
- Cottle elevator
- Hurd or malleable retractors
- Kerrison bone rongeur (2 to 3 mm)
- "Needle-nose" bone rongeur (straight fine-tip rongeur)

Key Anatomic Landmarks

- The styloid process is anterior to the stylomastoid foramen.
- The stylopharyngeus, stylohyoid, and styloglossus muscles all take their origin from the styloid process of the temporal bone.
- The facial nerve is posterior and lateral to the styloid process.
- The internal carotid artery is medial to the styloid process.
- An elongated styloid process is palpable in the tonsillar fossa and posterior floor of mouth.

Prerequisite Skills

- Tonsillectomy (see Chapter 192).

Operative Risks

- Injury to the facial nerve. Excessive use of electrocautery or aggressive resection of the styloid process to its attachment at the skull base risks injury to the facial nerve.
- Injury to the carotid artery. Dissection of the soft tissues medial to the styloid process risks injury to the internal carotid artery.

Surgical Technique

- The mouth retractor is placed with the tongue and the endotracheal tube in the midline. The tongue can be placed slightly to the contralateral side to provide greater access to the posterior floor of mouth.
- If tonsils are present, a tonsillectomy is performed on the surgical side.
- The tonsillar fossa is palpated to identify the elongated styloid process. The surrounding tissues are infiltrated with several milliliters of 0.5% xylocaine with 1:200,000 epinephrine.
- Using the suction tip or Hurd retractors, the soft tissues are pushed laterally and posteriorly to tent the tissues over the styloid process (Fig. 38.2). The constrictor muscle is then incised with electrocautery

down to the styloid process.

- A 0-degree Hopkins rod endoscope may be used to enhance visualization, especially when an assistant is retracting.
- After the styloid process is identified (Fig. 38.3), the tendinous attachments are also incised and the styloid process is skeletonized with a sharp Cottle elevator or a ring curette. It is important to maintain a subperiosteal plane of dissection on the styloid process to avoid injury to the internal carotid artery and facial nerve.
- A Kerrison rongeur is then inserted and the styloid process is removed as far superior as possible (Fig. 38.4).
- The wound should be palpated to make sure that most of the styloid has been removed and that a sharp point does not remain.
- Hemostasis is obtained with bipolar electrocautery and the wound is irrigated.
- A single-layer closure is performed with a chromic suture. No drains are required.

Common Errors in Technique

- Inadequate exposure. This may result from a limited incision, incision in the wrong location, or inadequate retraction of soft tissues.
- Fracture of styloid. If the styloid is fractured before it is completely exposed, it is difficult to dissect the periosteum. If that happens, grasp it with a clamp while dissecting.
- Incomplete excision of styloid. The Kerrison rongeur can be used to remove additional bone without injury to surrounding tissues.

Postoperative Period

Postoperative Management

- Perioperative intravenous antibiotics are administered for 1 to 2 doses. Oral antibiotics are not necessary.

- The patient is observed for several hours for edema and may be discharged the same day if able to take oral fluids.

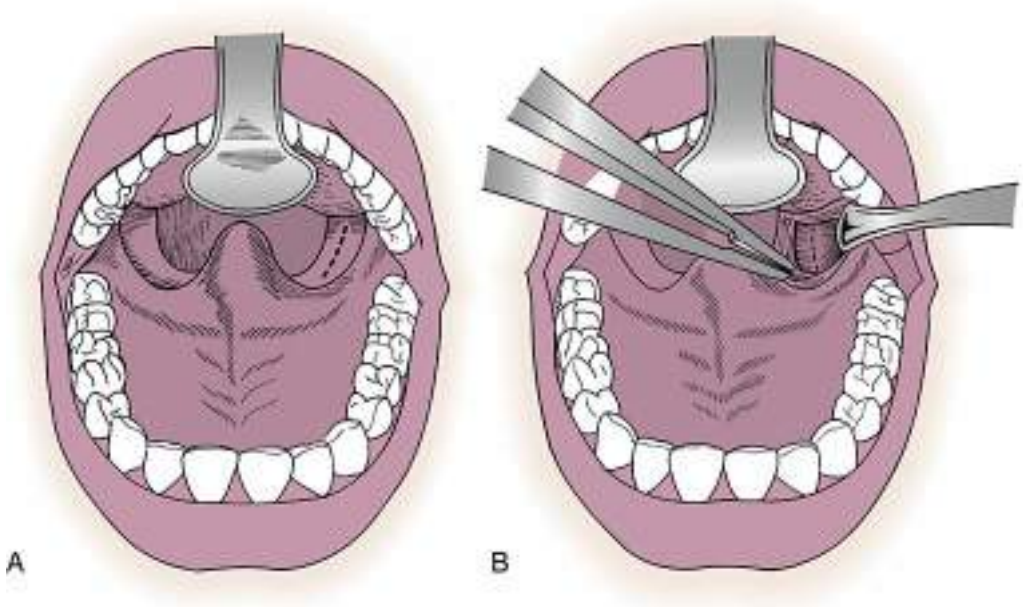

FIG. 38.2 **A** and **B**, Hurd retractors tenting the constrictor muscles over the styloid process and the incision carried down onto the styloid process under direct vision.

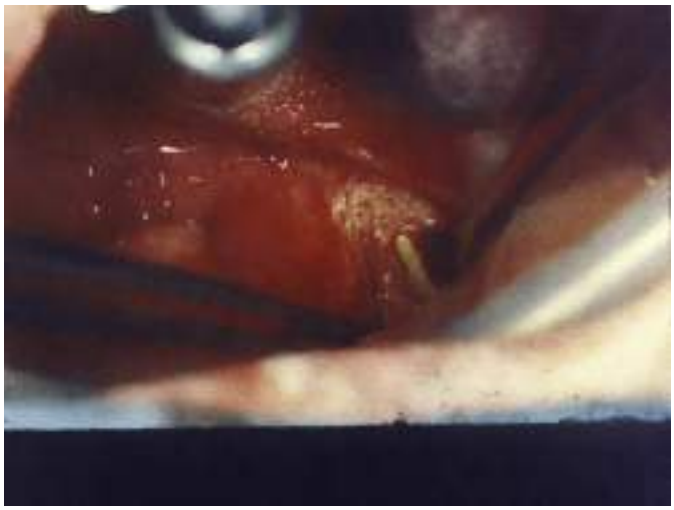

FIG. 38.3 The styloid process is exposed.

- Mild analgesics are prescribed.

- Chlorhexidine solution may be prescribed to rinse the oral cavity.
- The diet may be advanced as tolerated.
- Although most patients experience immediate improvement in symptoms, some pain from the surgery is to be expected.
- Observe for postoperative hematoma or infection.

Complications

- Beware of the possibility of an incorrect diagnosis. There are many cranial nerves in this area, each of which may have its own neuralgia with or without an elongated styloid process.
- Bleeding from the operative site may be encountered. Every effort should be made to prevent bleeding by the use of bipolar cautery.
- Injury to the carotid artery, which lies medial to the styloid process, is a potential complication. The surgeon's detailed knowledge of the anatomical structures in relation to the styloid process, including the ICA, will alert the surgeon to limit the dissection to the elongated styloid process, which can be helped by retraction of the soft tissues accurately displaying the styloid process.

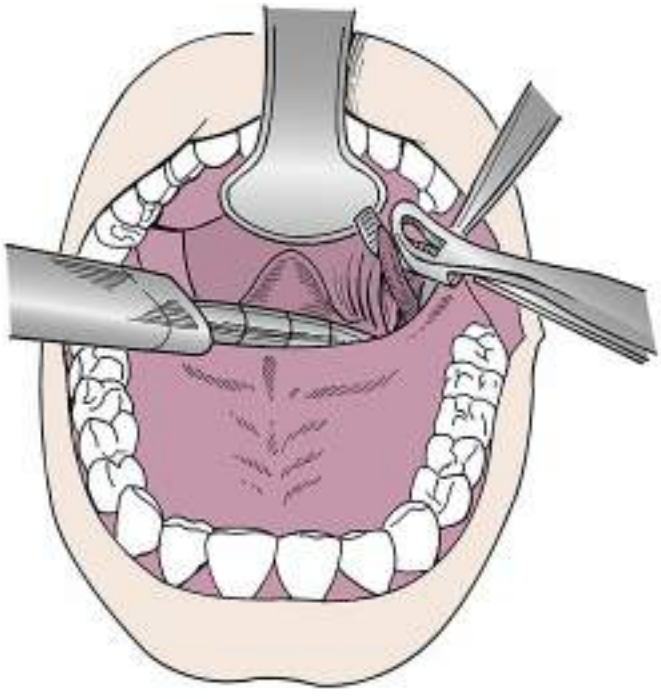

FIG. 38.4 The styloid process removed piecemeal with rongeurs.

- Injury to the glossopharyngeal nerve is possible.
- Incomplete removal of the styloid process may result in the patient's symptoms not being relieved.

Alternative Management Plan

- In patients with atypical presentation, the confirmation of Eagle syndrome is difficult. Medical management with analgesics, antidepressants, or anticonvulsants (gabapentin) may be considered first. Patients with long-standing pain are less likely to have complete resolution of symptoms with surgery.
- A transcervical approach may be used instead of a transoral approach.[3,4]
- Manual fracture of the styloid process without resection is not recommended due to risk of vascular injury.

Discussion

Evidence-Based Medicine Question

What are radiographic correlates of Eagle syndrome?

Eagle's original work considered an elongated styloid to be greater than 3 cm. In asymptomatic individuals, there is a wide range in the length of the styloid process (1.5 to 6.0 cm), and only a small percentage of patients with an elongated styloid process become symptomatic (4% to 10%).

The angulation of the styloid process may also be important. Variable results have been reported with increased anterior and medial angulation in some patient groups compared with controls. Using 3D-CT to make measurements, Kent et al. were unable to demonstrate a difference in styloid angulation but discovered a shorter distance between the tip of the styloid and the tonsillar fossa in patients with Eagle syndrome (12.7 ±

8.2 mm vs. 24.8 ± 4.9 mm).[5] This supports the hypothesis that pain results from compression of the glossopharyngeal nerve. The absolute length or angulation of the styloid process may be less important than its proximity to surrounding soft tissue structures.

Editorial Comment

Although Eagle syndrome is an uncommon problem and a potentially challenging diagnosis, our surgical team has personally made this diagnosis in three patients during the past 5 years. I want to stress the importance of a thorough preoperative evaluation because of the rarity of this diagnosis. Careful counseling of the patient and the setting of realistic expectations is important because of the risk of failure to resolve symptoms after surgery. With respect to my surgical team's vast experience in transoral surgery, in each of the patients that were referred to us, a thorough preoperative evaluation in the manner outlined in this chapter was performed, followed by successful resolution of symptoms after completing the procedure as nicely outlined here. Although I do not believe it is a must, our team has used optical magnification in each of the cases. In our experience in this limited number of patients, we feel that this significantly enhances the surgical view in particular for the identification and then control of both small arteries and veins as the dissection is carried lateral to the tonsillar pillars and constrictor muscles into the parapharyngeal space. With respect to the optical enhancement, we have evaluated both loupes magnification with a headlight or transoral robotic surgery (TORS). Each of these provided good visualization, but we have a preference for TORS, although we may have bias in this regard.

Bert O'Malley, Jr.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Eagle syndrome is characterized by all of the following except:

   a. **Episodic, tic-like pain in the throat**

   b. Styloid process greater than 3 cm

c. Shorter distance between the styloid tip and tonsillar fossa

d. Palpable styloid process in the tonsillar fossa

2. All of the following are helpful in establishing a diagnosis of Eagle syndrome except:

a. Three-dimensional computed tomography (3D-CT) scan

b. Injection of anesthetic into the tonsillar fossa to relieve pain

c. Palpation of the tonsillar fossa

d. **Facial nerve electroneuronography**

3. Contraindications for a transoral approach for Eagle syndrome include all of the following except:

a. Trismus

b. Complete calcification of the stylohyoid ligament

c. **Prior tonsillectomy**

d. Symptoms consistent with glossopharyngeal neuralgia

4. Which of the following structures has the least risk of injury with a transoral approach:

a. Facial nerve

b. **Hypoglossal nerve**

c. Internal carotid artery

d. Glossopharyngeal nerve

Additional Sources

Todo T, Alexander M, Stokol C, et al. Eagle syndrome revisited: cerebrovascular complications. *Ann Vasc Surg*. 2012;26:729 e1–e5.

This article emphasizes that individuals with an elongated styloid process may present with cerebrovascular symptoms. Compression of the carotid artery by the styloid may cause ischemic symptoms and cervical manipulation risks injury to the vessel wall with intimal dissection.

Transcervical Pharyngotomy

Garret Choby, and Eugene N. Myers

Introduction

The transcervical approach to the oropharynx and hypopharynx provides excellent exposure for the removal of a variety of lesions. The lateral pharyngectomy approach was first described by Cheever in 1878 and was popularized later by Trotter in the UK and Orton in the United States, who added their own modifications. This technique has been used most frequently as an effective approach to early stage squamous cell cancer of the oropharynx and hypopharynx and for tumors of salivary gland origin of the base of the tongue. It has also been used for access to arteriovenous malformations, removal of a complex foreign body, treatment of severe pharyngeal stenosis, and excision of a lingual thyroid.

The suprahyoid pharyngotomy was first described by Vidal de Cassis in 1826, and modifications have been described by several surgeons down through the years. Fairbanks Barbosa, in 1974, included the description of this technique in his classic textbook. This technique is used in situations similar to the lateral pharyngotomy, including the management of benign and malignant tumors of the base of the tongue, hypopharynx, and posterior pharyngeal wall, and excision of lingual thyroid. This technique has been used in our department for many years in the management of T1/T2 squamous cell cancer. It has provided a safe and efficient approach to the oropharynx and provides an excellent cure rate, normal speech, good cosmesis, and swallowing without clinical evidence of aspiration.[1] Similar reports from Moore and Calcaterra[2] regarding the successful use of this technique in the management of T3 lesions of the base of the tongue and by Zeitels[3] for limited lesions of the base of the tongue mirror our own experience.

Both the transhyoid and lateral pharyngotomy techniques offer a means of creating a corridor to the oropharynx and hypopharynx, which provides excellent exposure for the excision of a variety of lesions. It appears that over the years the lateral pharyngotomy approach has been more popular based upon the notion that it provides better exposure. In our own experience, the suprahyoid technique provides excellent exposure through a more direct route with less work involved. When more exposure is necessary, the suprahyoid approach may be extended to include a lateral pharyngotomy.

In the past several decades there has been an evolutionary change in the management of cancers of the oropharynx, largely driven by medical and radiation oncologists. They were inspired by the results of a VA trial for advanced cancer of the larynx, published in the *New England Journal of Medicine* in 1993, which revealed that chemoradiation had a cure rate similar to surgery/radiation.[4] The most appealing aspect of this study was that those patients cured with chemoradiation retained their voice. This nonsurgical approach acquired a new audience in the form of a generally healthier, younger group of patients whose oropharyngeal cancer is caused by human papillomavirus (HPV). They were attracted to chemoradiation as a potential cure for their cancer that did not require external surgery with a tracheotomy, scarring and potential deformity, and decreased functionality. This, of course, resulted in a dramatically reduced market for the classical transcervical pharyngotomy.

More recently the introduction of robotic surgery using the daVinci surgical robot offers a very successful means of excising oropharyngeal cancer with acceptable swallowing results and involving lower doses of adjunctive radiation, if at all.[5] This management scheme also includes neck dissections, since the majority of these patients will have cervical lymph node metastasis. This is an attractive management plan since it provides the patient with a high rate of curability and a low rate of disability in comparison with chemoradiation, which leaves a substantial number of patients with dysphagia and a permanent gastrostomy.

There are many patients in the United States and other countries who have cancer of the oropharynx and do not have access to chemoradiation or robotic surgery. These patients will find that the use of the established surgical techniques of transcervical pharyngotomy will offer them an opportunity for cure without downgrading their form or function.

Key Operative Learning

1. The transcervical pharyngotomy approach remains a viable option for resection of selected tumors of the oropharynx and hypopharynx.

2. The selection of the surgical approach should be properly tailored to the size, extent, and location of the patient's tumor.

3. A thorough examination of the head and neck, along with evaluation and palpation of the tumor under anesthesia, is essential for proper patient selection.

4. Care must be taken to avoid injury to the hypoglossal nerves (suprahyoid pharyngotomy approach) and superior laryngeal nerve (lateral pharyngotomy approach) to limit postoperative morbidity.

5. Aspiration in the immediate postoperative period is predictable and may adversely affect outcomes in the patient with severe chronic obstructive pulmonary disease (COPD).

6. A pharyngocutaneous fistula that fails to close with conservative management may require a tissue flap for reconstruction.

Preoperative Period

History

1. History of present illness
    a. Primary symptoms
        1) Pain
        2) Dysphagia
        3) Odynophagia
            a) May suggest invasion of deeper planes of the oropharynx
        4) Otalgia
        5) Weight loss
        6) Hemoptysis

7) Mass in the neck

8) Trismus

9) Dysarthria (hot potato voice)

a) May suggest invasion of muscles of mastication or a bulky tumor

b. Duration of symptoms

c. Previous assessment

1) Biopsy

a) All outside pathology slides should be reviewed at your own institution, especially if human papillomavirus (HPV) testing has not been completed.

2) Imaging—All prior imaging studies should be reviewed at your own institution.

a) CT

b) MRI

c) PET/CT

2. Past medical history

a. Comorbidities

1) General medical history

a) Previous history of cancer of the head and neck

2) Cardiovascular disease

a) Patients requiring long-term anticoagulation due to cardiac or thromboembolic history may be at increased risk for bleeding in the postoperative period.

b) Preoperative evaluation by a cardiologist is warranted in select patients with a known cardiac history.

3) Pulmonary disease

a) Many patients with cancer of the head and neck have a significant smoking history and usually have concomitant COPD.

b) Temporary aspiration is a predictable postoperative occurrence. Patients who cannot tolerate this due to impaired pulmonary function may be considered for laryngotracheal separation or laryngectomy to prevent life-threatening aspiration.

b. Social history

1) Tobacco use

a) Most patients in the older age group have a significant history of heavy smoking. These patients may undergo withdrawal symptoms similar to delirium tremens.

2) Alcohol abuse

a) Alcohol withdrawal is associated with increased perioperative morbidity in patients undergoing surgery of the head and neck, including increased risk of delirium tremens, aspiration, ventilator dependence, and death.

b) If heavy alcohol use is admitted or suspected preoperatively, consideration should be given to preoperative admission to the hospital or detoxification center to allow detoxification to take place prior to surgery.

3) Information regarding sexual activities should be elicited as part of a thorough history in those patients with an HPV etiology, since this is thought to be a sexually transmitted disease.

c. Medications

1) Anticoagulants/Aspirin/NSAIDs

2) Supplements that can increase the risk of bleeding

Physical Examination

1. Examination of the head and neck

a. Direct and indirect visualization of the oral cavity to assess for trismus, examination of the base of the tongue, larynx, and pharynx is essential. It is also important to evaluate the lateral and posterior extent and bulk of the mass as well as involvement of adjacent

structures.

- Indirect mirror laryngoscopy
- Flexible or rigid fiberoptic pharyngolaryngoscopy

b. Direct laryngoscopy under anesthesia is the most important examination to evaluate tumor extent and infiltration.

c. Bimanual palpation of tumors at the base of the tongue is essential to most accurately assess the extent of the disease and differentiate the tumor from the lingual tonsils.

- Palpation also assists in determining the mobility of the tumor and invasion of underlying and adjacent tissues.

d. Pay special attention to palpation for cervical lymphadenopathy.

Imaging

1. CT scan

   a. CT scan of the head and neck helps delineate the extent of the primary lesion and is especially helpful in evaluating bony anatomy, such as invasion of the cortex of the mandible.

   b. Excellent in determining suspicious cervical lymphadenopathy

   c. May also be used to screen the chest for metastatic cancer

2. MRI

   a. MRI is able to better define the extent of soft tissue invasion of the cancer into the deep musculature of the tongue or prevertebral tissues.

   b. Drawbacks to MRI include increased cost, longer time of the examination, and potential patient intolerance due to claustrophobia.

   c. The inability of the pharynx to elevate during deglutition suggests invasion of the prevertebral fascia in patients with cancer of the posterior pharyngeal wall.

3. PET/CT

   a. Valuable study to evaluate the primary cancer and to evaluate for

the presence of metastatic cancer

4. Barium esophagram

   a. This study may be used in cases of cancer of the posterior pharyngeal wall in which invasion of the prevertebral fascia is suspected.

   b. Limited laryngeal elevation during the bariumm esophagram may suggest invasion of the prevertebral fascia

Indications

1. Suprahyoid pharyngotomy approach

   a. Early stage cancer of the base of the tongue (T1/T2)

      1) Ideally, these cancers should be limited to the base of the tongue, posterior to the circumvallate papillae.

      2) May be combined with the lateral pharyngotomy approach for cancers involving the lateral pharyngeal wall or tonsil

      3) Usually combined with neck dissection

   b. Excision of cancer of the posterior wall of the oropharynx or hypopharynx

   c. May be used without neck dissection for benign lesions or low-grade cancers of salivary gland origin

   d. Useful for excision of a lingual thyroid

2. Lateral pharyngotomy approach

   a. Benign and malignant tumors arising from the lateral and posterior walls of the oropharynx or hypopharynx, postcricoid area, or base of the tongue (with involvement of the tonsil or lateral wall of the oropharynx)

      1) Depending on the extent and location of tumor, many of these lesions may also be amenable to endoscopic approaches, pending the availability of technology and equipment.

Contraindications

1. Suprahyoid pharyngotomy approach

   a. Cancer of the vallecula that involves the lingual surface of the epiglottis

      1) Excision of the epiglottis may lead to considerable postoperative complications with delayed deglutition and chronic aspiration.

   b. Cancer of the base of the tongue that extensively involves the tonsil or lateral pharyngeal wall

   c. Cancer involving the tongue anterior to the circumvallate papillae

      1) Cancers with this anterior extent are difficult to close primarily, may compromise the anterior surgical margin, and result in disability in swallowing.

   d. Patients with decreased pulmonary function who would not tolerate aspiration in the immediate postoperative period

2. Lateral pharyngotomy approach

   a. Patients with cancer that involves more than one-third of the pharyngeal circumference

   b. Patients with cancer who would be better suited for suprahyoid or total laryngectomy due to comorbidities

   c. Patients with decreased pulmonary function who would not tolerate aspiration in the immediate postoperative period

Preoperative Preparation

1. Imaging studies and any studies from previous biopsies or surgical procedures done elsewhere should be obtained and reviewed during surgical planning.

2. Patients who have not had a biopsy should undergo a direct laryngoscopy, biopsy of the tumor, and esophagoscopy.

3. Surgery for those patients with nutritional depletion should be delayed to bring the patient into positive nitrogen balance.

4. Patients should be seen by medical consultants and cleared for surgery.

5. Patients should stop taking aspirin, nonsteroidal anti-inflammatories, other anticoagulants, and supplements at least 7 days preoperatively. If there is a history of bleeding with prior surgery or trauma, then a coagulation profile is obtained.

6. Preoperatively, patients are counseled regarding the procedure, risks, and complications. The informed consent should be detailed and include the following risks: infection, bleeding, need for prolonged tracheostomy, dysphagia, aspiration, wound breakdown, and salivary fistula.

Operative Period

Anesthesia

1. Transcervical pharyngotomy is always carried out under general anesthesia.

2. Tracheostomy is generally performed as the first step in the surgery to secure the airway and to keep the endotracheal tube out of the operative field.

   a. Close communication with the anesthesia team during this portion of the surgery is critical to ensure a smooth transition in airway management.

   b. The technique for open tracheostomy is described in Chapter 78.

3. Many surgeons prefer to avoid long-acting paralytic agents during the surgery, especially during dissection along cranial nerves. This need should be communicated to the anesthesia team prior to the outset of surgery.

Positioning

1. The patient is positioned supine on the operating table.

2. A shoulder roll is helpful in extending the neck during tracheostomy, pharyngotomy, and neck dissection.

3. Intermittent pneumatic compression devices should be applied to the lower legs to prevent formation of deep vein thromboses.

Perioperative Medications

1. Standard perioperative antibiotics should be administered intravenously prior to incision.

   a. Contamination of the neck by the upper aerodigestive tract is expected during the operation; therefore, we typically administer ampicillin-sulbactam or clindamycin if the patient is allergic to penicillin.

Monitoring

1. Standard hemodynamic monitoring is required by anesthesia during surgery.

2. A Foley catheter should be inserted to monitor fluid dynamics and a rectal thermometer inserted to track the patient's temperature.

3. Although no nerve monitoring devices are typically used, many surgeons prefer the ability to directly stimulate nerves during the surgery. Therefore, long-acting paralytic agents are to be avoided.

Instruments and Equipment to Have Available

1. Laryngoscopy and esophagoscopy sets

2. Standard tracheostomy set with cannulas

3. Standard neck dissection set

Key Anatomic Landmarks

1. Suprahyoid pharyngotomy:

- Hyoid bone
- Vallecula
- Epiglottis
- Hypoglossal nerves

- Lingual arteries

2. Lateral pharyngotomy:

- Thyroid cartilage
- Carotid sheath
- Pharyngeal constrictor muscles
- Superior laryngeal nerve
- Hypoglossal nerve

Prerequisite Skills

1. Experience with neck dissection
2. Experience with airway management
3. Familiarity with the anatomy of the larynx and pharynx

Operative Risks

1. Bleeding
2. Infection
3. Dysphagia
4. Aspiration
5. Formation of a salivary fistula
6. Need for long-term tracheostomy

Surgical Technique

Suprahyoid Pharyngotomy

- Suprahyoid technique
  - A tracheostomy is carried out under endotracheal anesthesia; the endotracheal tube is removed and placed in the tracheostoma.
  - The neck and face are prepped and draped, with the face and both

sides of the neck exposed.

- In cases of squamous cell cancer, an apron flap incorporating the tracheostomy incision is elevated and bilateral neck dissections are carried out.
- Damp sponges are applied to the raw surface of the cervical flap, which is fixed to the drapes.
- The hyoid bone is identified and grasped with a tenaculum and brought into the wound. The suprahyoid muscles are sharply separated from the entire extent of the hyoid bone using electrocautery. As the dissection around the greater cornu is begun, the cornu is stabilized with the finger loop end of a hemostat, with traction exerted medially. This maneuver protects the hypoglossal nerve from injury. Dissection is completed medially along the cornu until the body of the hyoid bone is reached. The same procedure is carried out on the contralateral side.
- The suprahyoid musculature is retracted superiorly, revealing the hypoepiglottic ligament, which is transected.
- The mucosa of the vallecula is completely elevated off of the lingual surface of the epiglottis as far as its tip. This provides an additional margin of resection in the vallecula.
- An incision through the mucosa 1 to 2 mm superior to the tip of the epiglottis enables entrance into the pharynx (Fig. 39.1).
- A broad right-angled retractor is inserted into the pharynx superior to the base of the tongue. The base of the tongue is grasped with a tenaculum. Downward traction is exerted on the tenaculum and the base of the tongue drawn into the wound to provide tension on the mucosa to complete the pharngotomy incisions.
- The hypoglossal nerves and the lingual arteries are identified and mobilized using sharp and blunt dissection. Vessel loops are placed around these structures to aid in identification and retraction of these structures (Fig. 39.1).
- The tumor is identified and the resection margins marked with methylene blue (Fig. 39.2).
- Prior to excising the tumor, a black silk suture is placed into the anterior margin of resection in order to orient the specimen for the

pathologist.

- The lesion is then excised using electrocautery to prevent blood obscuring these incisions. If the cancer extends into the tonsil fossa, the mucosal incision can be extended in order to adequately excise the tumor.
- After removing the tumor and obtaining clear surgical margins with frozen section control, a nasogastric tube is placed and stabilized by placing a black silk suture into the angle between the upper lip and columella.
- A primary multilayer closure of muscle and mucosa is carried out (Fig. 39.3). In our series it has not been necessary to use a skin graft, regional, or vascularized flap.
- Copious irrigation of the wound is carried out, followed by the insertion of suction drains.
- As part of the closure of the skin flaps, the subcutaneous tissue must be sutured to the strap muscles in order to isolate the stoma from the neck wound to prevent contamination of the cervical wound when the patient coughs.
- The endotracheal tube is removed from the tracheostoma, and the tracheostomy tube is inserted. The breastplate of the tracheostomy tube is sutured to the skin of the tracheostoma to prevent dislodgement.

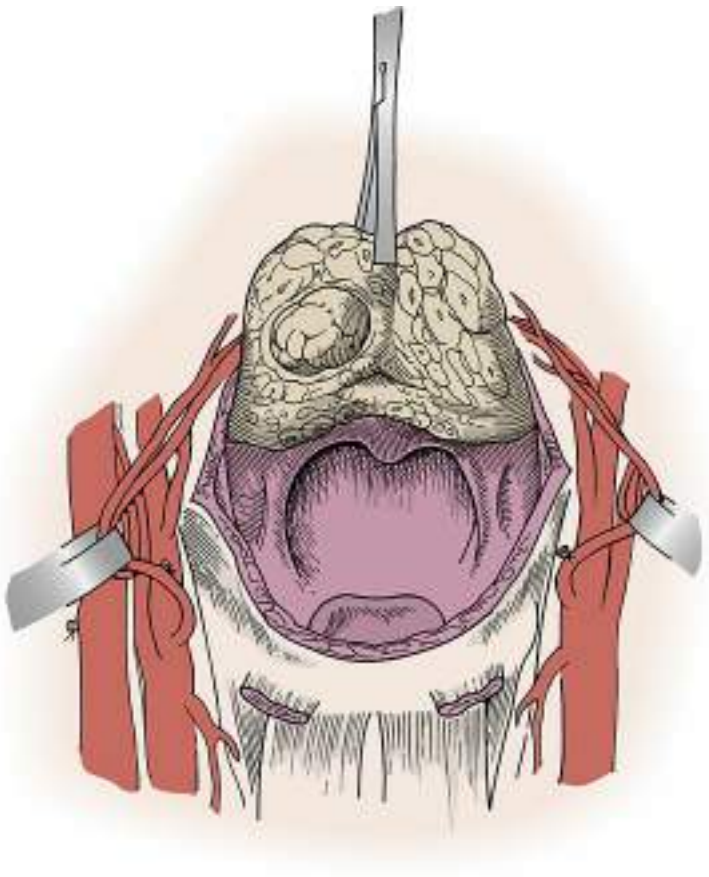

FIG. 39.1 Excellent exposure of tumors limited to the base of the tongue is achieved with this technique.

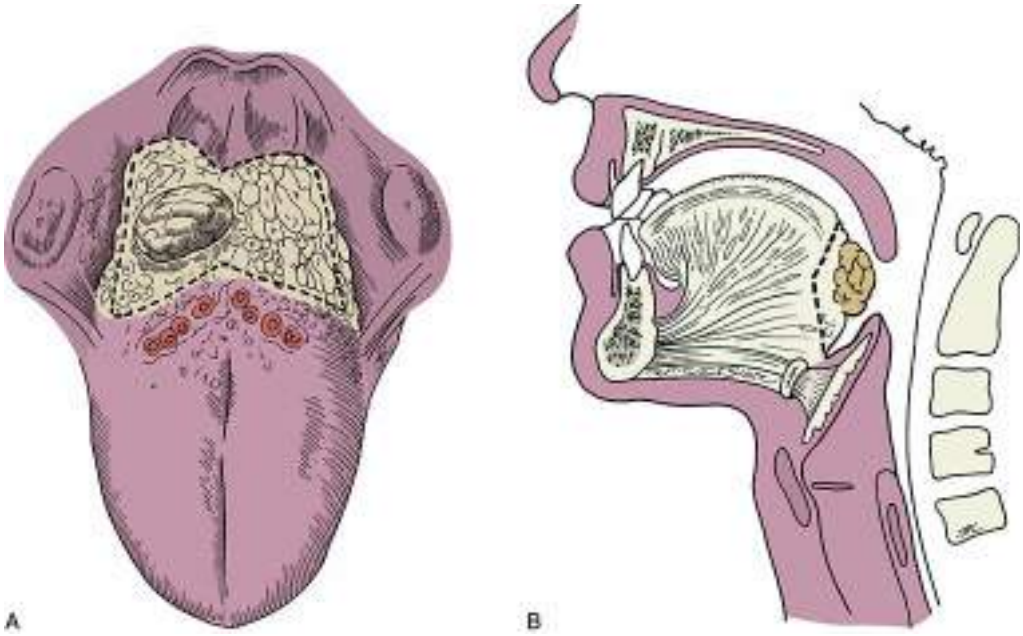

FIG. 39.2 **(A)** Schematic drawing demonstrating the

tissue to be excised. **(B)** Lateral schematic drawing of the area to be excised.

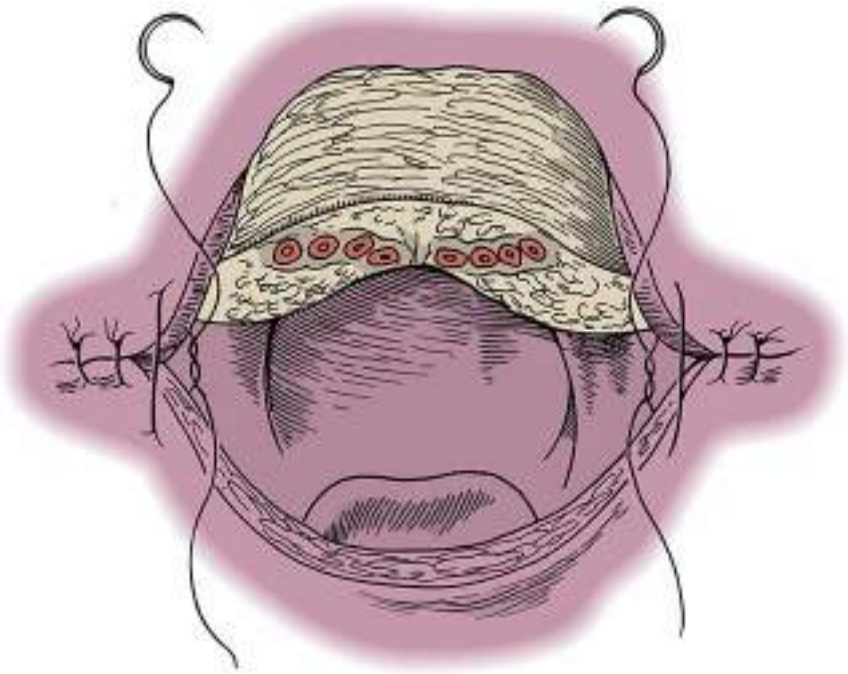

FIG. 39.3 The defect can be closed primarily.

Posterior Pharyngeal Wall

- After the pharyngotomy is completed, the cancer of the posterior pharyngeal wall is identified. The surgical margins are marked with methylene blue, and an incision is made in the superior aspect of the incision line. A black silk suture is inserted in the superior aspect of the specimen to orient the pathologist. The cancer is then excised, including the underlying constrictor muscles, as a deep margin of resection. Hemostasis is obtained with electrocautery, while clearance of the surgical margin is obtained using frozen section control (Fig. 39.4).
- Since primary closure is not possible, the application of a split thickness skin graft or dermal graft sewn to the prevertebral fascia provides rapid resurfacing of the wound; however, these grafts must be immobilized by a gauze bolus, requiring a return to the operating room and another general anesthesia to remove the bolus.

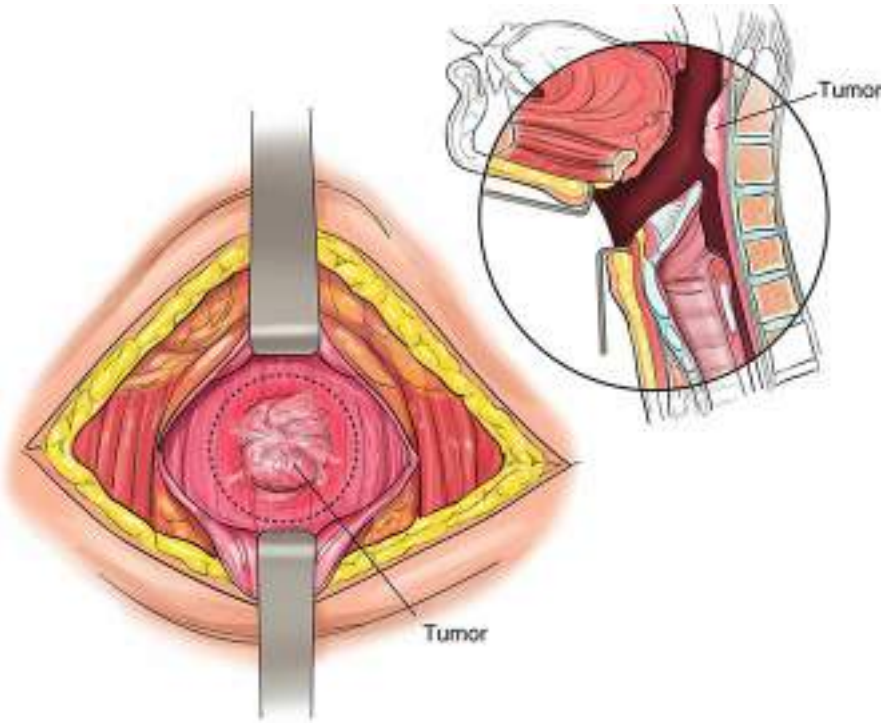

FIG. 39.4 The position of the tumor and line of excision.

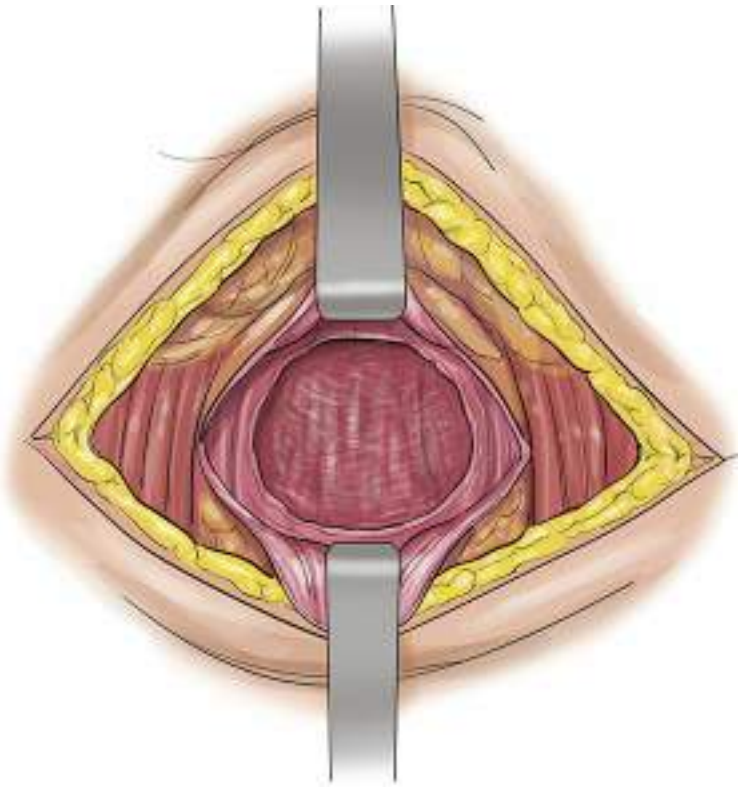

FIG. 39.5 Appearance of the wound after excision of the cancer.

- We have found that instead of using a skin graft, simply sewing the mucosal edges of the defect to the prevertebral fascia results in healing by second intent and rapid re-epithelization of the wound (Fig. 39.5).

Lateral Pharyngotomy

- Tracheotomy and neck dissections are carried out as described previously.
- The sternocleidomastoid muscle is retracted to expose the carotid sheath.
- The carotid sheath and its contents are retracted laterally in order to allow identification of the inferior constrictor muscle as well as the superior pole of the thyroid gland and its vascular pedicle.
- A double-pronged retractor is placed in the posterior edge of the thyroid ala, and the inferior constrictor muscle is incised along the length of the thyroid cartilage. Blunt dissection of the muscle off of the cartilage exposes the mucosa of the piriform sinus (Fig. 39.6).
- Dissection is carried superiorly to identify the origin of the superior thyroid and superior laryngeal artery.

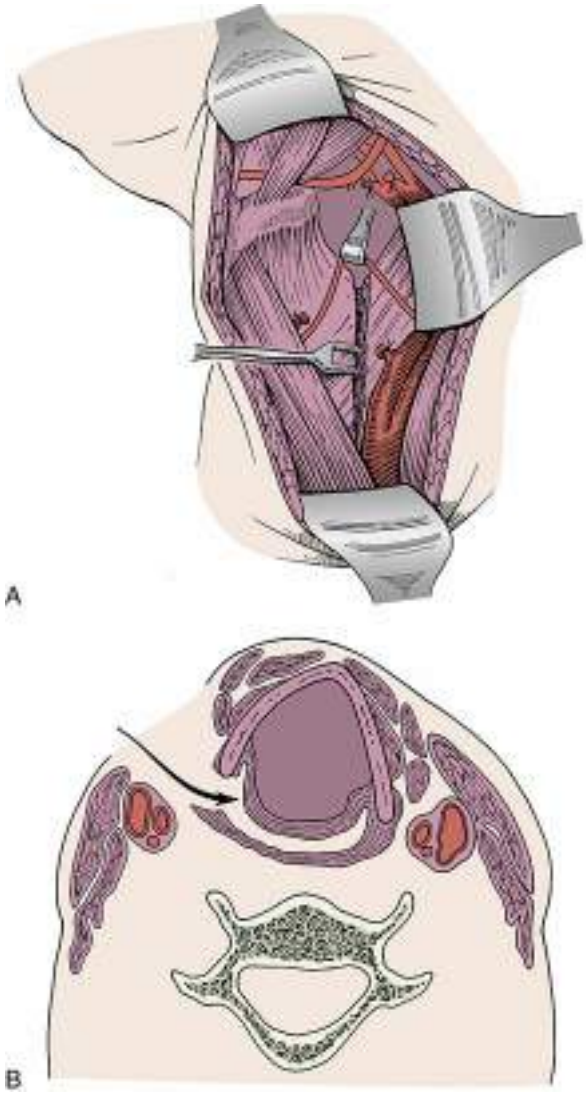

FIG. 39.6 **(A)** The superior laryngeal nerve is retracted upward and an inferior constrictor myotomy is performed to expose the mucosa of the piriform sinus and the lateral hypopharynx. **(B)** Axial view showing the surgical route *(arrow)* after myotomy.

- Retraction of the carotid bulb allows identification of the superior laryngeal nerve.
- The posterior belly of the digastric muscle is retracted.
- The hypoglossal nerve is identified cephalad to the superior laryngeal nerve as it enters into the submandibular triangle.
- Lesions of the oropharynx require a higher lateral pharyngotomy than lesions of the hypopharynx. The lateral pharyngotomy can be

extended superiorly to the nasopharynx or inferiorly to expose the hypopharynx.

- To enter the oropharynx, the incision is best carried out by placing the index finger along the base of the tongue, inferior and posterior to the tonsillar fossa, and away from the tumor.
- The finger tenses the mucosa, thereby facilitating performance of the pharyngotomy, and ensures that the incision is not carried through the tumor.

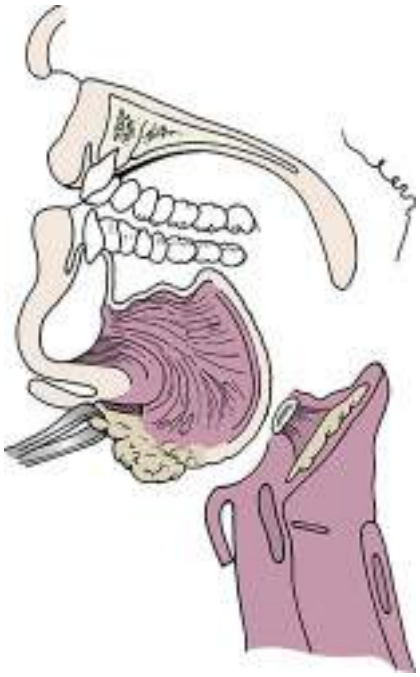

FIG. 39.7 The lesion of the base of the tongue exposed through a lateral pharyngotomy.

- The pharyngotomy is opened with sharp instruments or electrocautery as the surgeon and his assistant keep the mucosa under tension.
- Lesions located in the superior aspect of the hypopharynx may require inferior extension of the pharyngotomy.
- The tumor is then identified and excised, marking the specimen prior to excision to ensure proper orientation of surgical margins (Fig. 39.7).
- The wound is closed primarily as described for transhyoid pharyngotomy once assurance of clear surgical margins is obtained.

Common Errors in Technique

1. Injury to the hypoglossal nerves and lingual arteries may occur.

2. Injury to the superior laryngeal nerve may also occur.

3. Underestimating the extent of the tumor may lead to positive surgical margins and inability to perform a primary closure.

4. Lack of frozen section control may lead to positive margins.

Postoperative Period

Postoperative Management

1. Patients at our institution are transferred to a dedicated head and neck unit and do not require admission to the intensive care unit.

   a. The head of the bed is elevated to 30 degrees to diminish edema in the wound and to decrease the risk of gastropharyngeal reflux.

   b. Proton pump inhibitors may also be given intravenously to decrease the acidity of any gastropharyngeal reflux.

   c. Broad spectrum prophylactic perioperative antibiotics are continued for 24 hours postoperatively.

   d. Suction drains are maintained to gentle suction and remain in place until the output is less than 20 mL in 24 hours.

   e. Patients receive routine postoperative tracheostomy care (Chapter 78) and care of the neck dissection wound (Chapter 87).

   f. Patients are fed via nasogastric tube for 7 to 10 days postoperatively.

2. In most instances, decannulation is achieved prior to removal of the nasogastric tube and initiation of oral feeding by downsizing to an uncuffed tube, which is plugged and removed when normal swallowing without aspiration takes place.

   a. A speech language pathologist (SLP) trained in evaluating and managing patients with head and neck cancer postoperatively is vital in initiating postoperative oral feeding.

b. The SLP evaluates and instructs the patient on swallowing strategies.

c. When indicated, a fiberoptic endoscopic examination of swallowing (FEES) or modified barium swallow (MBS) may be used to better evaluate the swallowing function.

Complications

1. Wound infection

   a. Any sign of erythema of the skin or purulent exudate in the drains should be noted, and appropriate antibiotics should be administered.

   b. If the suction drains remain in place, the wound does not necessarily need to be opened unless an abscess has formed.

   c. If the drains have been previously removed, the wound should be opened in a manner that promotes external drainage.

2. Pharyngocutaneous fistula

   a. The surgeon should maintain a high degree of suspicion of fistula formation if the output in the suction drains appears purulent or saliva-like. The appearance of edema, erythema, and drainage may also be suggestive of a fistula.

      1) Although most fistulas should be diagnosed clinically, the presence of a high level of amylase in the drain output confirms a salivary fistula.

   b. The majority of salivary fistulas will heal with conservative management. Perhaps the most important aspect of managing a fistula is diverting the saliva away from the carotid arteries and out of the wound. This may be accomplished with maintenance of the suction drains or packing.

   c. If the fistula does not resolve with conservative management, other contributing factors should be investigated, including persistent cancer, tension on the mucosal closure, malnutrition, epithelialization, foreign body, or inadequate blood supply from previous surgery or radiation.

1) If none of these factors exist, it may be necessary for the patient to undergo a more complex reconstructive procedure such as pectoralis major myocutaneous flap (Chapter 174) or microvascular free flap (Chapter 169).

3. Aspiration

a. Postoperative initiation of swallowing should be instituted under the supervision of a well-trained SLP, as noted previously.

b. Aspiration events can lead to pneumonia or aspiration pneumonitis, potentially requiring ventilator assistance.

Alternative Management Plan

1. Nonsurgical management

a. Depending on the tumor type, location, and extent, nonsurgical therapy may be an acceptable alternative to surgery. The National Comprehensive Cancer Network (NCCN) outlines treatment options for patients with cancer of the head and neck. Radiation therapy or a combination of chemotherapy and radiation therapy may be an option.

2. Robotic surgery

a. Transoral robotic surgery (TORS) has been gaining in popularity since its introduction in 2004. In properly selected patients with limited disease, TORS has proved to be a safe and effective method of surgical resection, potentially sparing patients the need for radiation therapy. TORS offers acceptable short- and long-term quality of life outcomes and may help avoid the long-term morbidity of primary chemoradiotherapy.[5,6] An effective TORS program requires significant monetary investment and advanced surgical training and is therefore not available in all situations.

3. Palliative care

a. The patient's age, medical comorbidities, and wishes play a vital role in treatment decisions. Palliative care is an option for patients who do not wish to pursue curative therapy or whose age and medical status may preclude curative options.

b. At our institution, a supportive palliative care specialist is a vital member of our tumor board discussion team, as well as the inpatient and outpatient treatment team.

1) He or she offers insight into symptom management (e.g., pain, thirst, xerostomia) and end-of-life decision making such as hospice care.

Discussion

Evidence-Based Medicine Question

What is the evidence supporting suprahyoid pharyngotomy for squamous cell carcinoma of the base of the tongue?

The suprahyoid pharyngotomy approach has historically been criticized for providing perceived limited exposure of the tumor and the belief that violating the pre-epiglottic space may increase the risk of tumor seeding. A retrospective study was published at our institution of 13 patients who presented with T1 or T2 squamous cell carcinoma of the base of the tongue who underwent a suprahyoid pharyngotomy approach with neck dissection. Adjuvant therapy was provided according to NCCN guidelines. At the time of the publication, all patients remained cancer free without regional or local recurrence.[1] The transcervical pharyngotomy approach remains an important technique for the head and neck surgeon to address pathology, especially when more advanced technologies such as surgical robots and lasers may not be readily available.

Editorial Comment

Until recently squamous cell carcinoma of the oropharynx was almost exclusively a disease of males (with a male-to-female ratio of 2.5:1); it is alcohol and tobacco driven with a peak incidence between 55 and 75 years. The combination of tobacco and alcohol also gives rise to significant comorbidities, especially COPD.[7] Tobacco use is on the rise in low-income countries and in many middle-income countries, especially among those countries in which large numbers of the population live in

poverty. This addiction causes many very poor families to spend substantial amounts on tobacco, leaving less for food, health, and education, which results in malnutrition.[8] Research shows that individuals who avoid smoking in adolescence or young adulthood are unlikely to become smokers.[8] The risk of surgical complications was studied in a cohort of 100 consecutive patients, with cancer of the head and neck undergoing extensive ablative and reconstructive surgery.[7] In this study, 83% of the patients had some form of comorbidity and the majority of cases were cardiovascular, respiratory, or previous coexistent morbidity. Patients with advanced comorbidity developed a clinically important complication in 55% of cases. Naturally there is an association between complications and duration of hospital stay and its associated costs. Many of these complications were swallowing problems, usually due to COPD. The inclusion of swallowing therapists to the head and neck team has proved to be invaluable in mitigating this problem and preserving this aspect of the quality of life for this group of patients.

In recent decades this pattern has changed, driven by a decrease in numbers of smokers—at least in the United States—and a near epidemic of HPV-related squamous cell cancer of the oropharynx. The victims of this newly found cancer tend to be much younger, healthier nonsmoker/drinkers and are more curable, even with nonsurgical treatments.[9]

Based on the VA study in 1991 in which chemotherapeutic Cisplatin/5FU combined with radiation therapy was successful in being curative and preserving the voice in 67% of study patients with advanced cancer of the larynx,[4] this treatment was adapted for cancer of the oropharynx. Those in the younger nonsmoker group tended to have a far better cure rate than the older smoker and alcohol-using group. However, many of the cured had a poor quality of life due to swallowing difficulties caused by pharyngeal strictures requiring a permanent gastric feeding tube.

The TORS procedure, which uses the daVinci robot to successfully excise tumors of the base of the tongue, also reduced the number of patients who had previously been treated by transcervical pharyngotomy.[5] In the United States and Western Europe where these surgical robots are available, transcervical pharyngotomy for squamous cell carcinoma is rarely performed as a primary procedure. This of course

impacts our ability to teach this procedure, which may still be useful for benign and malignant tumors of the base of the tongue and for limited cancers of the posterior wall of the pharynx.[10] In countries in which patients do not have access to modern chemotherapy and radiation units are scarce, transcervical pharyngotomy still plays an important role in the treatment of oropharyngeal neoplasms.

Review Questions

1. The suprahyoid pharyngotomy approach is ideal for all of the following tumors, except

   a. T1/T2 squamous cell carcinoma of the base of tongue

   b. Early stage tumors of the posterior oropharyngeal wall

   c. Early stage salivary gland tumors of the base of the tongue

   d. **Tumors of the base of the tongue involving the lateral pharyngeal wall**

2. All oropharyngeal squamous cell carcinoma biopsy specimens should routinely be tested for

   a. **HPV**

   b. EBV

   c. HHV-8

   d. HIV

3. What portion of the physical examination is most critical to assess for tumor extent?

   a. Flexible fiberoptic pharyngolaryngoscopy

   b. **Palpation**

   c. Examination of the cranial nerves

   d. Palpation of the neck

4. Barium esophagram can be a helpful adjunctive imaging study in cases of suspected

   a. Metastasis to cervical lymph nodes

   b. **Invasion of the prevertebral fascia**

   c. Deep invasion of the base of tongue musculature

   d. Lateral pharyngeal wall tumor involvement

5. If a salivary fistula is nonhealing, which of the following should be suspected as underlying causes:

   a. Persistent tumor

   b. History of radiation

   c. Foreign body

   d. Epithelialization

   e. **All of the above**

Pharyngectomy

Jessica H. Maxwell, and Seungwon Kim

Introduction

A hollow viscus located immediately posterior to the larynx, the hypopharynx is related to the oral pharynx superiorly and the cervical esophagus inferiorly. It is divided into three anatomic sites: the pyriform sinuses (bilateral), the postcricoid mucosa, and the posterior pharyngeal wall. The postcricoid mucosa is the mucosa lying on the posterior aspect of the cricoid cartilage, which is also the anterior wall of the hypopharynx. The hypopharynx plays an important role in deglutition, as well as respiration. Coordinated activity in this laryngopharyngeal segment is essential for swallowing and protecting the airway from aspiration.

Squamous cell carcinoma of the hypopharynx accounts for only 3% to 5% of all head and neck squamous cell carcinomas.[1] Development of carcinoma of the hypopharynx is closely associated with the use of both tobacco and alcohol products.[2,3] Cancer of the hypopharynx has a dismal prognosis with the majority of patients initially diagnosed with stage IV cancer.[2,4] Treatment is dependent on the stage at presentation and often involves a combination of surgery, radiation, and chemotherapy.[5,6] Unfortunately, recurrence rates are high, approaching 50%, demonstrating the difficult task faced by head and neck surgeons in managing cancer of this unique subsite.[1]

Key Operative Learning Points

1. Squamous cell carcinoma of the hypopharynx has a propensity for regional metastases, and the majority of patients are diagnosed with stage IV cancer.

2. The standard approach to treatment of cancer of the hypopharynx is either partial or total pharyngectomy, often combined with total laryngectomy, followed by adjuvant chemoradiation.

3. Involvement of the prevertebral fascia and/or the common carotid artery is considered to be inoperable.

Preoperative Period

History

1. History of present illness
   a. Common presenting signs and symptoms include dysphagia, odynophagia, referred otalgia, and a mass in the neck.
      1) The duration, severity, and quality of these symptoms should be elicited.
      2) Choking or coughing with meals may indicate aspiration.
   b. Hoarseness or stridor suggests laryngeal involvement.
2. Past medical and surgical history
   a. A thorough past medical history should be obtained, including the patient's pulmonary function and cardiac history.
   b. Has the patient been diagnosed with cancer of the head and neck in the past or previously been treated with radiation therapy?
   c. Is there a history of immunosuppression?
3. Family history of cancer of the head and neck cancer or blood dyscrasias should be obtained.
4. Medications
   a. A full list of medications should be obtained, including the use of anticoagulants, antiplatelets, or herbal products.
5. Social history
   a. Determine the patient's smoking and alcohol history, as these are the most common risk factors for hypopharyngeal cancer.[3]

b. Current alcohol use places the patient at risk for postoperative alcohol withdrawal.

Physical Examination

1. Vital signs
   a. Basic vital signs, including oxygen saturation and body mass index (BMI)
2. Examination of the head and neck
   a. Ears
      1) Referred otalgia is common with cancer of the hypopharynx.
   b. Oral cavity/oropharynx
      1) A thorough examination of the oral cavity and oropharynx is important to rule out synchronous primary cancers in these patients who typically have a history of heavy tobacco and alcohol consumption.
      2) Dental evaluation is important for pretreatment planning. Patients with poor dentition may need to have dental extractions prior to radiation therapy preferably at the time of surgery.
   c. Neck
      1) Lymphatic drainage of the hypopharynx is directed toward the superior deep cervical lymph nodes (zones II and III); however, some cancers of the hypopharynx may drain to the retropharyngeal lymph nodes, and bilateral drainage is also possible.
      2) Cancer involving the pyriform sinus has an approximately 20% risk of contralateral lymph node metastasis.[7] The lateral wall of the pyriform is less likely than the medial wall to metastasize to the contralateral lymphatics.
3. Flexible fiberoptic laryngoscopy
   a. A key portion of the examination is direct fiberoptic laryngoscopy to confirm the presence of a hypopharyngeal lesion, and to determine

its extent.

b. Does the cancer involve the endolarynx, post-cricoid region, or posterior pharyngeal wall?

c. Does the cancer obstruct the airway? If the tumor causes significant obstruction of the larynx, an awake flexible fiberoptic intubation or an awake tracheostomy must be considered.

4. Cardiac and pulmonary examination

a. The status of these is a critical component of preoperative planning.

b. Candidates for organ-preservation surgery require excellent pulmonary function status. Preoperative pulmonary function studies are usually adequate for this assessment.

Imaging

1. Computed tomography (CT)

a. CT of the neck with contrast is a quick, easy, and cost-effective method for evaluating the extent of cancer of the hypopharynx.

b. Cervical lymph node metastases can be readily determined with CT. Metastatic cancer develops in 60% to 80% of patients with hypopharyngeal cancer.[8] Occult lymph node metastases are present in at least 20% to 40% of patients.[8] The risk is bilateral in patients with cancer involving the postcricoid mucosa, the medial wall of the pyriform sinus, or the posterior wall of the pharynx.

c. CT of the chest is important to evaluate for pulmonary metastases in patients with advanced stage cancer.

2. Magnetic resonance imaging (MRI)

a. Compared to CT, MRI provides better visualization of soft tissue planes.

b. MRI is useful in determining whether there is tumor involvement of the prevertebral fascia; a contraindication to surgery.

3. Barium esophagram

a. Fixation to the prevertebral fascia or bone can be ascertained preoperatively with video fluoroscopy when fixation of the pyriform

sinus is recognized during swallowing.

4. Positron emission tomography (PET)

   a. Because most patients present with advanced stage cancer, the risk of distant metastases at presentation is substantial. PET, often combined with CT, provides reliable pretreatment evaluation of distant metastatic spread.

Indications

1. Partial laryngopharyngectomy

   a. This procedure is appropriate for patients with cancer limited to the aryepiglottic fold, the medial wall of the pyriform sinus, and the anterior wall of the pyriform sinus, as long as they have adequate pulmonary function. Extension to the apex or lateral wall of the pyriform sinus is a contraindication to this procedure.

2. Total laryngectomy and partial pharyngectomy

   a. This procedure is most commonly performed in patients with carcinoma of the pyriform sinus that extends to involve the larynx medially, the apex of the pyriform sinus inferiorly, or the lateral wall of the hypopharynx laterally.

3. Total laryngopharyngectomy

   a. Cancer involving the postcricoid mucosa, advanced cancer of the posterior hypopharyngeal wall, and cancer involving the pyriform sinus with extension across the midline posteriorly require total laryngopharyngectomy. More extensive cancers that extend into the cervical esophagus are resected via total laryngopharyngoesophagectomy.

Contraindications

1. Extension of the cancer to the prevertebral fascia

   a. This can be evaluated with preoperative MRI and/or barium esophagram.

2. Encasement of the common carotid artery

a. While significant extension is visible on a preoperative CT scan, occasionally carotid artery involvement can only be determined intraoperatively. If carotid artery involvement is suspected but not confirmed preoperatively, we suggest starting with the neck dissection on the affected side in the event that the case must be aborted.

3. Distant metastases

a. It is imperative that these patients be discussed at a multidisciplinary conference for treatment options, including palliative care.

Preoperative Preparation

1. Preoperative medical clearance, particularly with regard to cardiac and pulmonary status

2. Laboratory tests should include a prealbumin and thyroid-stimulating hormone as these are correctable causes of delayed wound healing.

3. Consider a gastrostomy tube if the patient is unable to swallow and is malnourished.

4. Discontinue antiplatelet and anticoagulant medications if possible.

5. Have any biopsy or imaging studies done at another hospital reviewed by in-house experts.

Operative Period

Anesthesia

General

Positioning

Supine with a shoulder roll for neck extension and both arms tucked in at the patient's side

Perioperative Antibiotic Prophylaxis

1. Surgery involving the upper airway is classified as clean-contaminated. Antibiotic prophylaxis should target pathogens found in the upper aerodigestive tract.

   a. Ampicillin-sulbactam is the first choice.

   b. For patients who are allergic to penicillin, either clindamycin or ciprofloxacin combined with metronidazole is a reasonable alternative.

Monitoring

Standard anesthesia protocol for major surgery

Instruments and Equipment to Have Available

1. Direct laryngoscopy set with rigid esophagoscope

2. Major head and neck set

3. Operative microscope if free tissue transfer is necessary for reconstruction

4. Tracheoesophageal puncture kit with prosthesis

Key Anatomic Landmarks

1. Hyoid bone

   a. Must be identified and skeletonized. The pharynx is entered superior to the hyoid bone on the side contralateral to the cancer.

2. Hypoglossal nerve

   a. Identified deep to the greater cornu of the hyoid bone. Preservation of this cranial nerve is key to functional deglutition following surgery.

3. Pyriform sinuses

a. For partial pharyngectomy, the pyriform sinus contralateral to the tumor should be carefully dissected off of the lateral lamella of the thyroid cartilage and entirely preserved if possible (Figs. 40.1 and 40.2).

FIG. 40.1 This patient has advanced cancer of the larynx. Most of the cancer is confined to the intrinsic larynx; however, resection of the medial wall of the ipsilateral piriform sinus is required to obtain a deep margin. Preservation of the contralateral piriform sinus, as well as the ipsilateral lateral wall, will allow primary closure.

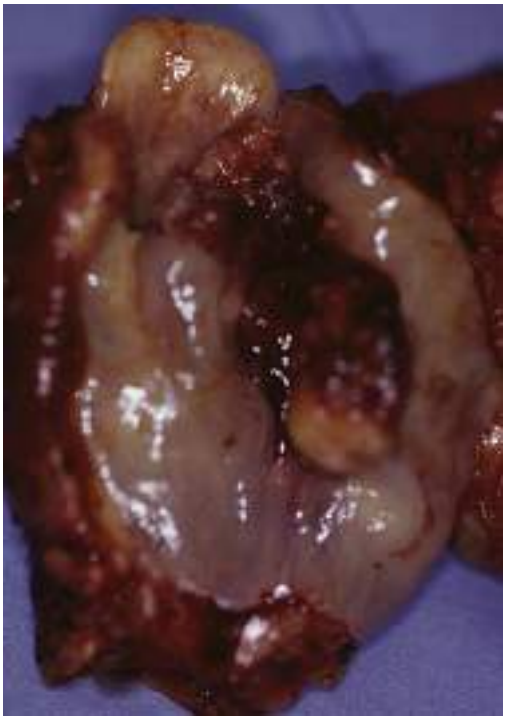

FIG. 40.2 This cancer of the piriform sinus extends to involve the entire lateral wall. During resection, the contralateral piriform sinus was carefully preserved.

Prerequisite Skills

1. Neck dissection
2. Laryngectomy

Operative Risks

1. Injury to the hypoglossal nerve
   a. The hypoglossal nerve is at risk during the laryngectomy portion of the case when the hyoid bone is dissected free from surrounding tongue musculature. The nerve runs just lateral and deep to the greater horn of the hyoid bone.
   b. Care must be taken to avoid injury to the hypoglossal nerve so that the patient has optimal swallowing function postoperatively.
   c. Injury to the hypoglossal nerve can be avoided by identifying the nerve during the neck dissection portion of the case. Once identified

laterally, the nerve can be traced medially until its relationship with the hyoid bone is clearly delineated.

2. Lack of preoperative identification of inoperability, either by involvement of the common carotid artery or prevertebral fascia

   a. Preoperative contrast-enhanced MRI provides excellent anatomic detail to determine whether there is involvement of the prevertebral fascia.

   b. We recommend obtaining preoperative staging CT scans within 1 month of surgery to avoid the risk of missing cancer invading into critical structures.

3. Injury to major vascular structures

   a. This may lead to significant hemorrhage intraoperatively, which requires immediate identification and repair.

   b. Delayed postoperative hemorrhage may be related to the displacement of a poorly secured vascular clip, a wound infection causing tissue breakdown, or persistent cancer.

   c. Carotid artery blowout is the most feared and devastating complication. This is more common in patients who undergo a radical neck dissection, have radiated tissues, and a postoperative pharyngeal leak.

      1) Tissue coverage with either a pectoralis flap or free tissue transfer can help to prevent this devastating outcome.

4. Pharyngeal leak

   a. Small leaks are managed conservatively by avoiding an oral diet, diverting the leak with a drain, and providing local wound care.

   b. Persistent large leaks require returning the patient to the operating room for repair and possibly local or free tissue reconstruction to prevent recurrence.

   c. Risk factors that predispose to pharyngeal leak include previous radiotherapy and hypothyroidism.[9]

Surgical Technique

1. Partial laryngopharyngectomy

   a. A direct laryngoscopy and esophagoscopy should be performed both prior to surgery for diagnosis and again at the start of the pharyngectomy for surgical planning.

   b. Neck dissection using an apron flap is accomplished bilaterally for cancer involving the medial wall of the pyriform sinus. Elective unilateral neck dissection may suffice for patients with cancer isolated to the lateral wall.

   c. The surgeon proceeds to perform a supraglottic laryngectomy.

   d. The supraglottic larynx is removed with the adjacent hypopharyngeal carcinoma in an effort to achieve at least a 15-mm mucosal margin in all directions.

   e. Reconstruction is accomplished by impacting the base of the tongue into the residual larynx.

   f. Prior to closure, a nasogastric tube is inserted in patients who have not had a gastrostomy.

   g. Closure of the residual hypopharyngeal mucosa is indirect and requires a second layer consisting of the residual strap muscles and digastric muscle.

   h. All wounds are drained with negative pressure.

2. Total laryngectomy and partial pharyngectomy (Fig. 40.3)

   a. Prepare the patient for a total laryngectomy and start with a superiorly based apron flap through the level of the stoma.

   b. Bilateral neck dissections of levels II to IV are performed in most instances.

   c. After completion of the neck dissection, the pharynx is entered through the vallecula contralateral to the cancer.

   d. Effort is made to preserve 100% of the uninvolved pyriform mucosa, which can be accomplished by releasing the pyriform sinus after having first incised the overlying constrictor muscles along the lateral lamella of the thyroid cartilage. The pyriform sinus is then gently dissected free from the endolarynx.

   e. The resection is next carried from the vallecula down along the

aryepiglottic fold to the lateral aspect of the arytenoid contralateral to the cancer. The remaining incisions in the mucosa are made under direct visualization so that the surgeon can ensure an adequate (15 to 20 mm) mucosal margin around the cancer.

f. At the completion of the resection, frozen section assessment of margins is mandatory.

g. Patients with 3 cm of residual pharyngeal mucosa in the transverse dimension can usually be closed primarily. If less than 3 cm of mucosa remains, a pedicle flap or free flap reconstruction may be required (Fig. 40.4). Prior to closure, a nasogastric tube is inserted in patients who have not had a gastrostomy.

h. If primary closure of the pharynx is successful, a primary tracheoesophageal puncture (TEP) is performed. Patients with a pedicle or free flap reconstruction typically benefit from secondary TEP after healing and adjuvant treatment are complete.

    1) The stoma is matured and wounds are closed over bilateral suction drains.

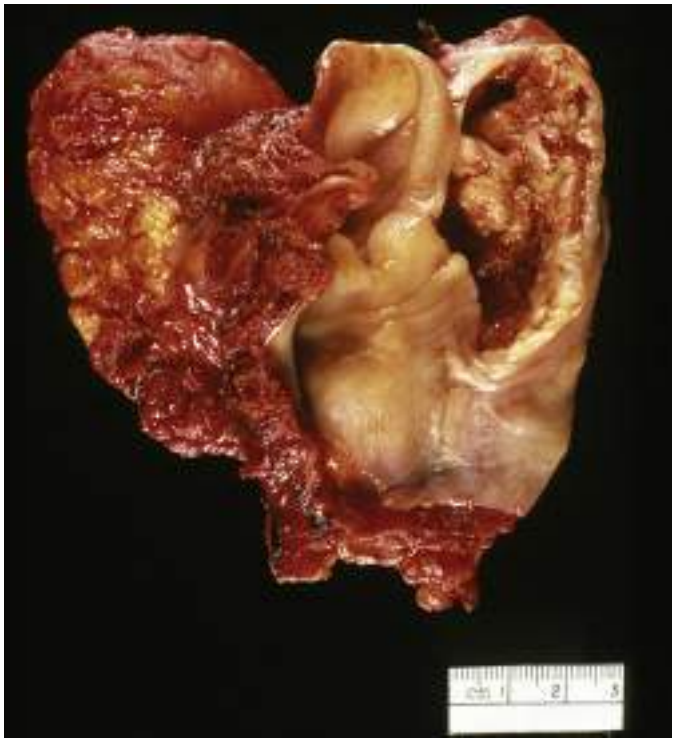

FIG. 40.3 This extensive hypopharyngeal cancer crossed the midline posteriorly. Laryngectomy and near-total

pharyngectomy were required.

3. Total laryngopharyngectomy (Fig. 40.5)

   a. Prepare the patient for a total laryngectomy and start with a superiorly based apron flap through the level of the stoma.

   b. Bilateral neck dissections are always performed.

   c. Enter the pharynx in the vallecula contralateral to the side of the cancer.

   d. Depending on the location of the cancer, release the uninvolved pyriform mucosa.

   e. Carry the dissection from the vallecula down along the lateral aspect of the epiglottis until the cancer is visualized.

   f. Obtain a 15- to 20-mm superior margin and then dissect a plane inferiorly between the posterior pharyngeal wall and the prevertebral fascia.

   g. Under direct visualization, ensure an adequate inferior margin and transect the larynx and pharynx inferiorly.

FIG. 40.4 This narrow island of residual hypopharynx cannot be closed primarily. It must be supplemented with a pedicle flap or free tissue transfer or resected and replaced with regional or distant tissue.

FIG. 40.5 This circumferential postcricoid lesion required total laryngopharyngectomy followed by appropriate reconstruction.

h. Reconstruction requires free tissue transfer, such as a tubed radial forearm free flap (Fig. 40.6 and Fig. 40.7). Free flap reconstruction using the jejunum is a viable option for large defects (Fig. 40.8); however, it has largely been replaced by free flaps from other sites. Prior to closure, a nasogastric tube is inserted in those patients who have not had a gastrostomy.

i. When cancer extends into the cervical esophagus, total laryngoesophagectomy is required.

j. The stoma is matured and wounds are closed with bilateral suction drains.

Common Errors in Technique

1. Inadequate visualization of the cancer and its extent during initial laryngoscopy

   a. Because entry into the pharynx is blind, a good understanding of the location of the cancer is essential to avoid cutting through it.

2. Inadequate skeletonization of the hyoid bone

   a. The release of the attachments to the hyoid bone assists in the rotation of the larynx. This is helpful when releasing the constrictor muscles from the thyroid lamella and the subsequent release of the pyriform sinuses.

b. Full exposure of the hyoid bone protects the hypoglossal nerve from injury.

Postoperative Period

Postoperative Management

1. Continue perioperative antibiotics for 24 hours.

2. If a total laryngectomy is performed, the stoma should be left open to air with humidification and frequent cleaning. If the stoma is obstructed by edema or by tissue reconstruction, then a soft Silastic laryngectomy tube can be placed.

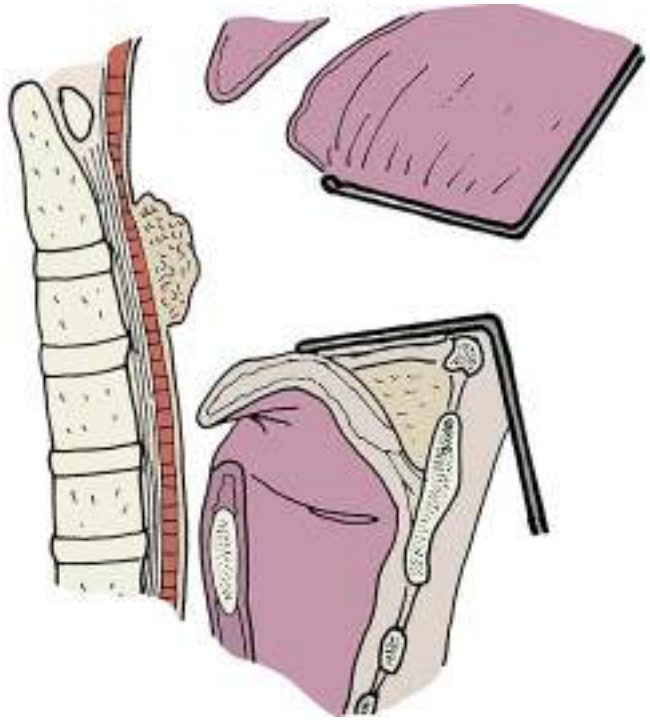

FIG. 40.6 A posterior pharyngeal wall cancer often requires free flap reconstruction. A radial forearm free flap provides thin pliable tissue for posterior pharyngeal wall reconstruction.

FIG. 40.7 The radial forearm free flap can be used for partial pharyngeal reconstruction. It can also be tubed for total reconstruction of the pharynx.

FIG. 40.8 The jejunum has vascular arcades, each serving approximately 25 cm of small intestine. This offers an ideal donor site for free tissue transfer.

3. Most patients temporarily require narcotic pain medications either through a feeding tube or peripheral IV.

4. Resumption of anticoagulants/antiplatelet medications depends on whether the patient had free tissue reconstruction. Patients with primary closure or local flap reconstruction may restart antiplatelet therapy on postoperative day 1.

5. Feeding through the nasogastric or gastrostomy tube is initiated when bowel sounds are present.

6. The integrity of the mucosal suture lines can be determined by contrast barium esophagram between 7 and 10 days postoperatively. If the suture lines are intact, oral alimentation with clear liquids is initiated and the nasogastric tube is removed. The diet can be advanced gradually as tolerated.

Complications

1. Hypothyroidism
    a. This increases the risk of delayed wound healing and pharyngeal leak.
    b. This should be managed with levothyroxine and close follow-up.
    c. A thyroid panel should be ordered 5 to 7 days after surgery.
2. Pharyngeal leak
    a. Small leaks are managed conservatively, keeping the patient NPO, diverting the leak with a drain, and providing local wound care.
    b. Leaks that fail conservative management require operative repair.
    c. Persistent leaks or leaks in patients with radiated tissues often require local or free tissue reconstruction to stop the leak and heal the wound.
3. Pharyngeal stenosis
    a. This is a late complication of pharyngectomy, which can be diagnosed with a barium esophagram. These patients often benefit from esophageal dilatation.
4. Carotid blowout
    a. The most devastating complication of surgery, which often occurs in patients who have been radiated, have a pharyngeal leak, and have a postoperative wound infection
    b. Immediate return to the operating room is paramount for the patient's survival.

Alternative Management Plan

1. Radiation therapy (RT)
    a. For patients with early stage cancer of the hypopharynx, definitive RT offers a good chance for local control and survival.
    b. The decision to use RT versus surgery depends on tumor accessibility, the patient's functional status, and the availability of expertise.
2. Radiation therapy in conjunction with chemotherapy (CRT)

a. This is a reasonable alternative to surgery in patients with advanced cancer of the hypopharynx.

b. Organ-sparing approaches, such as CRT, offer larynx preservation but do not confer a survival advantage to total laryngectomy.[10]

c. If the patient has impaired organ function at baseline, then surgical management is preferred over CRT.

3. Palliative chemoradiation

a. This is for patients with inoperable cancer or distant metastases.

Discussion

Evidence-Based Question

Does definitive chemoradiation confer a survival advantage over surgery followed by adjuvant radiation in patients with advanced hypopharyngeal cancer?

Functional organ-preserving approaches using a combination of chemotherapy and radiation therapy have largely replaced laryngopharyngectomy plus adjuvant radiation for patients able to withstand prolonged treatment with associated toxicities. Although definitive chemoradiation can permit the preservation of the larynx, it does not confer a survival advantage over surgery plus adjuvant radiation.[10] A multidisciplinary expert panel of the American Society of Clinical Oncology developed clinical practice guidelines for the treatment of laryngeal and hypopharyngeal cancer. They recommend that when feasible, most patients should be offered organ preservation approaches to manage hypopharyngeal cancer. However, in older patients with poor performance status or significant cancer involvement of the thyroid cartilage, laryngopharyngectomy plus adjuvant radiation is often recommended over organ-preserving approaches.

Editorial Comment

Squamous cell cancer of the hypopharynx often presents at a very late stage due to a paucity of symptoms and therefore carries a dismal

prognosis. Treatment options rely on a combination of surgery, radiation, and chemotherapy and carry high rates of complications and toxicities. Because of the close proximity of the hypopharynx to the larynx, these two subsites are often combined in both clinical trial investigations and treatment guidelines. It is paramount that all patients with advanced cancer of the hypopharynx are discussed prior to treatment by a multidisciplinary team with expertise in the treatment of cancer of the head and neck. Patient and family goals also must be taken into account when determining the optimal treatment regimen for each patient. Although functional organ preserving treatment approaches are widely recommended for most patients, potential toxicities and the possible need for salvage surgery must be adequately addressed with the patient and their family prior to treatment.

Review Questions

1. Bilateral cervical lymph node metastases are *least* likely to occur in which primary subsite?

   a. Posterior pharyngeal wall

   b. Posterior wall of the pyriform sinus

   c. **Lateral wall of the pyriform sinus**

   d. Postcricoid region

   e. Medial wall of the pyriform sinus

2. Which of the following is true regarding hypopharyngeal cancer?

   a. **Metastasis to retropharyngeal lymph nodes are often seen.**

   b. Metastasis to level I occurs frequently.

   c. CT is better than MRI in determining whether the prevertebral fascia is involved by the cancer or not.

   d. A margin of 5 to 10 mm is adequate when resecting a hypopharyngeal cancer.

   e. Advanced cancer of the hypopharynx has a less than 10% risk of

occult cervical metastases.

3. Which of the following is *true?*

   a. The majority of patients with hypopharyngeal cancer present with early stage disease.

   b. Patients treated successfully for all stages of hypopharyngeal cancer have a recurrence rate of less than 30%.

   c. Surgery followed by adjuvant radiation is standard of care for early stage hypopharyngeal cancer.

   d. **Definitive chemoradiation therapy does not confer a survival advantage over primary surgery for patients with advanced cancer of the hypopharynx.**

   e. Cancer involvement of the prevertebral fascia is not a contraindication to surgery.

Sheng-Po Hao

Introduction

Certain ethnogeographic groups have been found to have an increased risk of developing nasopharyngeal carcinoma (NPC). Studies have shown that among the Chinese, there is a very high incidence of NPC affecting 10 to 20 per 100,000 for men and 5 to 10 per 100,000 for women, causing NPC to sometimes be called the "Cantonese cancer." Most of these NPCs originate in the epithelial lining of the fossa of Rosenmüller, an area located posteromedially to the medial crura of the opening of the Eustachian tube.[1]

Screening, diagnosing, and monitoring NPC can now be done using several serological markers after studies demonstrated that a close relationship existed between NPC and the Epstein-Barr virus (EBV), a double-stranded DNA virus. Most NPCs carry the clonal EBV genomes and express EBV proteins. To screen the general population, serological markers such as EBC VCA IgA and DNase are used. RT-PCR methods that measure EBV DNA copy numbers in plasma are used to monitor the response to treatment and for early detection of local recurrence.[2]

Currently, radiation therapy (RT), chemotherapy, or combinations of both are the primary available modalities for treating NPC. More than 80% local control can be achieved through RT because of the high radiosensitivity of NPC, giving patients with early NPC a good possibility for cure. However, for patients with advanced-stage locoregional NPC, the standard treatment is Cisplatin-based chemoradiotherapy with or without neoadjuvant chemotherapy. In spite of its high radiosensitivity, patients with advanced NPC still have a 10% to 30% risk of local failure after the initial RT treatment. If local recurrence is suspected, performing a biopsy under nasopharyngoscopy

should be done.[1]

Key Operative Learning Points

- Perform medial maxillectomy and posterior septectomy to improve exposure and increase the working space area.
- Use the two nostrils/four hands technique.
- Resection with LASER on a curved applicator.
- Mark the deep margin of resection as the pharyngobasilar fascia and remove the Eustachian tube cartilage as far laterally as possible.
- Involvement of the bone of the skull base will require a navigation-guided endoscopic resection.

Preoperative Period

NPC patients who are monitored using the EBV serological markers typically do not complain of any symptoms. When there is a local recurrence, the NPC patient may experience the same symptoms experienced at the initial presentation of the cancer. The presence of a mass in the fossa of Rosenmüller or even from the nasopharynx should be investigated further for rNPC. However, there are some patients with whom careful nasopharyngeal examination does not reveal any obvious mucosal lesion. Some may appear as a small submucosal swelling beneath an intact mucosa. Therefore, performing a biopsy under nasopharyngoscopy is mandatory to establish the diagnosis of local recurrence.

The surgeon must evaluate the extent of the cancer by endoscopic examination as well as imaging studies. Magnetic resonance imaging (MRI) is superior in demonstrating soft tissue involvement compared with computed tomography (CT) scan. MRI is able to identify local recurrence, perineural invasion, skull base involvement, suspicious retropharyngeal lymph nodes, and cervical metastasis as well as early cancers that produce mild thickening of the mucosa. These advantages provide important information for good surgical planning and tumor mapping for endoscopic nasopharyngectomy.[3] Salvage surgery is

relatively contraindicated for patients who have distant metastasis.

A complete examination of the head and neck must be carried out, particularly in the nasal cavity and nasopharynx, to detect the presence of metastatic lymph nodes, including examination of the cranial nerves. Other important preoperative preparation includes ascertaining any anatomical variation, intraoperative navigation (in selected cases), blood-group matched packed red cells, and preoperative antibiotic. Patients with preexisting significant comorbidities should receive special attention. Anticoagulants or antiplatelet medications should be withheld (if possible) prior to endoscopic nasopharyngectomy.

History

- History of present illness
  - Nasal symptoms: nasal obstruction, blood-stained nasal discharge
  - Aural symptoms: ear blockage, hearing loss, otorrhea
  - Mass in the neck
- Skull base and cranial nerve involvement
  - Intractable headache
  - Sixth cranial nerve involvement which will be discovered by the presence of abducens nerve palsy
  - Unilateral facial numbness from involvement of the fifth cranial nerve
- Trismus
- Symptoms suggesting distant metastasis
- Weight loss, nutritional status
- Smoking
- Past medical history
  - Previous radiotherapy with or without chemotherapy
  - Previous surgery for NPC
  - Pulmonary disease, hypertension, diabetes, or ischemic heart disease

- Immunosuppression; for example, AIDS

- Medications
  - Anticoagulants
  - Allergies to antibiotics or analgesia

Physical Examination

- Nasal cavity and nasopharyrnx
  - Endoscopic examination of the nasopharynx may reveal a mass in the fossa of Rosenmüller and sometimes a small submucosal swelling
  - Determine extent of the tumor
    - Lateral extension
      - Eustachian tube
      - Torus tubarius
  - Roof of nasopharynx and posterior choanae
  - Inferior extension to oropharynx
- Examination of the neck
  - Palpate both necks for the presence of cervical metastases
  - Is the mass fixed or mobile?
  - Is there bilateral cervical metastasis?
- Examination of the skull base and cranial nerve
  - Is there evidence of sixth nerve palsy?
- Trismus
  - Anticipate difficult intubation and may require tracheostomy
- Examination of the ears
  - Middle ear effusion
- Examine oral cavity, pharynx, and larynx for synchronous primaries
- General health

- Nutrition
- Cardiovascular
- Respiratory
- Abdominal

Imaging

- MRI
  - Superior soft tissue resolution and tumor delineation
    - Parapharyngeal space or infratemporal fossa
    - Intracranial extension
    - Perineural invasion
    - Deep invasion to the vertebra body
    - Vascular involvement (carotid artery, cavernous sinus)
  - Presence of cervical metastasis
- PET CT scans
  - Restaging
  - To exclude distant metastasis (bone, lung, and liver)
  - To exclude cervical metastasis
- CT scan
  - Not required in all cases
  - MRI is preferred if available
- Chest radiograph
  - Metastases
  - Pulmonary and cardiac status
- Ultrasound of the liver

Indications

- Mainstay of treatment after radiotherapy failure[4]
- Lesions of the central, roof, or floor of the nasopharynx with minimal lateral extension
- Recurrent NPC with skull base bone involvement with the aid of navigation[5]

Contraindications

- Parapharyngeal space or infratemporal fossa involvement
  - Not a good candidate for salvage surgery, as it is difficult to achieve oncologically safe surgical margins in these areas[6]
- Significant dural involvement and intracranial extension
- Internal carotid artery or cavernous sinus involvement
- Medically unfit for surgery

Preoperative Preparation

- Evaluations
  - Otorhinolaryngologist—head and neck surgeon
  - Oncologist
  - Anesthesiologist
  - Nutritionist (if necessary)
  - Internal Medical Specialist optimizing medical illness (cardiopulmonary disease) if required
- Treat sinusitis if present
  - Not rare in rNPC patients
  - Bacterial culture of nasal secretion is obtained and culture-directed antibiotics prescribed for at least 7 days
  - Perform frequent nasal douching with saline before surgery
- Intraoperative navigation (if required)

- Postoperative high-dependency care (depending on the center)
- Discontinue antiplatelet drugs if possible

Operative Period

Anesthesia

- General anesthesia
- Oral endotracheal tube
- In patients who have trismus, intubation under fiberoptic guidance may be necessary. Temporary tracheostomy should be considered in patients who have severe trismus.
- The endotracheal tube is positioned away from the surgeon so as not to interfere with the operative site.

Positioning

- The patients are placed in the supine position with the neck slightly extended and the head resting on a donut.
- The nasal cavity is decongested for 15 minutes with cotton pledgets saturated with epinephrine 1:100,000.
- Careful inspection of the nasopharynx with a rigid endoscope: Inspection of the cancer and its extent is mandatory in order to formulate a good surgical plan.
- Lidocaine 1% mixed with 1:80,000 epinephrine is used to infiltrate the mucoperichondrium of the nasal septum, middle, and inferior turbinates, and around the cancer.

Perioperative Antibiotic Prophylaxis

- Clean contaminated surgery.
- Prophylactic intravenous antibiotics based on previous available bacterial culture data or antibiotic with good CSF penetration

(intravenous clindamycin).

- Additional intraoperative doses of antibiotic can be given every 6 hours in longer surgery.

Monitoring

- Routine anesthesia monitoring
- Hypotensive anesthesia (to reduce intraoperative bleeding that will obscure operative field)
- Intraoperative heating blanket to prevent hypothermia
- Maintain hydration and hemoglobin

Instruments and Equipment to Have Available

Endonasal skull base surgery set including:

- Navigation system
- Sinuscope set using the 0-degree and 30-degree Hopkins' scopes
- Kerrison rongeurs, suctions, forceps, curettes, tru-cutting instruments, and dissectors
- Cutting and diamond burrs
- Contact LASER set with curved applicator
- Bipolar cauterization set

Key Anatomic Landmarks

- Most cephalad portion of the upper aerodigestive tract
- Measuring nearly 4 cm in transverse diameter and 2 cm in its anterior-posterior dimension
- Boundaries:
  - Superior: sphenoid sinus and upper clivus

    - Posterior: lower clivus and body of the first cervical vertebra
    - Lateral: medial pterygoid plate
    - Anterior: communicates with the posterior nasal choanae
    - Inferior: communicates with the oropharynx
- Posterior and lateral walls lined by the pharyngobasilar fascia
    - Tough fibrotic layer
    - Inserts superiorly to the basosphenoid and laterally to the medial pterygoid plate
    - Continuing downward it becomes the buccopharyngeal fascia
- Between the roof and the lateral wall of the nasopharynx is a recess that is located superior to the torus tubarius where most NPC tumors are located. This area is called the fossa of Rosenmüller.
- Inferolateral wall is the Sinus of Morgagni, an incomplete cartilaginous ring through which the Eustachian tube and tensor veli palatini muscle travels.
- Tensor veli palatine muscle
    - Attached to Eustachian tube on its lateral side and to the scaphoid fossa floor
    - Muscle fibers converge into a tendon that curves around the pterygoid hamulus
    - Inserts into the palatine aponeurosis of the soft palate
    - Contracture of this muscle facilitates opening of the Eustachian tube lumen
- Levator veli palatine muscle
    - Originates from the petrous temporal bone's inferior surface
    - Traverses through the Sinus of Morgagni
    - Inserts into the palatine aponeurosis[4]

Prerequisite Skills

- Experience in skull base surgery and familiarity with the complex

anatomy.

- Open approach (see Chapter 43).
  - Cancer involving the carotid artery or unexpected extension, not amenable to endoscopic surgery and the patient may require conversion to an open approach.

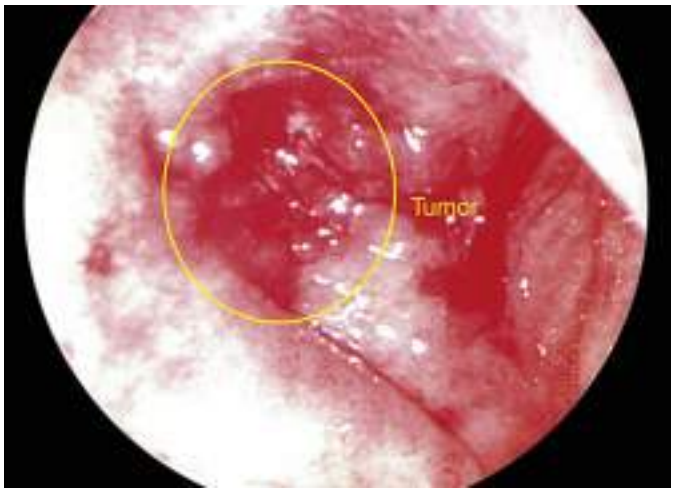

FIG. 41.1 Preoperative sinoscopy demonstrating rNPC over the right fossa of Rosenmüller.

Operative Risks

The major operative risk of endoscopic nasopharyngectomy is similar to any skull base surgery such as:

- Intracranial hemorrhage
- Pneumocranium or tension pneumocephalus
- CSF leak

Surgical Technique

- *Intraoperative evaluation after patient has been intubated*
  - Ensure the nose is properly decongested and anesthetized
  - Reassess the extent of the primary cancer (Fig. 41.1)

- *Surgical approach*
  - Good surgical access and good nasal decongestion is essential to attain adequate resection margins and to control bleeding.
  - Posterior septectomy is first performed to provide an unobstructed access to the nasopharynx. This allows the use of different instruments in each nostril, the so-called two nostrils, four-handed technique.
  - Ipsilateral middle and inferior turbinates are selectively removed.
  - Endoscopic medial maxillectomy can be carried out if more space is needed, especially in cases with some lateral extension.[7]
- *Endoscopic nasopharyngectomy*[6]
  - Dissection can be carried out using electrocautery or laser.
  - Continuous wave, contact diode laser (Diomed Co., Cambridge, UK) mounted on an angled applicator can be used to achieve a bloodless surgical field.
  - Visualization by 4-mm diameter, 0-degree, and 30-degree endoscopes (Karl-Storz, Tuttlingen, Germany) allow the widely exposed cancer to be resected with adequate surgical margins.
  - Incision usually begins along the ipsilateral sphenoethmoidal recess (Fig. 41.2).
  - Incision deepened to the bone, transversely connecting the septum above the nasopharyngeal roof to the ipsilateral fossa of Rosenmüller.
  - Ipsilateral sphenoid sinus ostium is identified and widened medially.
  - The face of the sphenoid sinus and rostrum are removed.

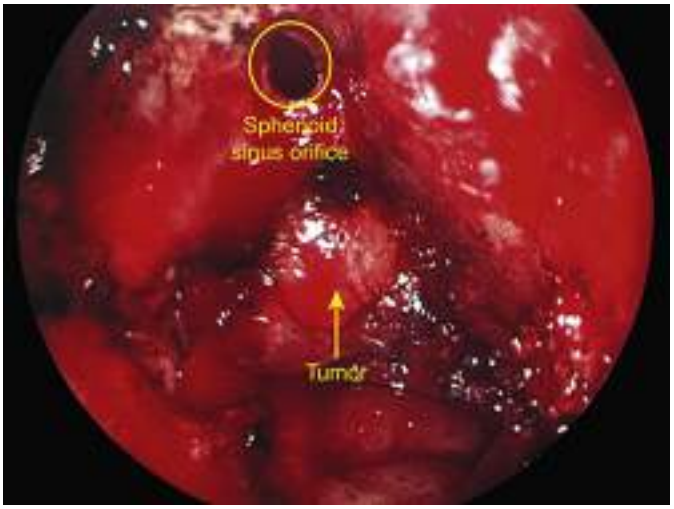

FIG. 41.2 Dissection of the cancer inferiorly using LASER dissection technique from sphenoethmoidal recess across to Eustachian tube cartilage exposing the sphenoid sinus.

- Nasopharyngeal mucosa is elevated away from the face of the sphenoid sinus in superior-to-inferior direction.
- The floor of the sphenoid sinus is then removed using a combination of Kerrison rongeur and cutting burrs.
- The mucoperiosteum is then elevated downward to the sphenoclival junction to expose the pharyngobasilar fascia.
- Electrocautery or laser is applied to separate the attachment of the tough pharyngobasilar fascia from the bone.
- The thick, tough fascia prevents invasion by the cancer and can be used as the deep margin.
- Lateral margin of the cancer is defined using cautery along the posterior edge of the ipsilateral Eustachian tube.
- Dissect laterally until the ipsilateral cartilaginous portion of the Eustachian tube is reached. Transect as laterally as possible.
- The bone of the base of the pterygoid plate can be removed for better exposure laterally.
- The mucosa is incised deep to the bone and then elevated medially. The lateral surgical margin should be assessed at this point.
- A vertical incision from the ipsilateral roof to the inferior border of the cancer is carried out.

- Medial and inferior mucosal incisions are carried out based on the extent of the cancer.
- The medial incision usually reaches the medial border of the orifice of the contralateral Eustachian tube.
- The contralateral lateral margin usually includes the contralateral fossa of Rosenmüller.
- The inferior incision is usually made at the level of the superior surface of the soft palate.
- Finally, the cancer is completely excised after careful dissection using the pharyngobasilar fascia as a deep margin. This strong fascia often offers an effective barrier for spread of the cancer and can be used as a deep margin (Fig. 41.3).
- A cutting burr is then used to remove some of the residual soft tissue and the clivus and sphenoid ridge in order to obtain additional clear surgical margins.
- The superior and medial portion of the pterygoid plate can also be removed for margin control.
- Frozen sections are obtained to ensure clear margins.[7]
- A raw surgical defect is left for secondary epithelization (Fig. 41.4).

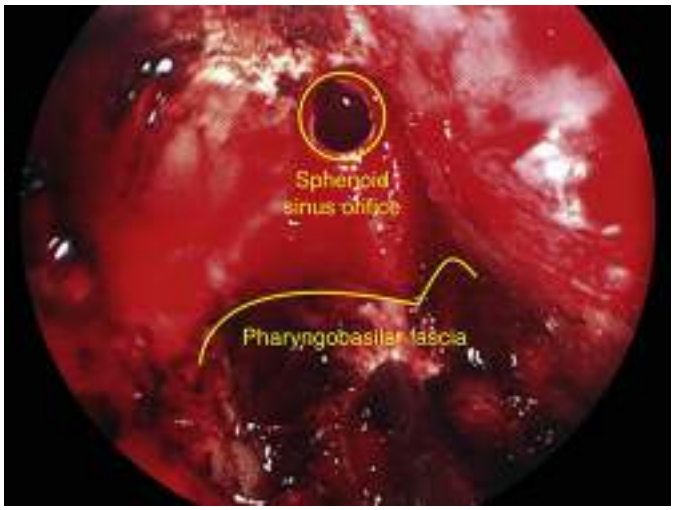

FIG. 41.3 Pharyngobasilar fascia deep to the pharynx and rNPC.

FIG. 41.4 Raw surgical defect after nasopharyngectomy on endoscopic view.

Common Errors in Technique

- Small exposure field.
- Performing posterior septectomy, lower middle turbinectomy, medial maxillectomy, and/or medial pterygoid plate and muscle removal provide better exposure and more working space for two nostrils/four handed technique.

Postoperative Period

Postoperative Management

- The patient is monitored for any complications.
  - Bleeding
  - Intracranial hemorrhage
  - Meningitis
  - Pneumocranium or tension pneumocephalus
  - CSF leak
- Intravenous antibiotic is continued for at least 3 days.

- Nasal packing and Foley catheter are removed between 24 and 48 hours.
- Patient may be discharged at postoperative day 3.
- Patient is instructed to irrigate the nasal-nasopharyngeal space with warm saline every day.

FIG. 41.5 Re-epithelized mucosa after 3 months postendoscopic nasopharyngectomy without evidence of recurrence or residual tumor.

- Endoscopic examination and diligent debridement of the defect every week are crucial until the wound heals satisfactorily, which usually occurs within 3 to 6 months (Fig. 41.5).

Complications

- Operative complications are rarely encountered in endoscopic nasopharyngectomy.
- Most common perioperative complication are:
  - Bleeding
    - Branches of the sphenopalatine artery. Time spent on meticulous hemostasis will prevent this problem.
  - Wound infection

    - Excessive accumulation of crust, and thus, frequent self-cleaning by irrigation or manual endoscopic debridement of crusts is extremely important.
- Osteoradionecrosis (ORN) of the nasopharynx[8]
    - Surgical bed has been heavily radiated and there is no local well-vascularized flap outside the radiation field.
    - Nasal septal flap is a good option for skull base or nasopharynx reconstruction.
    - Ipsilateral pedicle, or even from the contralateral sphenopalatine artery, is usually difficult to preserve during the nasopharyngectomy for surgical margin reasons, and the pedicle is usually also within the previous radiation field.
- Ascending meningitis
- Chronic headache

Alternative Management Plan

Patient can be offered transfacial nasopharyngectomy or a second course of concurrent chemoradiotherapy.

Discussion

Evidence-Based Medicine Question

What are the prognostic factors and survival for NPC patient treated with endoscopic nasopharyngectomy?

The primary treatment for NPC is radiotherapy with or without chemotherapy. However, 15% to 58% of the NPC patients experience recurrence.[9] Endoscopic nasopharyngectomy is a safe option for salvage treatment apart from re-radiation or palliative chemotherapy. Hsu et al. (2001) reported that the overall survival and locoregional relapse-free survival were 56% and 60% at 2 years, and were 30% and 40% at 5 years, respectively.[10] The results concur with the our own report in which the 5-year overall survival for stage I, 64.8%; stage II, 38.1%; stage III, 25.9%;

stage IV, 46.9%; and all stages, 48.7%.[7] Zou et al. (2015) in their series of 92 patients with rT1-T2 who underwent endoscopic nasopharyngectomy showed a remarkable 5-year overall survival and distant metastasis-free survival of 78.1% and 88.6%, respectively. The prognostic factor of local control are gender, margin status, adjuvant treatment type, and parapharyngeal space involvement, whereas dura or brain involvement, local recurrence, and adjuvant treatment type were significant impact factors of survival.[7] Zou et al. (2015) reported that the recurrent T staging is a significant prognostic factor for overall survival and distant metastasis-free survival.

Editorial Comment

Endoscopic Nasopharyngectomy

This section of our book includes four chapters on surgery of the nasopharynx. Professor Hao's chapter on Endoscopic Nasopharyngectomy features laser excision of recurrent NPC. Professor William Wei and Dr. Raymond Chang describe the latest technologic advances in their chapter entitled Robotic-Assisted Nasopharyngectomy. Professor Sheng-Po Hao presents an extensive, purely surgical technique using the Expanded Maxillary Swing Approach for Nasopharyngectomy and Professor Daniel Nuss has described the Facial Translocation Approach to the Nasopharynx.

Dr. Sheng-Po Hao, one of the outstanding authorities in the management of nasopharyngeal carcinoma (NPC), and has authored a well-organized, highly detailed chapter on Endoscopic Nasopharyngectomy. Most of the patients diagnosed with cancer of the nasopharynx are treated with a regime including platinum-based chemotherapy and radiation therapy. One of the main reasons for this has been the difficulty in achieving adequate exposure in this deeply seated anatomic site to be able to resect these cancers with a clear surgical margin. This chapter provides details on using the laser to resect these recurrent cancers.

The management of recurrent NPC is a vexing problem because despite the difficulties in adequately resecting the recurrent cancer, the alternative treatment is a second course of radiation therapy. The downside of this choice is using a treatment modality that was not

successful the first time. Retreatment may also result in unpleasant and dangerous sequelae such as severe trismus and ORN of the skull base.

We anticipate that NPC will become a technologically driven field which may change the treatment paradigm especially for early cases of NPC which may be managed by primary surgery. Advances such as the FLEX Robot, which has the ability to provide excellent exposure of the nasopharynx, may replace chemoradiation with its unpleasant side effects as the primary treatment of NPC.

Review Questions

1. Which of the following statements is true? The indication for endoscopic nasopharyngectomy:

   a. **Recurrence limited to nasopharyngeal mucosa**

   b. Recurrence involving the sphenoid sinus floor bone lateral to the foramen ovale

   c. Recurrence involving around the petrous part of the carotid artery

   d. Recurrence involving the brain parenchyma

2. Which of the following anatomical structures which does not form a natural barrier to the spread of NPC:

   a. Prevertebral fascia

   b. Pharyngobasilar fascia

   c. **Sinus of Morgagni**

   d. Floor of sphenoid sinus

3. What is NOT the technique performed to improve the view during endoscopic nasopharyngectomy:

   a. Posterior septectomy

   b. Medial Maxillectomy

   c. Inferior, middle, and superior turbinectomy

d. **Lateral pterygoid plate and muscle removal**

Robotic-Assisted Nasopharyngectomy

William I. Wei, and Raymond K. Tsang

Introduction

While radiotherapy with or without chemotherapy has been the mainstay of treatment for primary nasopharyngeal carcinoma (NPC), surgical resection of the recurrent cancer with the adjacent mucosal wall (nasopharyngectomy) has been established as an efficacious salvage treatment. Various open surgical approaches for nasopharyngectomy have been described in Chapter 43 and Chapter 44. With advancement in technology and endoscopic endonasal surgical techniques, it is now feasible to perform endoscopic resection in selected cases of patients who have recurrent NPC using an endoscopic endonasal approach. The endoscopic approach remains a challenging operation since the limited space in the nasal cavities and nasopharynx does not provide adequate exposure, which hampers instrumentation and reduces the dexterity of the surgeon. Alternatively, a transoral robotic-assisted approach allows a minimally invasive resection of a small NPC without resorting to major incisions and osteotomies. The surgical robot is a machine designed to assist the surgeon to perform complex surgical maneuvers in confined spaces of the body cavity. It has been successfully applied to the head and neck area for minimally invasive surgery for early cancers of the oropharynx, larynx, and hypopharynx.

The application of the surgical robot has several distinct advantages when applied to minimally invasive nasopharyngectomy. The 3D magnified view and stable endoscopic camera platform allow the surgeon to visualize the anatomy and pathology with unprecedented detail and clarity. The wristed instruments with multiple degrees of freedom allow for complex surgical maneuvers to be performed with dexterity in a narrow space such as the nasopharynx.

Unfortunately the current generation of surgical robots is not designed primarily for use in the head and neck area, and there are certain restrictions and limitations when applied to nasopharyngectomy, which we will discuss in this chapter. Note that the surgical robot discussed in this chapter is restricted to the da Vinci S or da Vinci Si model by Intuitive Surgical Inc. (Sunnyvale, California).

Key Operative Learning Points

- The major benefit of the surgical robot is from the wrist of the robotic arms that increases the surgical dexterity previously lost in endoscopic instruments. The use of the surgical robot allows traction and counter-traction of tissue during dissection.
- The major disadvantage of the surgical robot is the loss of tactile sensation, and this sense needs to be substituted by vision. An example is observing denting of tissue by surgical instruments to determine if it is hard or soft.
- The anatomy of the internal carotid artery in the parapharyngeal space (PPS) is highly variable. Trace the artery on the cross-sectional images carefully. Patients with a retropharyngeal internal carotid artery or the artery too close to the tumor are not suitable for robotic nasopharyngectomy.
- Recurrent NPC frequently arising from the fossa of Rosenmüller involved the Eustachian tube cartilage. Enbloc resection of the involved fossa of Rosenmüller and ipsilateral Eustachian tube cartilage is necessary for complete resection of the disease.
- Coverage of the raw bone of the clivus, preferably with vascularized tissue, is mandatory to minimize the risk of postoperative osteoradionecrosis.

Preoperative Period

History

1. History of present illness

a. History of previous NPC

b. History of treatment of NPC with radiation or chemoradiation

c. Diagnosis of local recurrence in the nasopharynx

d. Diagnosis of other malignant lesion in the nasopharynx

e. Benign lesions in the nasopharynx requiring resection

f. Presence of a mass in the neck

2. Past medical history

a. Details of prior treatment of NPC

b. Prior endoscopic nasal surgeries

c. Comorbid medical conditions that increase anesthetic risks

d. Presence of velopharyngeal incompetence/hypernasality—transpalatal surgery may exacerbate the velopharyngeal incompetence

e. Presence of trismus and mastication problems—a common problem following radiation to the nasopharynx precluding a transoral approach

f. Presence of loose teeth or teeth with radiation caries—teeth may be damaged during a transoral procedure

3. Medication history

a. Concurrent use of antiplatelet drugs—carotid stenosis is common in NPC patients after radiation

b. Use of herbal medicine—increase bleeding tendency

c. Allergies, especially to antibiotics

4. Mental and social status

a. Ability to give informed consent

b. Preference for surgical salvage over salvage radiotherapy

Physical Examination

1. Examination of the nasal cavities and nasopharynx

a. Identify the site and extent of the recurrent cancer with an endoscope.

b. The fossa of Rosenmüller should be inspected with a 30-degree endoscope.

c. Presence of intranasal adhesions

d. Presence of radionecrosis of the skull base

2. Examination of the oral cavity

a. Presence of trismsus—dental gap should be more than 3.5 cm for transoral robotic surgery (TORS)

b. Condition of the teeth, any loose teeth, or teeth with radiation caries

c. Velopharyngeal closure

3. Examination of the neck

a. Presence of metastasis to the neck

b. Adequate flexion and extension of neck

4. Histological diagnosis

Imaging Studies

- Cross-sectional imaging with contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) should be also performed before the operation.
- The location, extent, and relationship of the cancer to the internal carotid artery (ICA) are better appreciated with MRI while CT can better demonstrate the bony anatomy and any invasion of bone.
- The course of the internal carotid artery in the PPS should be identified. Retropharyngeal ICA is a contraindication to robotic resection.
- Positron emission tomography (PET)-CT scan is also useful in recurrent cancer as some posttreatment changes may mimic active tumor infiltration.
- PET-CT can also help to rule out distant metastasis that made cure impossible.

Indications

- Small central NPC recurrent after radiotherapy/chemoradiation
- Other cancers of the nasopharynx
- Small benign lesions in the nasopharynx
- Minimal extension to the PPS
- Minimal erosion of the cortex of the clivus
- Cancer invading the prevertebral muscles or the floor of the sphenoid sinus

Contraindications

- Cancer with lateral extension beyond the lateral pterygoid plate
- Cancers invading the posterior or lateral wall of the sphenoid sinus
- Large rT3 tumors with gross invasion of the clivus
- rT4 tumors with intracranial extension
- Cancers abutting or close to ICA (<1 cm)
- Cancers with anterior extension to the nasal cavity or pterygopalatine fossa. Most cancers with nasal extension will require endonasal endoscopic approach.
- Ectatic ICA located close to the lateral or posterior wall of the nasopharynx
- Presence of metastatic retropharyngeal lymph nodes adherent to the ICA
- Patient with trismus (for transoral approach)

The indications for selecting the robotic approach for nasopharyngectomy are similar to selecting an endoscopic approach. The operation is usually performed for small local recurrence of NPC after radiotherapy, though it can also be used to resect other benign and malignant tumors in the nasopharynx. The tumor should preferably be centrally located and small. The most lateral aspect of the cancer should

be medial to the lateral pterygoid plate as the current generation of surgical robot prohibits lateral access without extensive removal of the pterygoid process and pterygoid plates. As the current generation of robots lacks tactile sensation, intraoperative identification of the ICA may be difficult, and inadvertent injury is possible. Cancer with close proximity (<1 cm distance) to the ICA should not be operated on with a surgical robot.

Occasionally the local recurrence may be associated with recurrence in the superior retropharyngeal lymph nodes, or the patient may present with metastasis to an isolated retropharyngeal lymph node. Unlike in radiation-naïve patients, these retropharyngeal lymph nodes are usually adherent to or even partially encase the ICA. Removal of these lymph nodes will require sharp dissection of the lymph nodes from the ICA. Since the surgical robot lacks tactile feedback, this type of dissection should not be performed with a surgical robot.

Preoperative Preparation

- Otitis media with effusion frequently occurs after nasopharyngectomy. A preoperative pure tone audiogram as a baseline is useful for future reference.
- Plasma Epstein-Barr virus (EBV) DNA titer has prognostic implications in NPC and is useful for monitoring the response to treatment. A preoperative titer should be obtained for future reference.
- Dental consultation—loose or carious teeth should be removed prior to the operation
- The diagnosis of recurrent cancer should be confirmed with a biopsy prior to the definitive operation.
- The implications of operating without a positive histological diagnosis should be discussed with the patient.

Operative Period

Anesthesia

- The procedure is usually performed under general anesthesia. The patient should be intubated orally with a Ring-Adair-Elwyn (RAE) tube. The tube should be taped to the midline of the lower lip.
- Alternatively, tracheostomy can be performed first if prolonged edema in the upper aero-digestive tract is expected or if severe trismus prevents adequate opening of the mouth.
- Blood products should be readily available during the operation.

Positioning

- Patient is placed supine with neck slightly extended. The patient cart of the surgical robot will be docked at the head end of the patient. The bedside surgeon can be positioned on either side of the patient.

Perioperative Antibiotics Prophylaxis

- Standard antibiotics prophylaxis regime for intraoral surgery should be employed.

Monitoring

- Invasive and noninvasive monitoring for blood pressure, urine output, and central venous pressure should be employed during the operation.

Instruments to Have Available

- A Dingman retractor or Crowe-Davis retractor for opening the mouth
- Endoscopic holder or similar device to hold the mouth retractor in position
- Five-millimeter Maryland and 5-mm monopolar cautery spatula robotic instruments. Occasionally an 8-mm bipolar cautery scissor can be used in lieu of the 5-mm monopolar cautery for dissection.
- Zero-degree and 30-degree robotic telescopes
- Yankauer suction or similar metal suction device for the bedside

surgeon to evacuate smoke and blood from the operative field

Key Anatomic Landmarks

- The nasopharynx is situated posterior to the nasal cavities, about 9 to 10 cm behind the nostril. It is a box-shaped cavity surrounded by bony walls on all sides except the inferior aspect where it opens to the oropharynx. Fig. 42.1 is a line drawing showing the cross-section anatomy of the nasopharynx and adjacent structures.

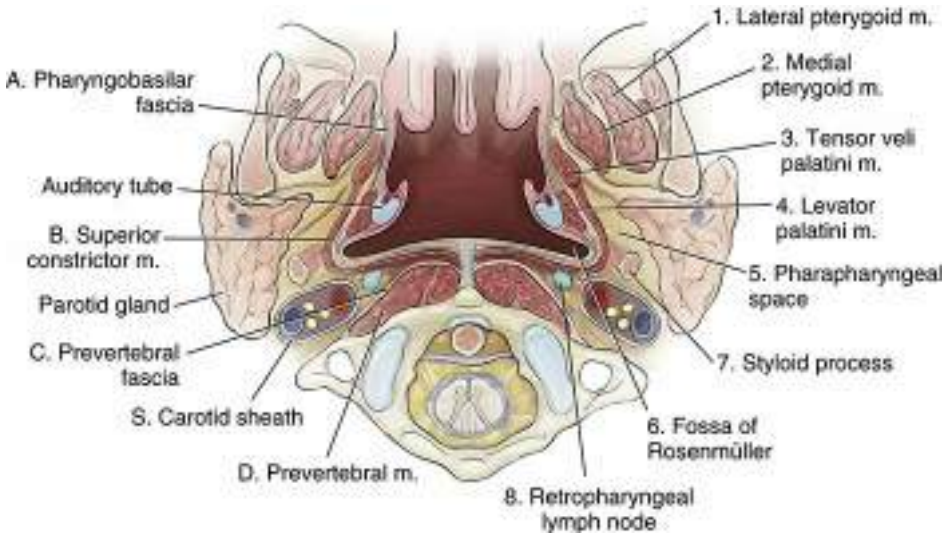

FIG. 42.1 Cross-section anatomy of the nasopharynx and the adjacent structures. A, Pharyngobasilar fascia; B, Superior constrictor muscle; C, Prevertebral fascia; D, Prevertebral muscles; S, Carotid sheath; 1, Lateral pterygoid muscle; 2, Medial pterygoid muscle; 3, Tensor veli palatini muscle; 4, Levator palatini muscle; 5, Parapharyngeal space; 6, Fossa of Rosenmüller; 7, Styloid process; 8, Retropharyngeal lymph node.

- The floor of the sphenoid sinus forms the roof and slants downward posteriorly as the clivus to form the posterior wall.
- The inferior aspect of the posterior wall is formed by the vertebral bodies of C1 and C2, with prevertebral muscles covering it. The roof and superior aspect of the nasopharynx are covered by mucosa and periosteum with no muscular layer.

- Posterior edge of the vomer denotes the midline and the anterior extent of resection
- The cartilaginous Eustachian tube penetrates the lateral nasopharynx wall to open into the nasopharynx. A recess, the fossa of Rosenmüller, is formed by the posterior crus of the Eustachian tube cartilage and the posterior nasopharyngeal mucosa. NPC frequently arises from this fossa.
- Fossa of Rosenmüller—recurrent cancers are often found deep in the fossa. The entire ipsilateral fossa and the ipsilateral Eustachian tube cartilage should be resected enbloc to ensure completeness.
- Medial pterygoid plate—the buccopharyngeal fascia should be detached from the medial pterygoid plate to remove the entire lateral nasopharyngeal wall.
- Prevertebral fascia—Resection should always include the prevertebral fascia as the deep margin. If imaging shows that the cancer has invaded the prevertebral muscles, then part of the muscles would need to be resected enbloc with the tumor.
- Lateral to the lateral nasopharyngeal wall is the PPS. NPC frequently extends to this area.
- The lymph nodes in the retropharyngeal space are the first echelon of lymphatic spread.
- The anatomy of the ICA in the PPS is highly variable. The ICA can abut on the fossa of Rosenmüller and travel in a medial course just deep to the mucosa of the lateral nasopharynx. It is imperative to trace the course of the ICA on imaging studies and ascertain that the ICA is not in close proximity with the intended resection area to avoid inadvertent injury.

Prerequisite Skills

- Basic transoral robotic surgical skills—certification for console surgeon in TORS. Experience with TORS will facilitate docking of the robot and manipulation of the robotic arms.
- Endoscopic endonasal surgery skills—It is not uncommon to perform

the superior resection with endoscopic endonasal approach. A nasoseptal flap (NS) is frequently required for coverage of the raw area after resection. Proficiency in endoscopic endonasal surgery is required to perform both procedures.

Surgical Technique

The surgical robot can be deployed by either the transoral, transnasal, or a combined transnasal and transoral route.[1] For the transoral route, the soft palate will be an obstacle for the robotic arms in approaching the nasopharynx. In the transnasal approach, bones of the medial wall of the maxilla and nasal septum need to be removed to increase the space for deployment of the robotic instruments.[2] There is more experience with the transoral route in the literature so that the discussion in this chapter will focus on the transoral route.

- A Dingman or Crowe-Davis retractor is placed to open the mouth and retract the tongue inferiorly. A plastic lip retractor is placed around the upper and lower lips to prevent injury to the lips by the robotic instruments.
- There are generally three techniques to manage the soft palate in deploying the surgical robot via a transoral approach: (1) midline palatal split, (2) palatal suspension, and (3) lateral palatal flap technique. The approach used most commonly includes the midline palatal split technique.[3]
- Midline palatal split approach
  - An incision is made extending from the incisor foramen to the uvula. The mucosa of the hard palate is incised down to the bony hard palate, and the soft palate is divided.
  - The soft palate is detached from the hard palate, and sutures are placed in the mucosa of the hard palate and through the entire soft palate. Using these sutures, the palate can be retracted laterally, thereby exposing the nasopharynx.
  - The approach is ideal for centrally located cancers, but the lateral reach of the instruments can be blocked by the retracted soft palate. Figs. 42.2 and 42.3 demonstrate the midline palate split incision and

the view of the nasopharynx from the telescope of the da Vinci robot.

- A 12-mm, 0-degree, or 12-mm 30-degree upward facing telescope can be used for visualization.
- There is a slight risk of a postoperative palatal fistula formation.

- Lateral palatal flap approach[4]
  - More suitable for laterally positioned tumor
  - From the anterior midline, an incision is placed in the inner aspect of the hard palate extending to the posterior hard palate, just medial to the alveolar mucosa. The incision is extended through the soft palate toward the superior pole of the tonsil (Fig. 42.4).

FIG. 42.2 Incision for the midline palatal split approach.

FIG. 42.3 View of the nasopharynx with the tumor in the central part after the soft palate was split in the midline. E denotes the right eustachian tube cushion.

- The entire mucosa of the hard palate is then elevated from the bone, and the greater palatine vessels are ligated and divided.
- The soft palate is detached from the hard palate and retracted toward the contralateral side using silk sutures. Care must be taken not to injure the contralateral greater palatine vessels as they are now the sole blood supply to the palatal mucosa.
- The entire ipsilateral nasopharynx and PPS can now be exposed and reached by the robotic instruments.
- A 12-mm 30-degree upward facing telescope is usually used since the angled telescope that can be turned 90 degrees laterally to visualize the PPS posterior to the medial pterygoid plate (Fig. 42.5).
- The disadvantage of this approach is the risk of palatal dysfunction due to division of the tensor veli palatini muscle, the risk of a palatal fistula, and middle ear effusion.

- Palatal suspension technique
  - Suitable for centrally and inferiorly located cancers
  - The approach does not divide the entire soft palate; instead the soft palate is elevated anteriorly using silk sutures.
  - To increase the extent of elevation, incisions are made in the superior aspect of the posterior pillar of the tonsils (Fig. 42.6).

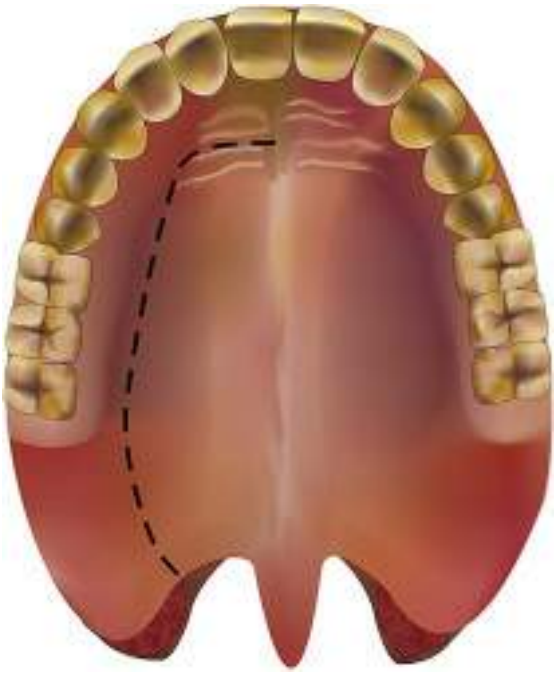

FIG. 42.4 Diagram demonstrating the incision for a left lateral palatal flap approach. *From Tsang RK, Mohr C: Lateral palatal flap approach to the nasopharynx and parapharyngeal space for transoral robotic surgery: a cadaveric study. J Robot Surg 7:119-123, 2013.*

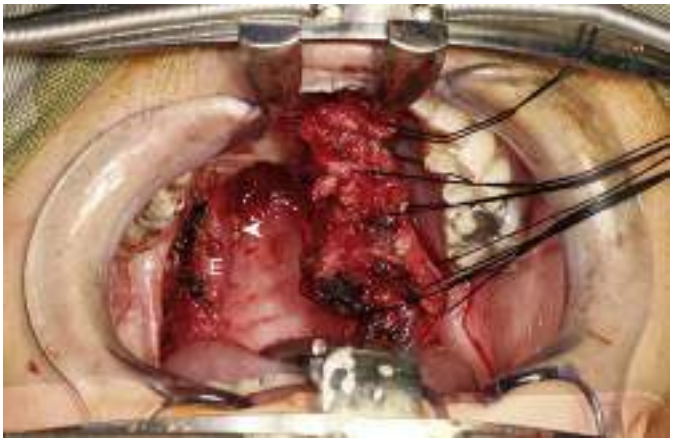

FIG. 42.5 View of the nasopharynx with the right lateral palatal flap approach. E denotes the right eustachian tube cushion and the *white arrowhead* points to the tumor in the right fossa of Rosenmüller.

- A 30-degree telescope facing upwards can then be inserted transorally to visualize the nasopharynx. Robotic instruments with the Endowrist can then reach the nasopharynx when deployed

though the mouth.

- Unfortunately the view of the nasopharynx is constrained, and the reaches to the upper nasopharynx superiorly and to the PPS laterally are difficult (Fig. 42.7).
- The advantage is that there is minimal disturbance of palatal function.

- Resection of the cancer
  - After exposure of the nasopharynx, the patient cart of the surgical robot is docked in the head end of the patient with robotic arms deploying in the oral cavity from inferior to superior direction.
  - The telescope arm is deployed in the midline and the two robotic instrument arms from the left and right sides. Fig. 42.8 is the floor plan of the operating room showing head docking of the patient cart, and Fig. 42.9 is the view of the mouth after deployment of the telescope and robotic arms.

FIG. 42.6 Incisions in the posterior tonsillar pillars for the palatal suspension approach. The soft palate and uvula are suspended anteriorly with sutures.

FIG. 42.7 View from a 30-degree telescope of the nasopharynx using the palatal suspension approach. *Arrow* points to the recurrent cancer in the inferior aspect of the posterior nasopharynx.

- Resection is usually performed with 5-mm robotic instruments due to space constraints. Five-millimeter Maryland forceps and 5-mm monopolar diathermy spatula are the usual choices.
- Alternative instruments included the 5-mm monopolar cautery hook, 8-mm monopolar scissors, or 8-mm bipolar Maryland forceps.
- A one centimeter mucosal margin is first marked with the cautery.
- Dissection usually proceeds from inferior to superior.
- The mucosa and superior constrictor are incised down to the prevertebral fascia. Depending on the findings on imaging, a cuff of prevertebral muscles or just the prevertebral fascia is resected with the mucosa of the nasopharynx.
- The Maryland forceps is used to grasp the resection specimen and provide counter-traction for the dissection to proceed from an inferior to superior direction. Fig. 42.10 demonstrates the dissection of the mucosa of the nasopharynx from inferior to superior.
- Depending on the cancer involvement of the fossa of Rosenmüller, the entire cartilaginous Eustachian tube or only the part of the posterior crus is resected enbloc.

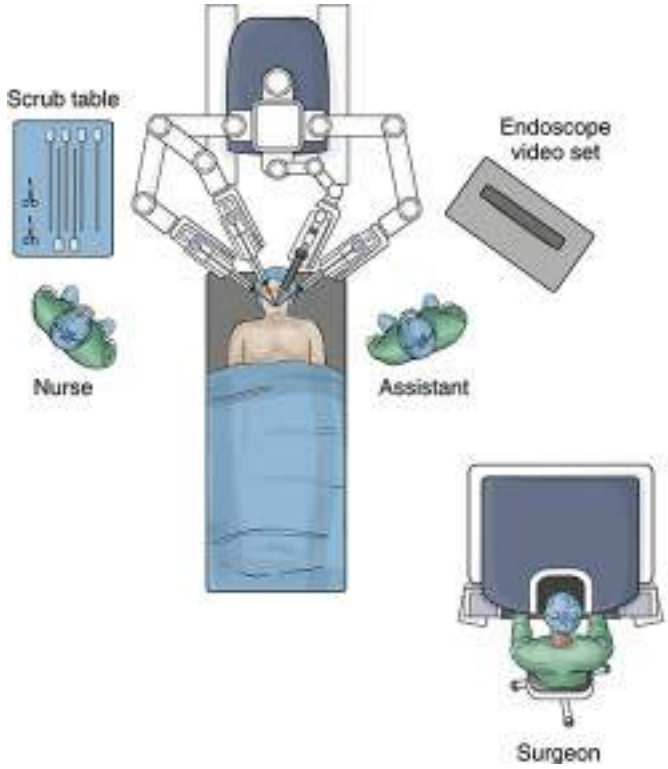

FIG. 42.8 Floor plan of the operating room showing docking of the patient cart from the head end of the patient. *Modified from Cho HJ, Kang JW, Min HJ, et al: Robotic nasopharyngectomy via combined endonasal and transantral port: a preliminary cadaveric study. Laryngoscope 125:1839–1843, 2015.*

FIG. 42.9 Docking of the patient cart from the head end with robotic instruments deployed.

- For cancers involving the entire fossa of Rosenmüller, the entire cartilaginous Eustachian tube should be resected.

- Alternatively, for cancers that just reach the fossa, only the posterior crus should be removed as a lateral margin.
- To resect the entire cartilaginous Eustachian tube, the mucosa and pharyngobasilar fascia are incised over the attachment of the medial pterygoid plate. The Maryland forceps is then used to grasp the Eustachian tube cartilage, retracting it medially.
- Care must be taken not to extend the dissection too far laterally and posteriorly, as this may injure the ICA.
- Dissection in the PPS may cause bleeding from the pterygoid venous plexus, and this bleeding may require bipolar cautery coagulation applied by the bedside surgeon.

FIG. 42.10 Dissection of the nasopharynx mucosa with the surgical robot proceeding from inferior to superior fashion.

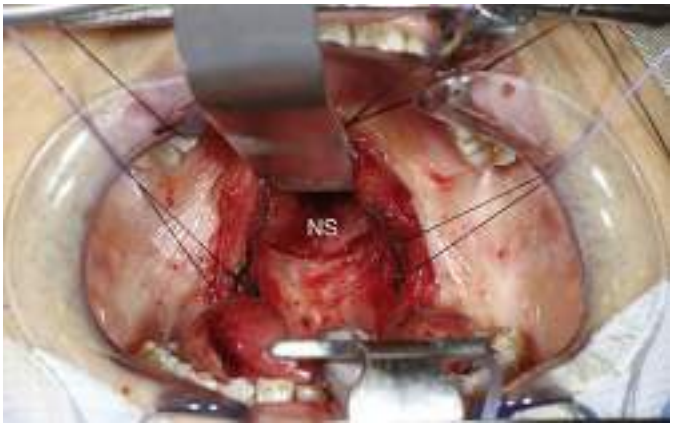

FIG. 42.11 The raw area of the nasopharynx was reconstructed with a nasoseptal flap. NS, nasoseptal flap.

- Once the parapharyngeal tissue is mobilized medially, the Eustachian tube cartilage can be divided close to the bony canal.
- Care must be taken not to bring the dissection too far laterally, as the ICA is located only a few millimeters lateral to the bony Eustachian canal.
- If a 30-degree telescope is used, it can be rotated to improve the lateral view when dissecting in the PPS.
- The prevertebral muscles insert into the inferior aspect of the clivus and in the superior aspect of the nasopharynx. The mucosa of the nasopharynx attaches directly to the periosteum of the clivus bone. The Maryland forceps are used to grasp the edge of the incision in the mucosa of the nasopharynx, and the monopolar spatula can be used to mobilize the mucosa of the nasopharynx off the clivus using blunt and sharp dissection down toward the cancer.
- The dissection converges toward the center of the resection specimen, and the entire specimen can be delivered through the oral cavity.

- Combined with endoscopic resection
  - Cancers situated in the roof of the nasopharynx or extending to the sphenoethmoidal recess will require removal of the floor and anterior wall of the sphenoid sinus.
  - This part of the resection is performed with endoscopic instruments. The inferior dissection is performed with the surgical robot, and the

specimen is left attached to the roof of the nasopharynx. The surgical robot is then undocked, and conventional endoscopic endonasal instruments are used for the second part of the dissection.[5] The anterior wall of the sphenoid sinus and the rostrum is then removed using a Kerrison rongeur or endoscopic bur until the specimen is freed from its superior attachment and removed.

FIG. 42.12 The appearance of the palate following the right lateral palatal flap approach.

- Mucosal margins should be harvested from the edge of the resection and sent for frozen section analysis. Further resection should be attempted if the frozen section analysis reports suspicious or positive margins.

- Coverage of the surgical field
  - Coverage of the nasopharynx is important in order to prevent osteoradionecrosis. Osteoradionecrosis is difficult to manage and severely impacts the patient's quality of life. Conventionally, the raw areas are covered with a free graft using mucosa of the inferior turbinate.
  - To improve the reliability of the coverage, an NS flap can be harvested and rotated inferiorly to cover the raw clivus bone.[6] Fig. 42.11 demonstrates the nasopharynx reconstructed with an NS.
  - The flap should be secured in place with a nasal tampon or urinary catheter balloon placed in the post-nasal space for 3 to 5 days.

- Closure of palatal wound
  - Closure of the palatal wound is important to restore normal function of the palate and to prevent formation of a palatal fistula.
  - Holes should be drilled in the posterior edge of the hard palate and sutures placed through them so that the soft palate can be reattached to the hard palate. The palatal wound should be closed with absorbable sutures in three layers, the nasopharyngeal mucosal layer, the muscular layer, and the soft palate mucosal layer.
  - For the lateral palatal flap technique, the tensor veli palatini muscle should be re-approximated carefully to restore the muscular function of the soft palate. A feeding tube should be inserted for nutritional support. Fig. 42.12 shows the closure of the palatal incision at the conclusion of the operation.

Operative Risks

- Bleeding from pterygoid venous plexus—Bleeding from the venous plexus is better controlled with bipolar cautery from the bedside surgeon. Alternatively, temporary packing and use of hemostatic agents can stop the bleeding.
- Injury to ICA—If ICA injury is suspected or has occurred, the procedure should be terminated, and an angiogram should be performed. The carotid injury is then managed by angiographic approach by the interventional radiologist.
- Upper airway obstruction from soft tissue swelling—The patient should not be extubated immediately after the procedure. Instead, the upper airway should be observed for any signs of swelling. If swelling is present, a tracheostomy should be performed. Alternatively, the patient can be left intubated and observed in the ICU for a period of time before extubation.

Common Errors in Technique

- Failure to employ a split palate approach—Although it is tempting to perform the surgery without splitting the palate, a palatal suspension technique is only feasible in very favorable anatomy and a central

cancer in the inferior aspect of the nasopharynx. A split palate approach will markedly improve the visualization of the cancer and increase the space for the manipulation of the robotic arm.

- Failure to use a 30-degree telescope—0-degree telescope gives a more direct view and is easier for the less experienced in manipulating the robotic instruments. The 30-degree telescope offers visualization around the corners like the viewing around medial pterygoid plates. Be prepared to switch to a 30-degree telescope when operating in the PPS.
- Failure to close the palatal incision properly in three layers—Careful closure of the soft palate incision in three layers (both mucosal layers and the muscle layer) is important to restore the palatal movement and prevent palatal fistula formation. The patient should also have nothing by mouth for 7 to 10 days to allow the wound in the palate to heal.

Postoperative Period

Postoperative Care

- Patients whose soft palate has been divided should be kept Nil per oral (NPO) and fed through a feeding tube for 7 to 10 days until the soft palate has healed completely.
- Antibiotics are given until the nasal packing is removed.
- After the nasal packing is removed, the patient should be instructed to perform nasal irrigations regularly using normal saline.
- Gentle endoscopic cleaning of the nasopharynx should be performed by the surgeon every 1 to 2 weeks until the nasopharynx has completely epithelized.
- Dissection around the medial pterygoid muscle can lead to fibrosis and trismus. Mouth opening exercise should be started in the early postoperative period. An assistive device like Therabite (Atos Medical Inc., Sweden) can help patients to achieve optimal mouth opening.

Complications

Intraoperative Complications

- Injury of the ICA is the one of the most serious complications. It will be impossible to control bleeding from the ICA with robotic techniques, and the surgeon has to rely on packing and angiographic techniques to control the bleeding. Conversion to an open nasopharyngectomy approach is also time consuming.
- As the surgeon is unable to palpate for the ICA in the PPS, identifying the location of the ICA in robotic nasopharyngectomy is more difficult than open nasopharyngectomy. Therefore, to prevent inadvertent ICA injury, in cases selected for robotic nasopharyngectomy, the cancer should not be in proximity to the ICA, preferably more than 1 cm away.
- The other source of bleeding is venous bleeding from the pterygoid plexus in the medial pterygoid muscles. This type of venous bleeding can be troublesome to control and can give rise to significant blood loss. Bipolar cautery by the bedside surgeon or with the 8-mm bipolar Maryland forceps can usually stop the bleeding.
- Alternatively, packing with adrenaline-soaked gauze can reduce the blood flow and allow accurate application of cautery. Application of hemostatic agents such as fibrin glue can also be helpful in stopping venous bleeding.
- Inadvertent injuries to the structures in the oral cavity such as the teeth and the lips can occur if the surgeon is not careful during the procedure. The bedside surgeon should also be vigilant in observing any movements of the robotic instruments that can cause injury and warn the console surgeon as the console surgeon would not be aware of the movements of the robotic instruments outside of the oral cavity.
- Edema of the airway and tongue is a potential life-threatening complication in any transoral robotic procedure. Patients undergoing a robotic nasopharyngectomy are especially at risk as they usually have had prior radiation therapy and the procedure typically takes 3 to 4 hours, longer than robotic oropharyngectomy.
- Retraction on the tongue should be released during procedures that do not require tongue retraction such as elevating NS or drilling out the

sphenoid sinus.

- At the conclusion of the procedure, the surgeon and the anesthetist should inspect the airway together and decide whether or not to proceed to extubation. If there is any concern about the adequacy of the airway, the patient should be kept intubated overnight, or a tracheostomy should be performed.

Long-Term Complications

- Palatal wound dehiscence and fistula formation. To prevent the formation of a palatal fistula, the soft palate wound should be carefully approximated in a three-layer, tension-free closure. The patient should be kept NPO and avoid excessive swallowing for a period of time to prevent dehiscence of the palatal wound.
- If the dehiscence is detected early, it can be repaired primarily; otherwise, a palatal fistula may need a rotational mucosal flap to repair it after the palate has healed.
- Even in the absence of a palatal fistula, patients may experience minor velopharyngeal incompetence especially when drinking fluids. This is due to the retraction of the soft palate during the surgery.
- Osteoradionecrosis of the skull base is a serious complication after nasopharyngectomy in patients who have had radiation to the nasopharynx. Osteoradionecrosis of the skull base is difficult to treat, and every effort should be made to prevent its occurrence.
- Exposing bone during the resection should be avoided, and a cuff of prevertebral muscles should be left covering the inferior aspect of the clivus and C1-C2 if the tumor has not grossly invaded the prevertebral muscles.
- Coverage of the raw surface of the clivus with an NS is better than coverage with a free soft tissue graft.
- The surgeon should clean the operative site regularly and débride the necrotic tissue and crusts in the nasopharynx to prevent local infection.
- Otitis media with effusion can occur if the Eustachian tube is resected.

Alternative Management Plan

- Nasopharyngectomy via endoscopic endonasal approach—Cases suitable for robotic nasopharyngectomy are also amendable to extended endoscopic resection. The advantages of robotic surgery will be lost, but the cost would also be lower. This approach requires a team of surgeons experienced in extended endoscopic nasal surgery.
- Nasopharyngectomy via various open approaches—For recurrent cancers that are contraindicated for robotic surgery, the cancers may still be amendable to resection via open approaches. The major advantage of open approaches is the better localization of the internal carotid artery and control of bleeding in case of catastrophic hemorrhage.
- Second course of radiotherapy—A second course of radiotherapy for treatment of recurrent NPC is possible with tolerable toxicities especially if the patient was treated more than 1 year previously and was treated with advanced three-dimensional techniques such as intensity-modulated radiotherapy (IMRT). The complication of a second course of radiotherapy is increased radiation toxicities. One wonders about the propriety of using a treatment modality for a second time that did not cure the cancer the first time. Surgical treatment avoids the additional radiation toxicities and thus should be considered unless the patient is not suitable for surgery.

Evidence-Based Question

How does robotic nasopharyngectomy compare with endoscopic nasopharyngectomy in terms of local control and morbidities?

Robotic surgery in the head and neck should be considered an extension of endoscopic head and neck surgery, in which the surgical robot improves the dexterity of the endoscopic surgeon by adding back the degrees of freedom of movements lost in conventional endoscopic surgery. This is the same for robotic nasopharyngectomy. There are no randomized trials comparing robotic versus endoscopic nasopharyngectomy, and there is only one case series reporting the early results of robotic nasopharyngectomy.[7] The local control rate in either

operation is comparable.

In terms of morbidities, both operations should be similar except for the complications from a palate split that may be necessary in some transoral robotic approaches. Robotic nasopharyngectomy tends to be faster as the robotic arms confer additional dexterity.

These operations are not mutually exclusive. The transnasal endoscopic approach is complementary to the transoral robotic approach in most cases as the superior aspect of the cancer is better approached from the nasal cavities, and bone removal tools are only available for the endoscopic approach. The robotic approach then can be used to remove the inferior and lateral part of the cancer with the additional advantages offered by the surgical robot.

Editorial Comment

The case selection of robotic nasopharyngectomy is similar to endoscopic nasopharyngectomy, and the survival outcome should be comparable. As robotic nasopharyngectomy is a relatively new procedure, and there are limited cases suitable for robotic nasopharyngectomy, the literature on outcomes of robotic nasopharyngectomy is rare. There is only one case series of 12 patients with short follow-up. The estimated 2-year local control rate was 86% and 2-year overall survival was 83%.[7] This is similar to the results of most endoscopic nasopharyngectomy series.[8]

The current generation of surgical robots is not designed for head and neck surgery and is too bulky to work in the head and neck area. A surgical robot called the Medrobotic Flex System has recently become available. It is designed with flexible and smaller arms that may be adapted for head and neck surgery application, including robotic nasopharyngectomy. To date, early preclinical trials of these new generation robots have shown promising results.[9,10] In the future, with smaller flexible robots, a robotic nasopharyngectomy may be performed without the need to split the soft palate, reducing the morbidity of the operation.

Review Questions

1. Which of the following is not an indication for robotic nasopharyngectomy?

   a. Small recurrent NPC in the midline but invading the sphenoid floor

   b. Small recurrent NPC confined in the left fossa of Rosenmüller

   c. Two-centimeter benign salivary gland tumor in the nasopharynx without extending to the PPS space

   d. **Recurrent NPC in the left PPS involving the foramen rontondum**

2. Which of the following is a complication after robotic nasopharyngectomy?

   a. **Palatal fistula**

   b. Nasal obstruction

   c. Ectropion

   d. Nonunion of osteotomy

3. Which of the following investigations is NOT necessary before deciding for robotic nasopharyngectomy for recurrent NPC?

   a. Contrast CT scan of the nasopharynx

   b. Contrast MRI scan of the nasopharynx

   c. **HPV status of the original cancer**

   d. Biopsy of the suspected lesion

Maxillary Swing/Transpalatal/Midface Degloving With Le Fort I Osteotomy Approach for Nasopharyngectomy

Sheng-Po Hao

Introduction

Nasopharyngeal carcinoma (NPC) is a squamous cell carcinoma of an undifferentiated type. This cancer is endemic among Chinese, having the highest incidence of 10 to 20 per 100,000 for men and 5 to 10 per 100,000 for women. It is sometimes called the "Cantonese Cancer" because of its prevalence as one of the most common cancers of the head and neck among Chinese. The most common site of origin of NPC is from the epithelial lining of the area posteromedial to the medial crura of the Eustachian tube opening in the nasopharynx, which is also called the fossa of Rosenmüller.[1]

Several serologic markers have become useful as a means of screening, diagnosing, and monitoring NPC after establishing that it is closely related to the Epstein-Barr virus (EBV), a double-stranded DNA virus. NPC has since become a model for EBV viral carcinogenesis after studies showed that most NPC cancer cells express EBV proteins and carry the clonal EBV genomes. Screening in the general population can now be done using serologic markers, such as EBV VCA immunoglobulin A (IgA) and DNase, whereas reverse transcription polymerase chain reaction (RT-PCR) methods measure EBV DNA copy numbers in plasma to monitor treatment response and early detection of local recurrence.

To summarize:

1. For general population screening, serologic diagnosis can be made using EBV VCA IgA.

2. For early detection of local recurrence, a nasopharyngeal swab should be taken for LMP-1 gene detection.

3. For monitoring treatment response and to detect possible recurrence, RT-PCR–based plasma cell–free EBV DNA detection should be used.

4. Currently available therapeutic modalities for NPC are radiation therapy (RT), chemotherapy, or a combination of both. Effective local control is more than 80% using the current RT techniques because of the high radiosensitivity of NPC. A high cure rate is seen among patients with early-stage cancer who undergo RT. Cisplatin-based chemoradiotherapy with or without neoadjuvant chemotherapy has demonstrated significant survival improvement and is currently the standard treatment strategy for patients with advanced locoregional disease.[1]

Despite being a radioresponsive tumor, 10% to 30% of NPC patients develop local failure in the nasopharynx after the initial RT treatment. Whether it is persistence or recurrence after the initial radiation therapy (RT)/concurrent chemoradiation therapy (CCRT), salvage nasopharyngectomy is the treatment of choice. Proceeding with a second course of RT will only expose the patient to the risk of developing osteoradionecrosis (ORN) of the skull base, a potentially fatal complication of high-dose RT, without any assurance that the previously treated NPC cells will respond. Salvage nasopharyngectomy results in better outcomes than most of the published literature on re-radiation.

However, nasopharyngectomy requires skill and training and has posed a real challenge for head and neck surgeons. With the advances in skull base surgery, it is now possible to effectively control NPC recurrence or persistence using salvage nasopharyngectomy with acceptable mortality and morbidity.[2]

Key Operative Learning Points

- Try to preserve or reestablish the blood supply to the bone when performing a facial bone disassembly.
- Perform a medial maxillectomy and posterior septectomy to improve exposure and increase the area of working space.

- During resection, the deep margin is marked by the pharyngobasilar fascia while making sure to remove as lateral as possible including the Eustachian tube cartilage.
- Depending on the extent of the cancer, several different approaches may be used.
- The use of rigid three-point bone segment fixation may prevent nonunion or ORN.

Preoperative Period

Local failure (persistence and recurrence in the nasopharynx) occurs in 16% to 48% of patients with NPC after initial RT. Salvage nasopharyngectomy has become the mainstay of treatment after RT failure, and the key to a successful surgery is proper patient selection. Preoperative period is essential to ensure that the patient is eligible for salvage nasopharyngectomy.

Before proceeding with nasopharyngectomy, all patients require thorough medical history including medical status, physical examination, as well as endoscopic examination. Firstly, it must be established that (1) these patients do have local recurrence or persistent NPC by performing biopsy(s) of the primary site, (2) ultrasound and possible guided fine-needle aspiration biopsy for any suspicious regional recurrence should be used, and (3) there is no distant metastasis. It is advisable to use Positron emission tomography–computed tomography (PET-CT) to exclude the possibility of distant metastasis. MRI with its excellent soft tissue resolution may also be used to evaluate the extent of the cancer and help to plan the surgical approach accordingly.

Other important preoperative preparation includes blood group and matched packed cells and preoperative antibiotic. Patients with pre-existing significant comorbidities should receive special attention. Anticoagulants or antiplatelet medications should be withheld (if possible) before salvage nasopharyngectomy.

History

1. History of present illness

a. Nasal symptoms: blood-stained nasal discharge, nasal blockage

b. Aural symptoms: ear blockage, hearing loss, and otorrhea

c. Mass in the neck

d. Skull base and cranial nerve involvement

1) Intractable headache

2) Sixth cranial nerve involvement, which will result in abducens palsy

3) Unilateral facial numbness from involvement of the fifth cranial nerve

e. Symptoms suggesting distant metastasis

f. Weight loss, nutritional status

g. Smoking

2. Past medical history

a. Previous radiotherapy with or without chemotherapy

b. Previous surgery for NPC

c. Pulmonary disease, hypertension, diabetes, or ischemic heart disease

d. Immunosuppression (e.g., acquired immunodeficiency syndrome [AIDS])

3. Medications

a. Anticoagulants

b. Allergies to antibiotics or analgesia

Physical Examination

1. Nasal cavity and nasopharynx

a. Endoscopic examination of the nasopharynx may reveal a mass in the fossa of Rosenmüller and sometimes a small submucosal swelling.

b. Determine extent of the cancer.

1) Lateral extension

a) Eustachian tube

b) Torus tubarius

2) Roof of nasopharynx and posterior choanae

3) Inferior extension to oropharynx

2. Examination of the neck

a. Palpate both sides of the neck for the presence of cervical metastases.

3. Examination of the skull base and cranial nerves

4. Trismus

a. Anticipate difficult intubation. May require a tracheostomy

5. Examination of the ears

a. Middle ear effusion

6. Examine oral cavity, pharynx, and larynx for synchronous primaries.

7. General health

a. Nutrition

b. Cardiovascular

c. Respiratory

d. Abdominal

Imaging

1. Magnetic resonance imaging (MRI)

a. Superior soft tissue resolution and tumor delineation

1) Parapharyngeal space or infratemporal fossa

2) Intracranial extension

3) Perineural invasion

4) Deep invasion to the vertebral body

5) Vascular involvement (carotid artery, cavernous sinus)

b. Presence of cervical metastasis

2. PET-CT scans
    a. Restaging
    b. Exclude cervical metastasis.
    c. Exclude distant metastasis (bone, lung, liver).
3. CT scan
    a. Not required in all cases
    b. MRI is preferred, if available
4. Chest radiograph
    a. Lung metastases
    b. Pulmonary and cardiac status
5. Ultrasound of the liver

Indications

- Recurrent cancer confined to the nasopharynx
- Modified/classical facial translocation for cancer with lateral extension medial to the foramen ovale
- Combined preauricular infratemporal subtemporal approach together with a transfacial/facial translocation approach for rNPC extend lateral to the foramen ovale and into the parapharyngeal space. (It is usually difficult to achieve a sound oncologic resection [no safety margin], and thus a second course of combined chemoradiation therapy might be a better option.)[3]

Contraindications

- Patients with proven distant metastasis
- Cancer involving the dura.
- Encasement of the petrous part of the internal carotid artery

Preoperative Preparation

1. Multidisciplinary team evaluation
   a. Otolaryngologist—head and neck surgeon
   b. Oncologist
   c. Anesthesiologist
   d. Nutritionist (if necessary)
2. Physician
   a. If required optimizing medical illness (cardiopulmonary disease)
3. Confirm the histopathologic report before definitive surgery.
4. Review the radiologic imaging (PET-CT and MRI) for planning of resection of the cancer and surgical approach.
5. Treat sinusitis if present.
   a. A bacterial culture of nasal secretion is obtained and culture-directed antibiotics prescribed for at least 7 days.
   b. Perform frequent nasal douching with saline before surgery.
6. Postoperative high dependency care (depending on the center)
7. Discontinue antiplatelet drugs if possible.

Operative Period

Anesthesia

- All salvage nasopharyngectomy operations are performed under general anesthesia.
- Endotracheal intubation through the oral cavity
- Fiberoptic-guided intubation may be needed for patients presenting with trismus.
- In rare circumstances, tracheostomy should be considered in patients with severe trismus.

Positioning

- The patient is placed in the supine position.
- The head is turned to the contralateral side and slightly extended.

Perioperative Antibiotic Prophylaxis

- Clean-contaminated surgery
- Prophylaxis intravenous antibiotics should be administered 2 hours before surgery based on the bacterial culture result (if available).
- Choice of intravenous antibiotic may differ among surgeons, but a broad-spectrum antibiotic with good cerebral spinal fluid (CSF) penetration is recommended.
- Succeeding doses of intravenous antibiotics can be given every 6 hours if the surgery lasts longer.

Monitoring

- Routine anesthesia monitoring
- Hypotensive anesthesia (to reduce intraoperative bleeding that will obscure operative field)
- Prevent hypothermia by using intraoperative warm-air blanket.
- Maintain fluid balance and hemoglobin level.

Instruments and Equipment to Have Available

The different open approaches to the nasopharynx require dissection through soft tissue and facial bones. The instruments and equipment required to carry out a successful surgery are:

1. Excision set

2. Sinuscope set (0- and 30-degree Hopkins telescopes)

3. Osseous set with oscillating saw, burr, and reconstructive plate and screws

4. Skull base set including Kerrison rongeurs, forceps, curettes, tru-cutting instruments, and dissectors

5. Cutting and diamond burrs

6. Contact LASER set with curved applicator

7. Bipolar cauterization set

Surgical Anatomy

- The nasopharynx, a hollow cubic space above the soft palate and posterior to the nasal cavity
- The most cephalad portion of the upper aerodigestive tract
- Lined by pseudostratified ciliated columnar epithelium
- Boundaries:
  - Superior: sphenoid sinus and upper clivus
  - Posterior: lower clivus and the body of the first cervical vertebra
  - Lateral: medial pterygoid plate (formed by an incomplete cartilaginous ring with a natural defect inferolaterally called the sinus of Morgagni).
  - Anterior: communicates with the posterior nasal choanae
  - Inferior: communicates with the oropharynx
- The posterior and lateral wall of the nasopharynx are demarcated by the pharyngobasilar fascia, a dense and tough fascia that originates from the pharyngeal tubercle of the occipital bone posteriorly and inserts anteriorly into the posterior sharp end of the medial pterygoid plate (serves as a good barrier to the spread of NPC).
- It continues inferiorly as the buccopharyngeal fascia.
- The spread of NPC
  - Superiorly: floor of the sphenoid sinus and invades the sphenoid sinus and skull base
  - Laterally: through the sinus of Morgagni, extending along the Eustachian tube toward the base of the pterygoid plate and into the

parapharyngeal space, eventually gaining access into the area of the foramen ovale

- NPC that spreads laterally to the foramen lacerum may involve or encase the petrous internal carotid artery, which would then prevent complete resection of the recurrent cancer.[3]

Prerequisite Skills

- Surgeons should be familiar with development and elevating a skin flap, as well as osteotomies.
- Basic skills to manage intraoperative bleeding in a relative narrow and deep space are mandatory.

Operative Risks

Because the nasopharynx is closely related to the cavernous sinus, internal carotid artery, and dura, iatrogenic injury to these vital structures can be life threatening and render the nasopharyngectomy some operative risks with potentially devastating consequences.

Surgical Technique

Salvage nasopharyngectomy has been the mainstay of treatment after radiation failure. Various surgical approaches to the nasopharynx have been developed, such as transpalatal, midface degloving/Le Fort I osteotomy, transfacial/facial translocation/transmaxillary, mandibulotomy, transpterygoid, and infratemporal fossa approaches.

Intraoperative Evaluation and Preparation After Patient Has Been Intubated

- Ensure that the nasal cavities are properly decongested and anesthetized using cotton pledgets soaked in epinephrine with a 1:100,000 dilution for 15 minutes.
- Inspect the nasopharynx carefully using a rigid endoscope to examine the entire cancer and make a good surgical plan.

- Infiltrate the planned facial incisions, mucoperichondrium of the nasal septum, middle and inferior turbinates, and the area around the cancer using a combined solution of 1% lidocaine and 1:80,000 epinephrine.

Le Fort I Osteotomy via Midfacial Degloving Operative Technique

The steps for this technique are as follows:

1. Standard transfixion incision from the tip of the nose inferiorly to the nasal floor

2. An intercartilaginous incision is placed and extends laterally beyond the margin of the upper lateral cartilages and connects medially with the transfixion incision. Circumvestibular release is completed with a full-thickness incision at the pyriform aperture and nasal floor up to the periosteum.

3. Separate the dorsum of the nose and upper lateral cartilages by dissecting through the intercartilaginous incisions using a Freer elevator.

4. Make a horizontal incision above the gingivobuccal sulcus from one maxillary tuberosity to the other then elevate the periosteum, exposing the anterior and lateral maxillary walls.

5. Extend the dissection to the edge of the piriform aperture and to the incisions placed intranasally to allow elevation of the upper lip together with the tip of the nose. Maintain a cuff of mucosa to allow easy closure of the gingiva.

6. Dissect the soft tissues up to the infraorbital rim, exposing and identifying the infraorbital nerve, lateral maxillary wall, piriform aperture, and the zygomatic pillar of the maxilla. The infraorbital nerve is preserved unless it is involved by the cancer. Mobilization of the soft tissues can be extended superiorly up to the nasofrontal angle and glabellar area.

7. Place titanium miniplates over the bony maxilla, prefolded; then screw holes are made.

8. Perform a horizontal maxillary osteotomy starting anteriorly from the piriform aperture toward the lateral wall of the maxilla and the

zygomatic pillar.

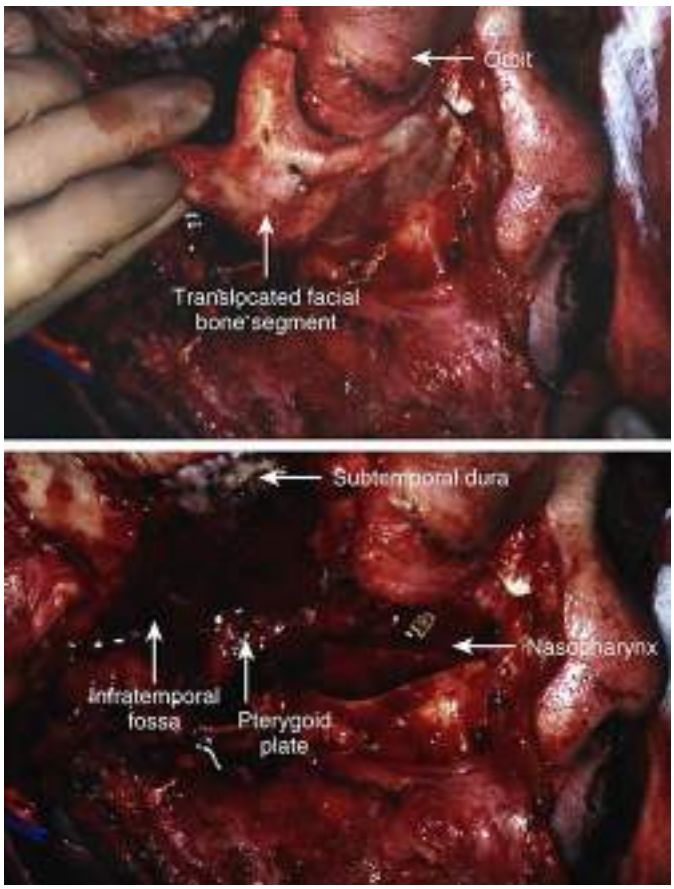

FIG. 43.1 With elective temporary disassembly of the facial skeleton, the facial translocation approach provides an excellent surgical exposure of the nasopharynx and skull base, to facilitate extensive resection of tumors. Upper arrows indicate orbit and translocated facial bone segment. Lower arrows indicate horizontal: upper-subtemporal, dura, lower-nasopharynx; vertical: lateral-infratemporal fossa, medial-pterygoid plate.

9. Separate the nasal septum from the anterior nasal spine and maxillary septal crest using a sharp osteotome while avoiding laceration of the nasal mucosa.

10. An osteotomy is then performed to separate the maxilla using a sharp chisel from the piriform aperture posteriorly to the pterygoid plates and palatine canal vessels passing through the inferior meatus.

11. Finally, downfracture the maxilla.

12. Dissection is limited laterally by the pterygoid and temporal muscles; posteriorly by the clivus, posterior wall of the sphenoidal sinus, and the greater wing of the sphenoid bone; and superiorly by the anterior cranial fossa.

13. After excision of the tumor, the bony buttresses are approximated using wiring or titanium plates and 4 weeks of intermaxillary fixation.

Facial Translocation Approach

The technique of developing a lateral nasal wall mucoperiosteal flap in the modified facial translocation approach:

1. Infiltrate the nasolabial groove using a solution of 1% lidocaine mixed with 1:100,000 epinephrine and proceed with a lateral rhinotomy incision.

2. The incision is placed along the nasal ala without involvement of the nostril and is carried down in a stepwise fashion.

3. As the incision is developed, stop first at the medial edge of the maxillary bone, making sure to preserve the mucoperiosteum of the lateral nasal wall. Do not transect the full thickness of the lateral nasal wall while gaining access into the nasal chamber and dividing the feeding vessels.

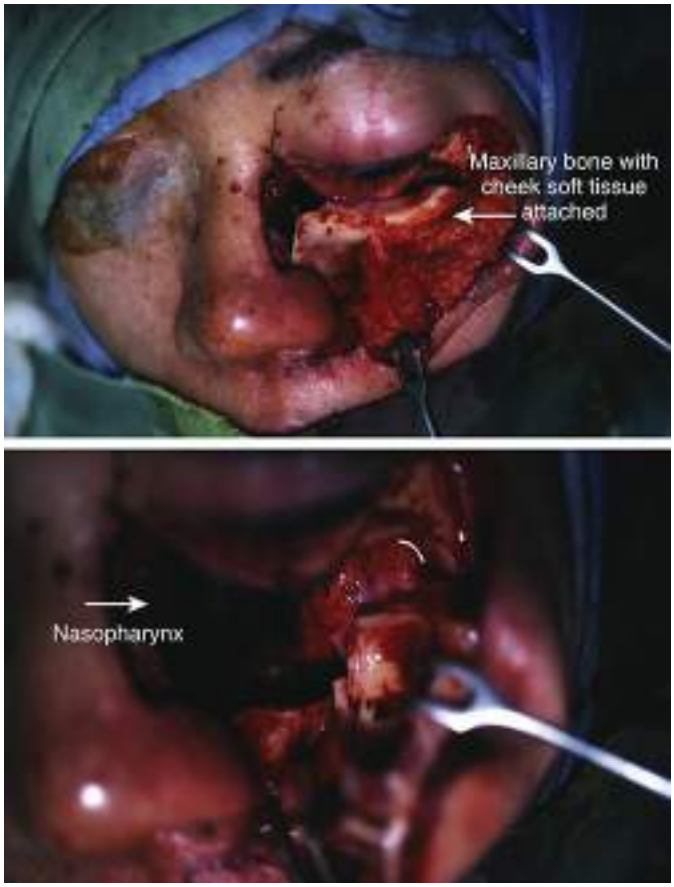

FIG. 43.2 In the maxillary swing approach, the maxilla is left attached to the cheek soft tissue to retain its blood supply, and the facial soft tissue and bone are swung laterally to expose the paranasal sinuses, nasopharynx, and skull base. Upper arrows indicate maxillary bone with cheek soft tissue attached. Lower arrows indicate nasopharynx.

4. Using a Cottle elevator, gently elevate the mucoperiosteum of the lateral nasal wall from the lateral bony wall of the maxilla. Continue elevating the mucoperiosteum posteriorly toward the posterior end of the inferior turbinate, superiorly toward the middle turbinate until the natural orifice of the maxillary sinus is reached, and inferiorly to the nasal floor (Figs. 43.1, 43.2).

5. Perform an osteotomy along the nasal bone, anterior wall of the maxilla, and possibly the lateral wall of the maxilla and orbital floor. Temporarily remove the facial bone segment and proceed with a medial maxillectomy (see Fig. 43.3).

6. Remove the medial bony maxillary wall to access the maxillary sinus. After removing the posterior wall of the maxillary sinus, further exploration of the nasopharynx and skull base can now be done (Fig. 43.4).

7. The anteriorly based lateral nasal wall mucoperiosteal flap is developed after dividing the mucosal attachment with the surrounding soft tissues. Ensure that the neck of the developed mucoperiosteal flap that connects it to the anterior nasal soft tissues is as broad as possible (Fig. 43.5).

8. The lateral nasal wall mucoperiosteal flap is then delivered anteriorly for better exposure. After removing the inferior turbinate mucoperiosteum off the concha, partially remove the inferior turbinate bone.

9. After the skull base tumor is excised, this lateral nasal wall mucoperiosteal flap is transferred to cover the defect and placed against the inner surface of the translocated bone graft.

FIG. 43.3 Modified facial translocation I: lateral rhinotomy incision and facial osteotomy.

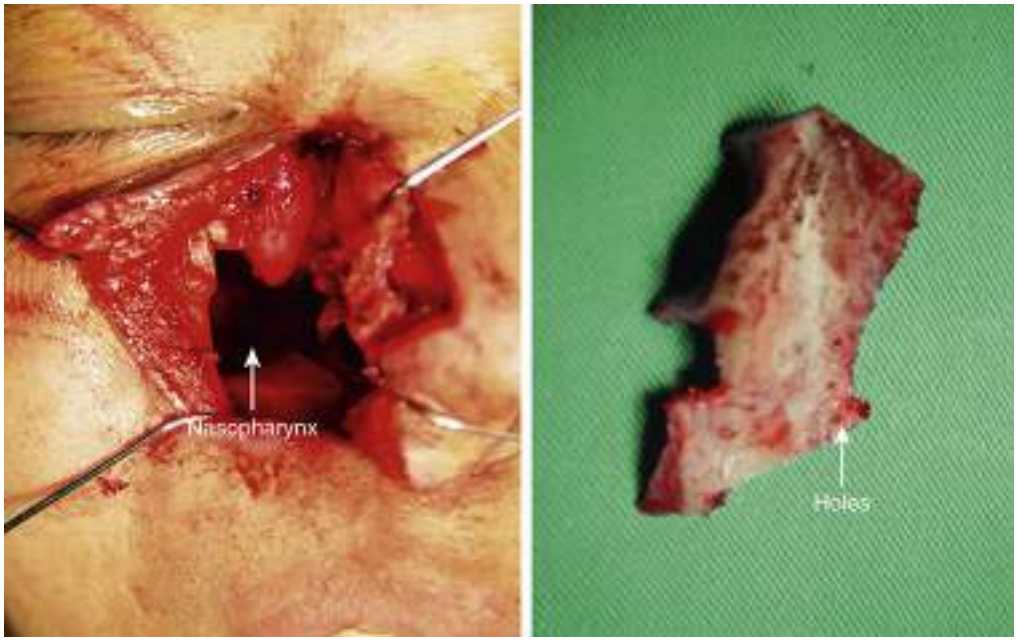

FIG. 43.4 Modified facial translocation II: medial maxillectomy to approach nasopharynx. Holes are created along the free edge on the temporary removed bone segment, ready to suture the flap against the bone. Left: arrows indicate nasopharynx and right: arrows indicate drilling hole.

10. Attach the flap to the translocated facial bone segment using meticulous suturing via drilled holes placed in the bone graft. Reassemble the translocated bony segment with the remaining facial skeleton using fixation with microplates (see Fig. 43.5).

11. Close the lateral rhinotomy incision.

12. Place a Foley catheter into the hollow sinoparanasal space and inflate to provide additional support to the mucoperiosteum flap against the translocated facial bone segment.

13. Remove the Foley catheter after two days.

By using the soft tissues of the cheek and the transposed lateral nasal wall mucoperiosteal flap to cover the translocated facial bone segments, this method of the modified facial translocation technique will assist in the revascularization of the bone segments and prevent necrosis even during RT. This modification allows resurfacing of the bone segments' inner defect, improving its viability even in rNPCs that have been

heavily irradiated, without interfering with the detection of early local recurrence.

Common Errors in Technique

Viability of the Translocated Facial Bone Graft

- The vascular supply of the disassembled bone fragments is maintained by keeping the osteotomized bone fragment attached to the soft tissues of the cheek, similar to the maxillary swing approach.
- Devascularized free bone graft, after the soft tissue is elevated, increases the risk of developing ORN after RT.
- Preserving the attachment of the bony fragments to the soft tissues might be technically difficult, especially after removal of the anterior wall of the maxillary sinus in the previous lateral rhinotomy or Caldwell-Luc surgery. In addition, accidental injury to the internal maxillary artery may occur during the osteotomy of the lateral wall that is usually performed in a blind method. Injuring the internal maxillary artery causes profuse bleeding that may be difficult to control unless the translocated facial bones are removed as a free bone graft.

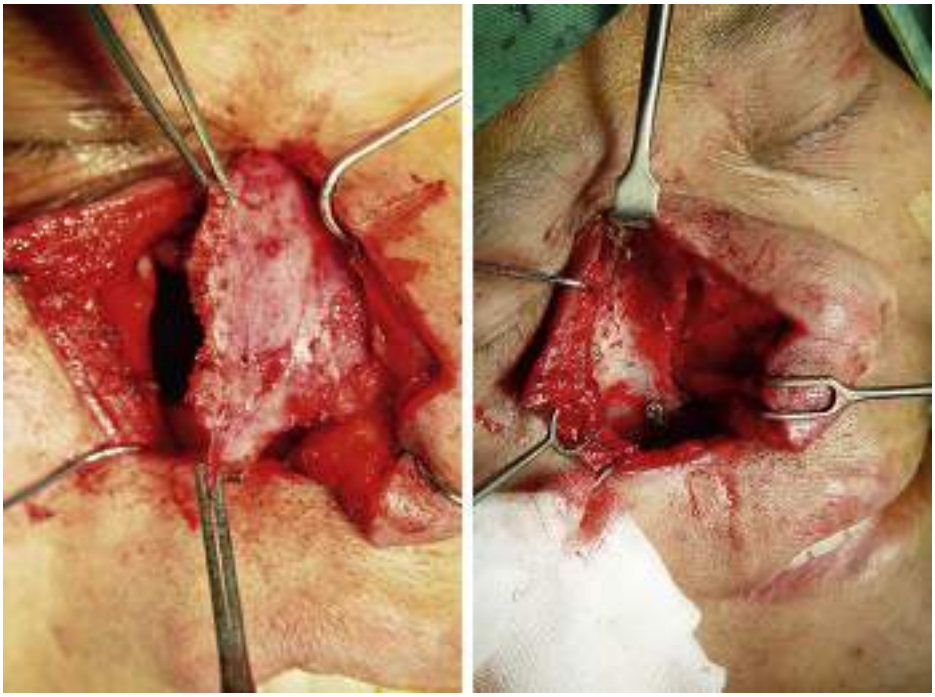

FIG. 43.5 Lateral nasal wall flap is developed and transposed to reconstruct the inner defect of the translocated bone. The bone segment is secured with a three-point fixation to the remaining facial bone.

- The inner defect of the translocated bone segment may be reconstructed using a vascularized soft tissue flap to decrease the risk of developing bone graft necrosis after RT.

Modified Facial Translocation

- Several technical modifications to the facial translocation approach have been improved to avoid bone graft necrosis, such as:
  - Three-point fixation to secure and immobilize the facial bone graft to avoid microtrauma that would interfere with bone union
  - The facial bone unit is secured to the facial soft tissue by suturing the cheek soft tissue flap to the drilling holes of the facial bone unit in free bone graft technique.
  - The lateral nasal wall can be preserved and transposed to resurface the inner aspect of the translocated facial bone unit if it is far away from the tumor and remains free of disease.

Postoperative Period

- The patient is monitored for any complications.
  - Bleeding
  - Intracranial hemorrhage
  - Meningitis
  - Pneumocranium or tension pneumocephalus
  - CSF leak
- Usually no need for intensive care unit (ICU) care unless a combined neurosurgical resection is carried out
- A compression dressing should be applied to the facial incisions for 24 hours to prevent postoperative edema.
- The inflated Foley catheter can be removed after 24 to 48 hours.
- Intravenous antibiotics should be continued for at least 48 hours, after which it may be shifted to the oral form.
- The patient can be discharged from the hospital after 48 hours if there are no complications.
- Careful instructions are given to the patients regarding irrigation of the nasopharyngeal cavity after the seventh postoperative day.
- Nasal irrigation should be continued for 3 to 6 months to allow the mucosa to re-epithelialize.

Complications

- There was nearly no surgical mortality, and the immediate surgical morbidity is reported between 13.2% and 22%.
- Common complications encountered are:
  - Bleeding
  - Infection
  - ORN

- Bone necrosis of the nasopharynx, facial bones, and skull base
- Self-irrigation to keep a good local hygiene is mandatory to prevent the ORN.

Alternative Management Plan

Re-irradiation with or without chemotherapy

Discussion

Evidence-Based Medicine Questions

The maxillary swing or the midface degloving provides excellent anterior approaches to the nasopharynx. Both approaches are suitable for cancer confined to the nasopharynx with limited extension to the parapharyngeal space. The maxillary swing approach, introduced in 1991, allows the anterior and lateral part of the cancer to be visualized clearly. The contralateral nasopharynx can also be approached by removing the posterior part of the nasal septum. With such adequate exposure, en bloc removal of the cancer with wide margins is feasible. At the same time, the petrosal part of the internal carotid artery can be controlled if necessary. The midface degloving approach involves degloving the midface, bilateral medial maxillectomies, and dislocation of the nasal septum without any facial incision needed.

In both midface degloving, as well as the maxillary swing, the superior exposure of the cancer is lacking and limited inferiorly by the hard palate. Cancer involvement to the pterygoid plate or the foramen ovale area requires a combined neurosurgical approach, such as subfrontal approach for superior exposure of the cribiform plate, fovea ethmoidalis, and planum sphenoidale.[4] When combined with a subtemporal approach, a lateral extension of NPC to the sphenoid ridge and foramen ovale area can be resected.[2]

For both the approaches, there is no significant difference in 5-year local progression-free survival, locoregional progression-free survival, and overall survival rates. However, for subgroup T1 and T2 tumors, the maxillary swing approach is associated with better survival rates than

the midfacial degloving approach when used to perform a salvage nasopharyngectomy.[5]

Editorial Comment

Le Fort I Osteotomy via Midfacial Degloving Operative Technique

Midfacial degloving was first introduced in an attempt to preserve as much functional tissue as possible without cosmetic deformity while still allowing adequate exposure of bilateral maxillary and lower nasal cavity. It was first introduced as a facial degloving procedure by Portmann in 1927 but was used for excision of neoplastic diseases by Conley and Price. It is a versatile technique with the advantage of allowing excellent bilateral exposure of the bony structures of the midface, while avoiding any skin incisions, and with a low complication rate. It also tolerates better the ischemic and cicatrizing effects of radiation because it allows preservation of the vascular and lymphatic vessels of the soft tissues of the face. Midfacial degloving approach can be combined with the following Le Fort I osteotomy approach for nasopharyngectomy.

The Le Fort I osteotomy is a procedure that provides safe exposure for cancers located in the nasopharynx and skull base while providing superior cosmetic results by avoiding facial scars. Von Langenbeck first described it in 1861 and in 1867 by Cheever for a pterygopalatine fossa tumor and nasopharyngeal tumor, respectively. Several complications include malocclusion, hemorrhage, and subcutaneous emphysema, as well as the small possibility of palatal necrosis. However, it has been shown that if the periosteum is preserved after maxillary osteotomy, there is no need to preserve the incisive canal vessels, descending palatine arteries, and superior alveolar arteries. The prevention of complications entails adequate knowledge of the anatomy and surgical technique, as well as observing procedures that promote good postoperative vascularization, such as avoiding excessive traction on the vascular pedicles or detachment of the palatine mucosa. Closure of the soft palate should be done in layers to lessen the risk of postoperative velopharyngeal incompetence.

Facial Translocation Approach

Facial translocation is a concept that originated from the facial compartment disassembly and is considered as one of the best surgical approaches to the nasopharynx and skull base. Temporarily disassembling the facial skeleton provides excellent exposure and the most direct approach to the nasal cavity, paranasal sinuses, orbital cavity/apex, nasopharynx, frontal bone, and infratemporal fossa. It also allows the surgeon to access rNPC tumors that have developed lateral extension outside to the nasopharynx but medial to the foramen ovale.

Facial translocation allows extensive resection of cancers while still allowing preservation and reliable reconstruction of critical structures through approximation and fixation of the facial fragments at the end of the procedure. The entire anterior and middle cranial base may also be accessed by combining the facial translocation approach with elective craniofacial osteotomies and, optionally, with neurosurgical subfrontal or subtemporal approaches. Another advantage of the facial translocation approach is that it avoids the formation of bony defects that downgrades the cosmetic effect postoperatively, such as in the conventional lateral rhinotomy approach wherein part of the maxilla is removed without reconstruction, thereby creating a bony defect that results in a paranasal depression.

There are certain modifications of the facial translocation. For example, Dr. William I. Wei used the maxillary swing as a new approach to the nasopharynx. Dr. P.J. Catalano described an extended osteoplastic maxillotomy approach as a new procedure for wide access to the central skull base and infratemporal fossa. As a rule, in the facial translocation approach, the facial osteotomy can be electively carried out according to the anatomic location and the extent of the cancer.

Facial Translocation Approach to the Nasopharynx

Meghan N. Wilson, Neal M. Jackson, and Daniel W. Nuss

Introduction

The facial translocation approach (FTA) for access to the cranial base was first described in the late 1980s by Dr. Ivo P. Janecka and colleagues at the University of Pittsburgh.[1–3] The FTA was one of a number of landmark approaches described in the early days of the evolving new discipline of skull base surgery. At that time—before intraoperative imaging and image-guided navigation were widely available—most skull base approaches were based on the premise of obtaining broad anatomic exposure for the purposes of safe recognition and protection of critical skull base neurovascular structures and obtaining enough space in which to achieve complete tumor removal and repair. The FTA used the concept of modular "craniofacial disassembly" to achieve these goals. Over time, the utility, indications, and technical adaptations of the FTA have evolved, and although many other less invasive approaches have since been described, the FTA still has unique advantages in the management of certain skull base tumors,[4,5] especially those involving the nasopharynx (NP) and adjacent compartments.

Historically the NP was considered a difficult anatomic target for extirpative surgery because of its central location in proximity to critical anatomy of the brain, brainstem, carotid and basilar arteries, orbits, and multiple cranial nerves. The FTA is a versatile approach (actually a system of approaches)[3] that gives extremely broad exposure of the NP and these adjacent structures. Tumor location and pathology will guide the surgeon to tailor the most appropriate approach. A multidisciplinary discussion for surgical planning is valuable and may include Otolaryngology, Neurosurgery, Vascular surgery, and Reconstructive

surgery teams, as well as Interventional Radiology and Radiation and Medical Oncologists.

Key Operative Learning Points

1. The surgeon must have detailed knowledge of the vital structures of the NP, the face, and the adjacent compartments (infratemporal fossa [ITF], orbit, paranasal sinuses, and cranial vault).

2. The best approach is decided upon after assessing tumor location, tumor pathology, and the surrounding structures involved. If there is intracranial extension, consultation with an experienced Neurosurgeon is essential.

3. A thorough conceptual understanding of the sequence of steps in the FTA is essential for a safe, successful application (Figs. 44.1–44.6).

4. When cranial nerves (in particular the distal branches of the trigeminal and facial nerves) must be displaced in the FTA, sharply transecting the nerves and carefully re-approximating them at the end is preferred over vigorous or prolonged stretching of the nerves and results in better functional outcomes.

5. Orienting the horizontal incision at the level of the zygoma will protect the orbicularis oculi innervation as it enters the muscle below this level.

6. Temporary tarsorrhaphy at the end of the surgical procedure is important to prevent scar contracture and eversion/ectropion of the lower eyelid.

7. It is helpful to use a drill to mark the attachment point of the medial canthal tendon on the nasolacrimal bone to facilitate accurate reattachment.

8. Transection of the coronoid process increases the mobility and reach of the temporalis muscle transposition, which can be accomplished easily as long as there is due care to avoid compromising the blood supply.

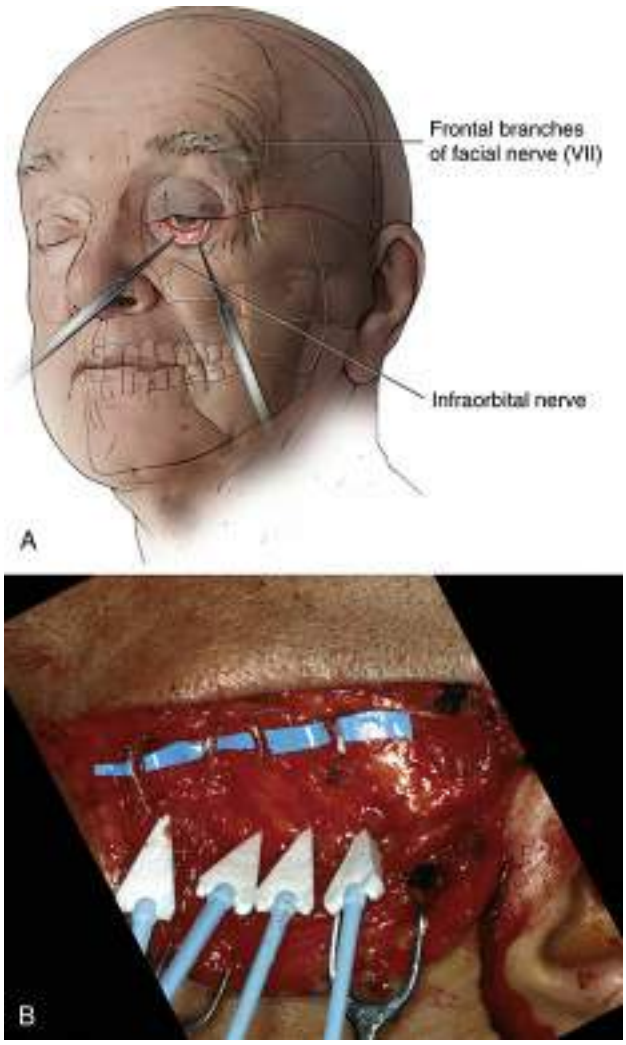

FIG. 44.1 **A,** Incision design for facial translocation (see text for details). **B,** Surgical view of zygomatic-temporal portion of the incision, with multiple frontal-temporal branches of the facial nerve identified and tagged prior to division. These nerves will be repaired at the end of the procedure. Reproduced with permission from Fig. 20.5 from Myers EN, Snyderman CH, Gardner P (eds). Master Techniques in Otolaryngology–Head and Neck Surgery: Skull Base Surgery; Nuss DW: Facial translocation approach to the central cranial base. Lippincott Wolters Kluwer: Philadelphia, PA; 2015.

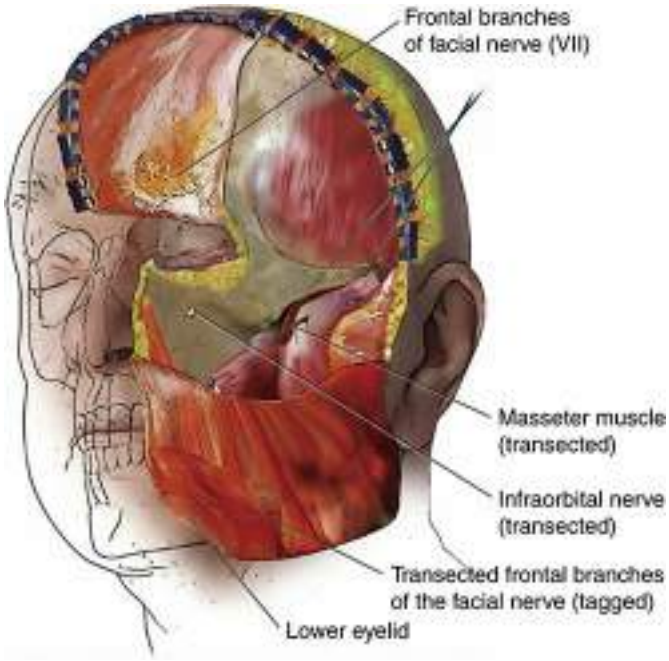

FIG. 44.2 Exposure of the craniofacial skeleton after reflection of the soft tissue envelope (see text for details). Reproduced with permission from Fig. 20.6 from Myers EN, Snyderman CH, Gardner P (eds). Master Techniques in Otolaryngology–Head and Neck Surgery: Skull Base Surgery; Nuss DW: Facial translocation approach to the central cranial base. Lippincott Wolters Kluwer: Philadelphia, PA; 2015.

9. When considering reconstruction, the most important concerns are closure of the dura and protection of the carotid artery.

Preoperative Period

History

1. History of present illness

   a. Ask about any neurologic deficits, emphasizing dysfunction of any cranial nerves.

      1) Dysfunction of cranial nerve V, the trigeminal nerve, is common in tumors of this area. This may present as unilateral sensory loss, facial dysesthesia, and/or mastication dysfunction (including malocclusion or deviation of the jaw).

      2) Dysfunction of cranial nerve VI is also common with tumors of

the NP, where there is ready access to the cavernous sinus and the orbital apex; this is manifested by diplopia and limited lateral gaze.

3) Dysfunction of cranial nerve VII is uncommon with nasopharyngeal tumors. However, the facial nerve will be manipulated in the FTA, and it is important to counsel patients that the innervation to the forehead will be disrupted and will require 6 to 9 months after neurorrhaphy before brow elevation function will return.

4) Tumors from the NP may spread laterally to involve the jugular foramen and thus may result in deficits of the lower cranial nerves (IX to XII), and tumors invading the temporal bone or posterior fossa may lead to sensorineural hearing loss and vestibular dysfunction.

5) Patients with preoperative dysphagia and aspiration should be counseled that surgery may worsen these problems, and consideration may be given to the placement of a feeding tube.

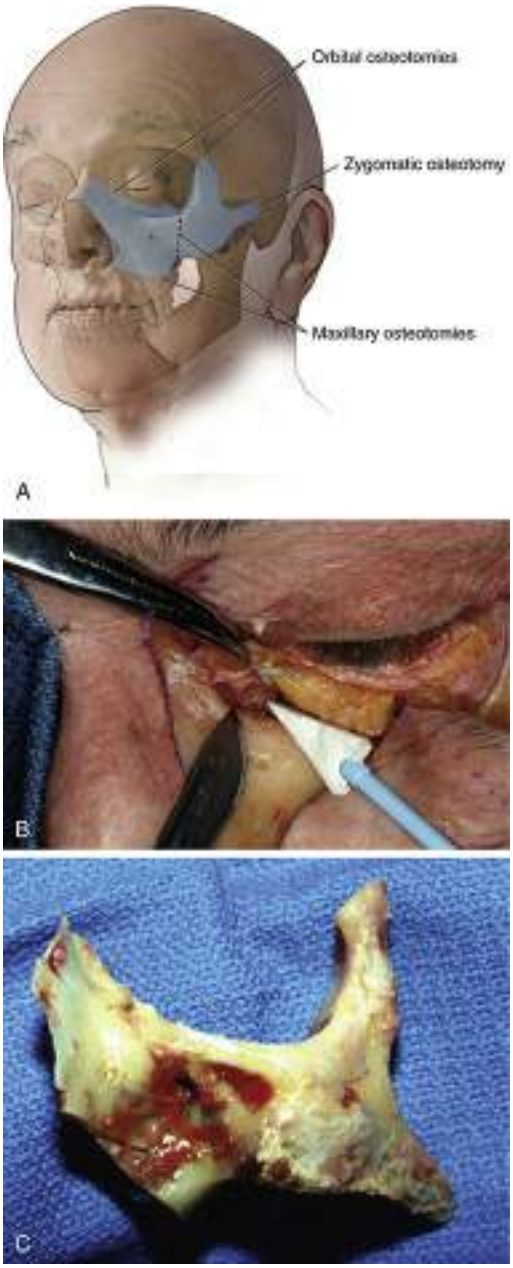

FIG. 44.3 **A,** Diagram of osteotomies of the orbital-zygomatico-maxillary skeleton. **B,** Lab dissection of medial orbit after subperiosteal exposure of the nasal-maxillary skeleton, release of the lower eyelid, showing nasolacrimal duct (pointer) prior to transection. **C,** Operative photo of orbito-zygomatico-maxillary segment after temporary removal; note that the infraorbital foramen has been enlarged and V2 has been released from the bone prior to explantation of the bony segment. Reproduced with permission from Fig. 20.11 from Myers EN, Snyderman CH, Gardner P (eds). Master Techniques in Otolaryngology–Head and

Neck Surgery: Skull Base Surgery; Nuss DW: Facial translocation approach to the central cranial base. Lippincott Wolters Kluwer: Philadelphia, PA; 2015.

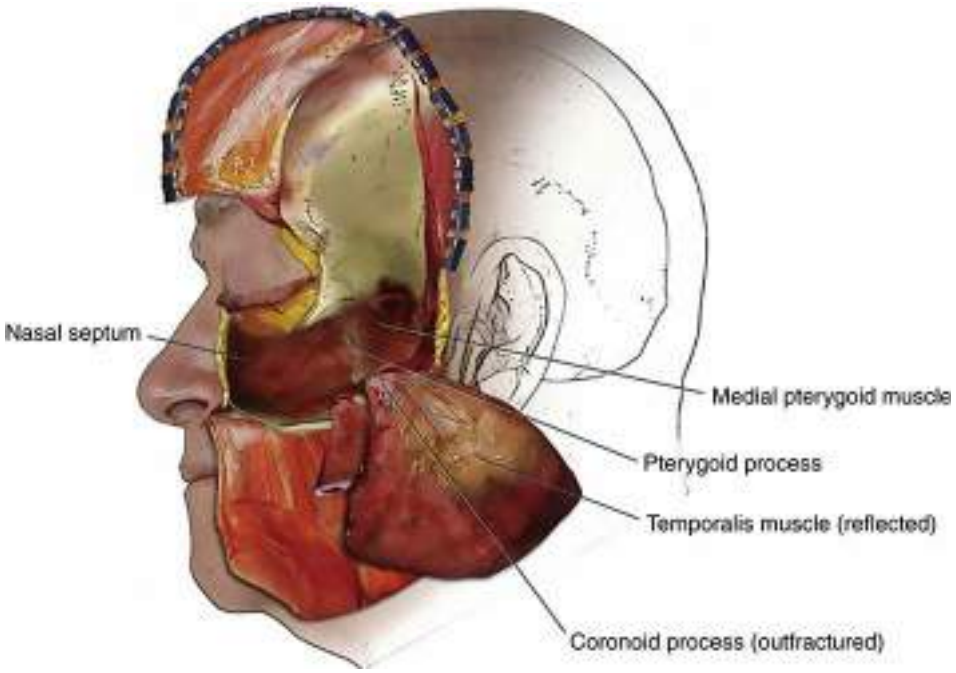

FIG. 44.4 Exposure achieved after orbital-zygomatico-maxillary osteotomies and reflection of temporalis muscle from the skull, revealing the view through the infratemporal fossa toward the nasopharynx (NP). At this point, resection of the pterygoid process will provide comprehensive access to both sides of the NP. Reproduced with permission from Fig. 20.12 from Myers EN, Snyderman CH, Gardner P (eds). Master Techniques in Otolaryngology–Head and Neck Surgery: Skull Base Surgery; Nuss DW: Facial translocation approach to the central cranial base. Lippincott Wolters Kluwer: Philadelphia, PA; 2015.

6) Conductive hearing loss with middle ear effusion may indicate compression of the Eustachian tube (ET) by tumor mass effect.

b. Ophthalmologic history is important, including any visual losses or diplopia.

2. Past medical history

a. Some patients being considered for FTA will have a history of nasopharyngeal carcinoma (NPC). It is important to note that primary NPC is initially treated (after confirmatory biopsy) with

chemoradiation in almost all cases. Surgery is usually reserved for recurrences. FTA is reserved for extensive recurrences requiring very broad access.

b. Any history of prior head and neck surgery or radiation must be taken into consideration with regard to tissue vascularity and viability; these factors may affect the incision design and the selection of reconstructive methods.

c. The medical health and functional status of the patient are important, as surgery via the FTA may be lengthy, depending on the pathology and reconstructive needs.

d. If the patient smokes, counseling and cessation are important both for perioperative healing and long-term survival.

Physical Examination

1. The NP must be carefully evaluated by endoscopy prior to surgical planning. Pathology in the NP can often spread to the ITF, which is relatively inaccessible to direct visualization and palpation on physical examination. However, important signs of ITF pathology can be elicited with a thorough examination of the head and neck, with special attention to the function of the cranial nerves as outlined above.

2. Assess for trismus; this will provide information about a possible invasion into the pterygoid musculature and is essential for the preoperative planning of airway management.

3. Evaluate visual function and document visual acuity.

4. Obtain audiometry to document hearing status, as either conductive or sensorineural hearing loss may result from skull base lesions.

5. Rarely, extensive tumors of the NP may involve the pituitary fossa or affect its regional blood flow, resulting in endocrine imbalance. Endocrinopathies may be variable, but the physical examination should look in particular for evidence of hypothyroidism or cortisol-related dysfunction, as these in particular may be detrimental to healing and thus cause significant perioperative complications.

Imaging

1. With nasopharyngeal diseases, imaging plays an essential role in precise tumor location and may suggest the type of pathology. Computed tomography (CT) and magnetic resonance imaging (MRI) are complementary and both are needed. Demonstration of bony involvement and widening of the foramina is best seen on CT, while the evaluation of soft tissue planes and tumor extension along neural structures is best seen on MRI.

2. It is critical to assess the functional status of the internal carotid artery (ICA) and its precise anatomic relationship to tumors of the NP, as this will influence details of the approach. If there is concern for ICA involvement following CT and MRI imaging, a Magnetic Resonance Angiography (MRA), computed tomography angiography (CTA), or formal angiogram should be considered. If intraoperative manipulation of the ICA is likely, the team should consider preoperative evaluation of collateral cerebral blood flow with a balloon occlusion test. Consultation with a Vascular Surgeon (or vascular neurosurgeon) may be warranted if intraoperative vascular bypass is a possibility.

3. Evaluation of regional and distant metastatic cancer is dictated by the histology and stage of the tumor. CT/positron emission tomography (PET) scanning is warranted to detect evidence of distant metastases.

Indications

Prior to FTA, tissue biopsy with pathologic confirmation of histology is desirable, as with any major extirpative cases. Open or transnasal endoscopic biopsy is usually straightforward, but if transnasal biopsy is inconclusive, an image-guided fine-needle aspiration of the tumor beyond the NP (e.g., in the ITF) may be considered. Biopsy is not indicated for highly vascular lesions with characteristic imaging findings, such as juvenile nasopharyngeal angiofibroma (JNA).

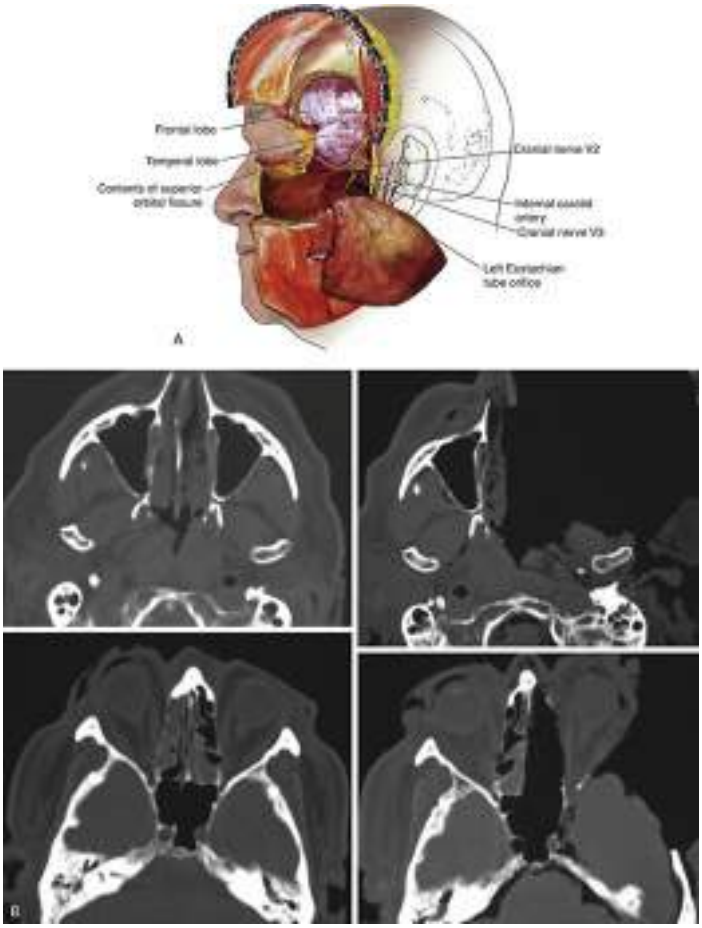

FIG. 44.5 **A,** Frontotemporal craniotomy provides additional access to intracranial compartments. For extensive nasopharyngeal tumors, this additional access will enable extirpation of tumor extensions involving the foramen ovale, the foramen spinosum, and the orbital apex, as well as drilling of the clivus if needed. **B,** Axial computed tomography sections of the dissected specimen showing the extent of anatomy accessible with the facial translocation approach (FTA). *Top row*: at the level of maxillary sinuses, before and after FTA. *Bottom row*: at the level of orbits, before and after FTA. Reproduced with permission from Fig. 20.13 from Myers EN, Snyderman CH, Gardner P (eds). Master Techniques in Otolaryngology–Head and Neck Surgery: Skull Base Surgery; Nuss DW: Facial translocation approach to the central cranial base. Lippincott Wolters Kluwer: Philadelphia, PA; 2015.

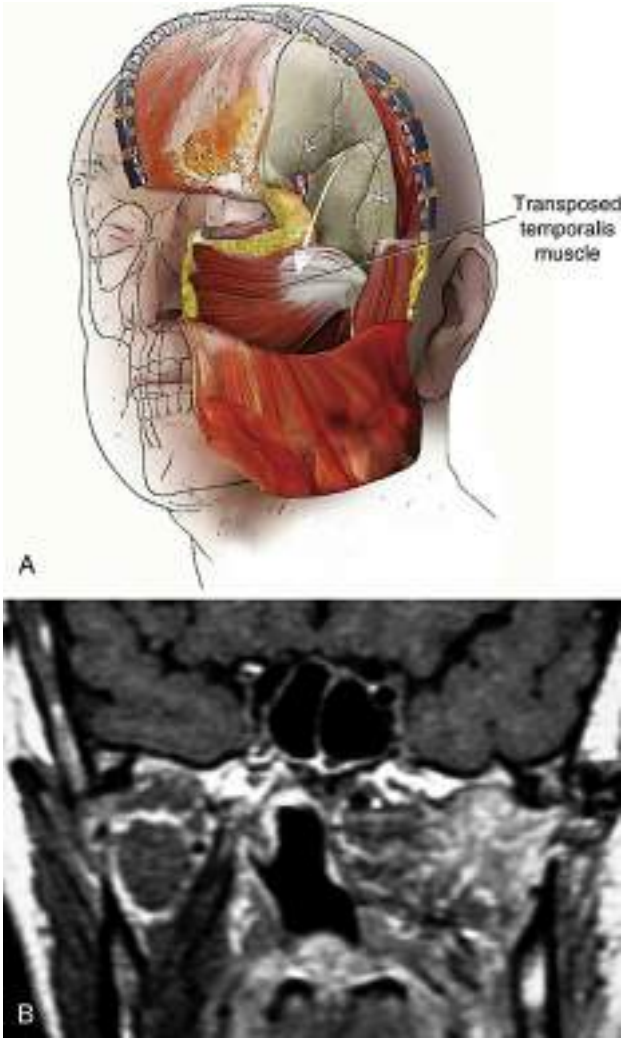

FIG. 44.6 Temporalis muscle transposed for reconstruction of cranial base defect after facial translocation approach. **A,** Diagram of the flap inset. **B,** Magnetic resonance imaging showing transposed flap in place, reconstituting the lateral nasopharyngeal wall and isolating the cranium from aerodigestive contamination. Reproduced with permission from Fig. 20.14 from Myers EN, Snyderman CH, Gardner P (eds). Master Techniques in Otolaryngology–Head and Neck Surgery: Skull Base Surgery; Nuss DW: Facial translocation approach to the central cranial base. Lippincott Wolters Kluwer: Philadelphia, PA; 2015.

Listed below are examples of indications for the FTA for lesions involving the NP.

1. Extensive JNA extending through the skull base to the orbit, middle cranial fossa, and cavernous sinus, which are not amenable to purely

endoscopic or less invasive approaches

2. Carcinomas of the NP originating primarily on the lateral wall of the NP that have not responded to, or recurred after, radiation or chemoradiation

3. Chordomas of the clivus and the surrounding structures, especially those with extension across the midline and to the craniovertebral junction

4. Sarcomas of the NP, pterygoid, and sphenoid region

5. Extensive transcranial lesions, such as meningiomas, nerve sheath tumors, and congenital tumors involving the NP and extending to the ITF, orbit, and cranium

6. Minor salivary gland neoplasms of the NP or adjacent areas, with intracranial, ITF, or lateral pharyngeal extent

7. Certain non-neoplastic disorders including complex encephaloceles, cerebrospinal fluid (CSF) leaks, and advanced infectious processes of the central skull base

Contraindications

There are no absolute contraindications to the FTA. Relative contraindications are as follows:

1. Medical comorbidities with an increased risk for general anesthesia

2. A failed balloon occlusion test in tumors involving the ICA raises concerns and the need for additional planning and discussions with the patient. In some cases, extracranial to intracranial bypass surgery may be an option. Some of these discussions will depend on the pathology and expected outcome.

3. Extensive invasion of brain parenchyma by a malignant tumor is another relative contraindication. In many tumors, resection of the brain is not an acceptable treatment; however, in some cases, such as an aggressive meningioma, resection of some brain tissue may be reasonable. Multidisciplinary planning with a Neurosurgeon is needed to discuss and plan treatment options and surgical techniques in these cases.

4. Smaller tumors often can be addressed through less invasive approaches. This is particularly true in well-defined central skull base lesions that may be amenable to an endoscopic endonasal approach. Quantitative analysis of relative advantages of different methods of access to the skull base can be helpful in selecting the best approach[6]; ultimately, each surgeon or surgical team must select approaches based on their own experience and results.

5. Not all lesions are appropriate for surgical therapy. Biopsy-proven hematologic lesions such as lymphoma and plasmacytoma are best treated with nonsurgical therapy. Consideration for surgical therapy for metastatic cancer is limited to decompression.

Preoperative Preparation

1. Both CT and MRI scans should be reviewed and available in the operating room. If any endoscopic approach is planned as an adjunct to FTA for tumor removal, image-guided navigation is recommended.

2. Blood products should be available, especially when dealing with highly vascular lesions.

3. Reconstructive considerations should be discussed prior to the start of the surgery and additional team members prepared to participate if necessary.

Operative Period

Anesthesia

1. General anesthesia is required. Preoperative assessment of the airway is critical to the safe induction of anesthesia. Depending on the patient, traditional induction and laryngeal exposure may be possible. In other cases (e.g., patients with trismus), fiberoptic intubation may be needed, or if postoperative airway compromise is expected, a tracheostomy may be advisable.

2. FTA surgery can be lengthy. If an orotracheal endotracheal tube is used, it should be secured using either a dental wire to the teeth or a

circum-mandibular wire on the contralateral side. This will prevent accidental dislodgment as the head is turned and repositioned throughout the case.

3. If neural or electromyography (EMG) monitoring will be performed, it is important to communicate to the anesthesia team the need to avoid paralytic agents.

Positioning

1. The patient should be positioned supine. The head should be supported on an appropriate, padded headrest. Mayfield pins are usually reserved for cases in which intracranial microneurovascular work is anticipated. The patient must be sterilely prepped and draped to allow exposure of the entire head and neck. Access to the neck for proximal control is important if the ICA is at risk.

2. Anithromboembolism stockings should be applied to the legs and the body properly padded to prevent pressure-related ischemia.

Perioperative Antibiotic Prophylaxis

1. Antibiotic prophylaxis should provide coverage against the skin flora and upper aerodigestive tract flora. If intracranial surgery is anticipated, the use of an antibiotic with good penetration of the blood-brain barrier should be considered.

Monitoring

1. EMG monitoring of the frontalis branches of the ipsilateral facial nerve is routinely performed. Select cranial nerve monitoring (e.g., vagus nerve via laryngeal EMG endotracheal tube) is indicated for some cases.

2. Electrophysiologic monitoring (somatosensory evoked potentials or electroencephalography) is initiated in select cases depending on what neural and vascular territories are at risk.

3. A lumbar drain is sometimes helpful if significant intradural dissection is anticipated.

Instruments and Equipment to Have Available

1. Nerve integrity monitoring system
2. Magnifications (surgical loupes and/or microscope)
3. Fine dissection scissors
4. Periosteal elevators
5. Rainey clips
6. Reciprocating and oscillating saws
7. Rongeurs
8. 7-0 or 8-0 nylon sutures
9. Crawford nasolacrimal tubes
10. Midface/cranial plating system
11. Vascular instrument set if the carotid artery is at risk

Key Anatomic Landmarks

1. During elevation of the scalp flap, one must incise down to the deep temporalis fascia at a level above the superior orbital rim and follow this plane inferiorly to prevent injury to the frontal (a.k.a. temporal) branch of the facial nerve.

2. Knowledge of the location and course of each neurovascular structure is important, particularly cranial nerves VII, V, and IX to XII; the internal maxillary artery; and the carotid artery.

3. The blood supply to the temporalis muscle is located deep in the muscle (deep temporal branches of the internal maxillary artery).

4. To identify skull base foramina, the lateral pterygoid plate can be followed posteriorly to identify the foramen ovale, foramen spinosum, and the spine of the sphenoid bone. These structures all have a fixed relationship to the ICA.

Prerequisite Skills

1. Hemi- or bi-coronal incision and flap elevation

2. Parotidectomy techniques including facial nerve dissection

3. Maxillectomy or additional facial skeletal osteotomies

4. Midface/cranial plating

5. Experience with incisions and closure of eyelid lacerations

6. Regional muscle flap elevation

7. Abdominal adipose tissue harvest

Operative Risks

1. Temporary or permanent dysfunction of cranial nerves (especially frontalis paralysis and V2 numbness)

2. CSF leak

3. Orbital injury resulting in diplopia, ocular dystopia, blurring, or blindness

4. ICA injury or other vascular injury and resultant cerebrovascular accident, death

Surgical Technique

1. Ensure functionality of EMG monitoring of the frontalis branch of the ipsilateral facial nerve.

2. Carefully mark incisions and inject with Xylocaine and epinephrine (1 : 100,000). Incisions will include a lateral rhinotomy incision and a hemicoronal incision extending preauricularly. A connecting horizontal incision will be drawn along the level of the zygoma to the lateral canthus and then through the inferior fornix of the eyelid (Fig. 44.1A).

3. An incision can be extended into the neck if necessary for management of metastases in the neck or control of the carotid artery.

4. When making the horizontal incision across the zygoma, first incise just through the skin and superficial subcutaneous tissues, and then identify the frontalis branches of the facial nerve. Loupe magnification and EMG confirmation should be used to identify the nerve branches. There are between three and six separate branches of the facial nerve that cross the zygoma; each should be preserved if possible (Fig. 44.1B).

5. Each frontalis branch should be sharply transected and a 7-0 nylon suture attached to each of the transected ends to facilitate locating each end and reapproximating them at the end of the procedure.

6. Extend the dissection deeply to the temporal adipose tissue pad, then through this adipose tissue to the zygomatic arch.

7. The lower facial soft tissue flap can then be released and retracted inferiorly dissecting in the plane of the parotid-masseteric fascia. This is deep to the parotid gland and branches of the facial nerve. The masseter muscle as well as the coronoid process should be exposed (Fig. 44.2).

8. Next, the lateral rhinotomy incision is made, up to the level of the medial canthus. The depth of this incision should extend to the periosteum of the nasal and maxillary bones.

9. The palpebral conjunctiva of the lower lid is then incised, extending medially to divide the medial canthus and meet the lateral rhinotomy incision. The incision is then extended through the lateral canthus to connect to the temporal incision.

10. The eyelid incision should be dissected deeply down to the orbital rim, freeing the eyelid from the surrounding maxilla and orbital rim in a subperiosteal plane.

11. The nasolacrimal duct must be divided. This should be done as distally as possible at the medial orbital floor (Fig. 44.3).

12. When the medial canthal ligament is released, it is helpful to mark the location to enable exact reattachment at the end of the case. We recommend marking this with a small drill bit.

13. The lower face flap is further released by dissecting the premaxillary soft tissue in a subperiosteal plane. The infraorbital nerve (V2) will be identified and transected, and it too will be tagged for re-approximation at the end of the procedure.

14. The infraorbital nerve is mobilized by using a fine elevator to slightly widen the foramen and push the proximal nerve end through the foramen, and then it is released from attachments at the floor of the orbit. At this stage, its point of emergence from the foramen rotundum is easily found.

15. The premaxillary soft tissue is now mobilized down to the Le Fort I line, and the skeleton of the lower orbit, nose, maxilla, and zygoma should now be fully exposed.

16. At this time, the hemicoronal incision is made, and the frontotemporal soft tissues are elevated from the underlying temporalis muscle, staying deep to the tagged frontalis branches.

17. The periorbita is released from the medial and lateral walls of the orbit as well as the orbital floor to protect the orbit during osteotomies. The ethmoidal arteries should be tied, clipped, or cauterized if the tumor extends to the anterior cranial fossa or ethmoids.

18. The last step in preparation for osteotomies is to release the masseter muscle from the zygomatic arch.

19. It is now time to complete osteotomies to mobilize the orbito-zygomatico-maxillary (OZM) skeleton using a reciprocating saw or side-cutting drill bits.

20. An ipsilateral Le Fort I osteotomy extending laterally from the pyriform aperture is performed, followed by osteotomies at the medial orbital wall, nasal bone, frontozygomatic suture line, and posterior zygomatic arch at the attachment to the temporal bone (Figs. 44.2–44.3).

21. Osteotomies can be extended or customized as needed depending on the extent of the lesion.

22. The bone should be placed in a saline solution to preserve it for later reconstruction. Mucosa from the maxillary sinus should be removed, as the sinus will be obliterated during closure and reconstruction.

23. To access the infratemporal space, the temporalis muscle should be detached in its entirety from its origin on the skull and reflected inferiorly. It is essential to use due caution near the inferomedial aspect of the muscle, where its blood supply originates (Fig. 44.4).

24. An osteotomy of the coronoid process of the mandible can now be

performed, if needed, to increase inferior rotation of the temporalis muscle. Again, the vascular pedicle must be protected.

25. The posterior and lateral walls of the maxilla can be removed with rongeurs.

26. The internal maxillary artery branches (sphenopalatine branches) are ligated.

27. An osteotomy is performed at the pterygoid plates at the skull base with a reciprocating saw or rongeurs.

28. At this point, the surgeon should be able to see the entire maxillary floor, nasal cavity, ipsilateral sinuses, NP, ETs, clivus, the orbital contents with periorbita still intact, ITF, and foramen rotundum.

29. If there is intracranial tumor, a craniotomy can now be performed by the neurosurgical team. Depending on the location of the tumor, a frontotemporal or temporal craniotomy will be performed (Fig. 44.5A).

30. Tumor resection will now include involved segments of the NP, together with any involved portions of the ET, pterygoid plates and muscles, sphenoid floor, and adjacent skull base, as dictated by the extent of the disease. The extent of open, three-dimensional access achievable by the FTA is quite broad (Fig. 44.5B).

31. Once the tumor resection is complete, attention is turned to the reconstruction.

32. Bony reconstruction of the middle fossa floor is not necessary; however, it is necessary to have well-vascularized tissue against the dura to separate the cranium from the aerodigestive tract below. The temporalis muscle is well suited for this purpose (Fig. 44.6). If this flap is not viable for any reason, or was part of the resection, vascularized tissue must be brought via free tissue transfer.

33. If the carotid artery has been exposed, it must also be covered with well-vascularized tissue.

34. The osteotomized OZM bone segment can now be replaced and fixated to adjacent healthy bone. It is important to ensure rigid fixation with a craniofacial plating system. All mucosa should be removed prior to replacement.

35. Once the temporalis muscle is translocated for reconstruction or removed with tumor resection, the temporalis donor site must be reconstructed to prevent concavity and cosmetic deformity. Autologous free adipose tissue grafting is well tolerated and usually satisfactory for reconstruction. A variety of implants for this purpose are available, but in our experience adipose tissue is a better choice in the acute setting.

36. The infraorbital nerve is now reapproximated. Neurorrhaphy is performed with 6-0 nylon suture.

37. The nasolacrimal duct should be redirected to its natural canal into the nose and stented using a Crawford stent for 6 to 8 weeks.

38. Soft tissue re-approximation should be performed carefully to ensure proper positioning without tension. Medial and lateral canthal placement must be precise, especially in affixing the medial canthal ligament at the previously marked location.

39. A temporary tarsorrhaphy is recommended to decrease scar contracture and the risk of ectropion.

40. The frontalis branches are now re-approximated with neurorrhaphy sutures (7-0 or 8-0 nylon) or entubulation techniques.

41. Meticulous soft tissue closure in layers will lead to minimal scar formation.

Common Errors in Technique

1. Improper placement of facial incisions or improper re-approximation, resulting in increased scar visibility

2. Improper reconstruction leading to facial asymmetry

3. Improper re-approximation of nerve endings, leading to poor functional healing

4. Failure to secure the bone graft may result in non-union and subsequent infection or deformity.

5. Compression of periorbita when replacing the OZM bone graft may result in entrapment of orbital soft tissues leading to diplopia.

Postoperative Period

Postoperative Management

1. Saline nasal spray is used to minimize nasal crusting. Periodic nasal endoscopy and débridement of crusts are needed until mucosalization of the transposed temporalis muscle is complete (6 weeks to several months).

2. Antiseptic rinse is used intraorally.

3. Antibiotics are continued 24 to 48 hours postoperatively.

4. Trismus may result from dissection of the masticator space and can be treated with a bite appliance (i.e., TheraBite) and stretching exercises.

5. A temporary tarsorrhaphy and traction stent are maintained for 1 to 2 weeks.

6. A nasolacrimal stent is maintained for 1 to 2 months.

7. In cases in which the dura is opened, early recognition for signs of CSF leak in the postoperative period is important as a lumbar drain or reoperation may be indicated.

Complications

Outcomes after FTA have been generally acceptable, but because of the magnitude of the procedure, there is the potential for significant morbidity.[7] Complications of the FTA can be understood in the context of the anatomy dissected during the FTA.

1. A major morbidity relates to the trigeminal nerve. Sacrifice of the trigeminal nerve or any of its branches may be required for tumor resection, so some of these complications may be unavoidable. Facial anesthesia puts the patient at risk for self-inflicted injury, especially when chewing food. V1 anesthesia carries a high risk of corneal ulcer and must be managed aggressively.

2. The transection and re-attachment of the frontalis (facial) nerve branches will lead to forehead paralysis that can be expected to resolve

within 6 to 9 months when careful neurorrhaphy is done. If other branches of cranial nerve VII have been dissected or weakened, eye closure may be affected. It is essential to protect the eye from exposure keratitis in these cases to prevent further morbidity.

3. Trismus is common postoperatively both immediately due to pain and chronically due to pterygoid musculature scarring/fibrosis. Beginning 2 to 3 weeks after surgery, patients should regularly perform jaw opening and stretching exercises to prevent trismus.

4. Osteomyelitis of the OZM bone graft can occur with poor fixation of the bone or inadequate soft tissue coverage, especially with a history of irradiation.

5. Vascular complications can be severe, especially during or following dissection along the ICA. Bleeding is a risk and can be difficult to control. In the cases of ICA occlusion, ischemic brain injury is possible even with a satisfactory preoperative balloon occlusion test. These patients must be diligently managed to minimize neurologic complications.

6. Intradural dissection places the patient at risk of an immediate or delayed postoperative CSF leak.

7. Cosmetic deformities may arise even with careful planning of incisions and reconstruction. Facial scarring is generally acceptable, especially if placed along the margins of facial subunits. If the temporalis muscle is sacrificed or transposed, this leads to a depression in the temple that should be reconstructed with a free graft or implant at the time of surgery or at a secondary procedure.

8. Poor alignment of the medial canthus will result in facial asymmetry.

9. Ectropion can occur.

10. Conductive hearing loss and middle-ear effusion almost always results. Tympanostomy tube placement is usually deferred for 2 to 3 months after surgery because of concern for CSF leakage.

11. Velopharyngeal insufficiency may result if extensive pterygoid resection and disruption of the tensor veli and levator veli palatine muscles have taken place. Appropriate supportive care with speech pathology input is required.

Alternative Management Plan

Some neoplasms in this area are amenable to treatment with external beam radiation with or without chemotherapy. Discussion at a multidisciplinary tumor board will assist in deciding the best and alternate treatment plans.

Discussion

Evidence-Based Medicine Question

What is the role for FTA in the era of endonasal skull base surgery?

Endonasal endoscopic skull base surgery has produced excellent functional and oncologic outcomes in recent years, and endoscopic surgery conducted in expert hands can now address some of the problems for which FTA was originally designed. However, for extensive tumors and tumor-like conditions involving the NP and extending to the central skull base, and especially recurrent tumors, open-access surgery, such as FTA, is still sometimes needed. The anatomy of each patient as well as the pathology and extent of the tumor requires careful evaluation prior to selecting an approach for resection.

Editorial Comment

The FTA provides unparalleled access to the nasopharynx, central skull base and infratemporal skull base in the coronal plane. When properly performed, the morbidity is acceptable. In order to avoid transection of the temporal branches of the facial nerve, I prefer to omit the skin incision from the lateral canthus to the preauricular incision. By working on both sides of this bridge of skin, visualization and tumor dissection are adequate in most cases.

With the advent of endoscopic techniques, the FTA is rarely used anymore for pathology of the NP and central skull base. Combined anterior approaches (endoscopic endonasal and transmaxillary) provide adequate visualization and room for instrumentation. Nevertheless, familiarity with the FTA is important when other approaches are not

providing adequate access or when resources are limited.

Review Questions

1. During elevation of a bicoronal scalp flap, which plane is correct for dissection?

   a. On the temporalis muscle

   b. **On the deep temporalis fascia**

   c. On the temporoparietal fascia

   d. In the subcutaneous tissue

2. During dissection, it is important to know the location of all cranial base foramina and neural structures. In relationship to the lateral pterygoid plate, where is the foramen ovale?

   a. Superior

   b. Inferior

   c. Medial

   d. **Lateral**

3. What is the main blood supply for the temporalis, and where does it travel in relation to the muscle?

   a. Superficial temporal artery, medial to the muscle

   b. Superficial temporal artery, superficial to the muscle

   c. Deep temporal artery branches, medial to the muscle

   d. **Deep temporal artery branches, deep to the muscle**

4. For which tumor scenario should the Facial Translocation Approach be considered when planning surgical options?

   a. Esthesioneuroblastoma extending through the cribriform plate with intracranial extension as well as posterior extension of tumor into the sphenoid sinus

b. T3N1M0 Nasopharyngeal carcinoma that was just diagnosed with no previous treatment

c. **T3N1M0 Nasopharyngeal carcinoma recurrent 2 years following radiation treatment**

d. Juvenille nasopharyngeal Angiofibroma filling the right nasal cavity, tumor filling the nasopharynx, and tumor extending through the pterygopalatine fissure into the infratemporal fossa

Esophagoscopy and Hypopharyngoscopy

Sameep Kadakia, and Raymond Chai

Introduction

Disorders of the esophagus present a challenge to the otolaryngologist owing to the broad variety of pathology and oftentimes nonspecific nature of patient complaints. Using a mirror, Bozzini in 1809 was credited with the first attempts to evaluate the esophagus.[1] Initially described in 1868 by Kussmaul, the straight esophagoscope underwent multiple refinements until the early 1900s when Chevalier Jackson introduced the technique and instrumentation of modern rigid esophagoscopy.[2,3] After fiberoptic illumination was pioneered for this technique in the 1930s, flexible endoscopy was introduced in the 1960s and eventually led to the creation of the transnasal endoscope in the 1990s.[4-6] The evolution of the technique and instrumentation reflects the challenges associated with evaluating the esophagus. The advent of flexible and rigid endoscopy has afforded the modern day practitioner several methods for conducting a thorough patient-specific assessment.

The diagnosis and management of esophageal disorders requires a thorough understanding of esophageal anatomy. The esophagus is a muscular conduit extending from the inferior portion of the pharynx to the superior portion of the stomach. At the approximate level of the sixth cervical vertebra, the esophagus begins at the pharyngoesophageal junction in the hypopharynx and descends to the level of the 11th thoracic vertebra, where it enters the cardia portion of the stomach.[7,8] Shortly after its takeoff, the esophagus has a gentle leftward curvature until the level of the fifth thoracic vertebra, at which point it resumes its midline course. A second leftward curve of the esophagus can be appreciated as it crosses the descending aorta prior to entering the

esophageal hiatus of the diaphragm; however, some sources have also noted the thoracic esophagus to have a right curvature due to the main stem bronchus.[9,10]

The esophagus measures 22 to 25 cm in total length and can be divided into cervical, thoracic, and abdominal portions.[10] The cervical esophagus begins at the cricopharyngeus and extends to the suprasternal notch, the thoracic portion from the suprasternal notch to the diaphragm, and the abdominal portion from the diaphragm to the stomach.[7,8] Throughout its length, there are three constrictions of the conduit that the endoscopist should be familiar with. Approximately 16 cm from the upper incisors, the first and narrowest constriction occurs at the cricopharyngeal sphincter. At 23 to 27 cm from the upper incisors, the second constriction occurs at the level of the left main stem bronchus. The final constriction occurs at the gastroesophageal sphincter, 38 to 40 cm from the upper incisor teeth.[7,8,10]

Histologically, the esophagus is composed of four circular layers: mucosa, submucosa, muscular layer, and adventitia. The esophagus lacks a serosa, a unique characteristic that differentiates it from the rest of the gastrointestinal tract.[7,8]

Key Operative Learning Points

1. Flexible and rigid esophagoscopy allow for visualization and instrumentation of the esophagus under specific situations. Understanding both techniques allows the practitioner to perform a safe and thorough evaluation depending on the patient's general medical condition, ability to tolerate the procedure, and suspected diagnosis.

2. Understanding esophageal anatomy allows the endoscopist to safely perform esophagoscopy while minimizing the potential for complications such as perforation.

Preoperative Period

History

- History of present illness

- Age of the patient
- Description of dysphagia or pain
  - Onset, provocation, progression, duration of episodes
  - Is this the first time or has this been repetitive/ongoing?
  - What maneuvers or interventions has the patient tried to combat the problem?
  - Is there dysphagia to solids, liquids, or both?
  - Any accompanying symptoms—postnasal drip, heart burn, globus sensation, hoarseness, weight loss, weakness, lethargy, night sweats, hemoptysis, cough, neck masses?

- Past medical history
  - History of cancer
  - History of radiation to the head or neck
  - Cardiac or pulmonary disease
  - Rheumatologic conditions such as scleroderma
  - Arthritis or vertebral problems that would limit motion of the neck
- Past surgical history
  - What surgery has the patient had in the past?
    - Any spinal fusion surgery?
    - Any chest, abdominal, or mediastinal procedures?
- Family history
  - Rheumatologic conditions in the family
  - History of cancer of the head and neck
  - Family history of dysphagia
- Social history
  - Very important to collect detailed history of smoking and alcohol use because these are risk factors for cancer
- Medication
  - Many medications can cause dryness and lead to a sensation of

difficulty swallowing.

Physical Examination

- Always undertake a thorough examination of the head and neck.
- Examination/observation of the head and neck
  - Look for obvious deformities, masses, ulcerations, and gross abnormalities.
- Palpation of the head and neck
  - Carefully inspect the neck for masses and adenopathy; also palpate to see if any pain can be elicited.
  - Assess range of motion of the neck to assess for fibrosis and ability to extend or flex neck.

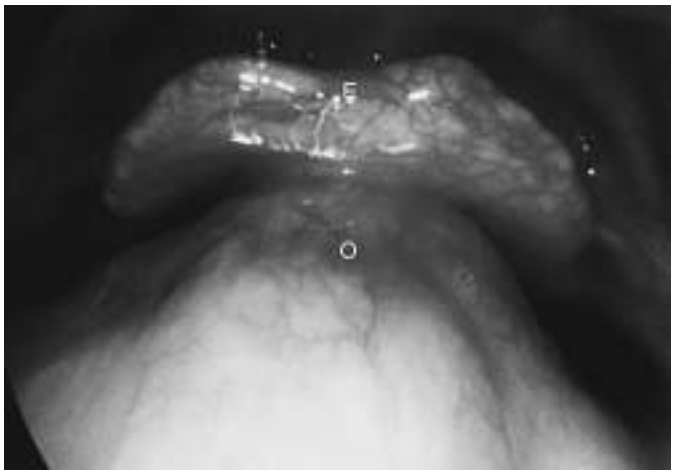

FIG. 45.1 Transnasal endoscopy showing a cervical osteophyte *(O)* displacing the epiglottis anteriorly *(E)*.

- Nasal endoscopy
  - Should routinely be performed on patients with dysphagia related to the laryngopharyngeal complex or the cervical esophagus (Fig. 45.1)
  - The nasal mucosa should be sprayed with a topical anesthetic/decongestant, such as lidocaine with phenylephrine.
  - Nasal endoscopy will help assess for dynamic movement of the

laryngopharyngeal complex.

- Evaluate the patency of the airway and the mobility of the vocal folds.
- Evaluate for the presence of masses or mucosal abnormalities.

Imaging

- Not required but may be helpful to determine elements of disease pathology. Oftentimes, patients may be referred for a swallow evaluation with a speech-language pathologist to identify salient features of the dysphagia not reported by the patient. This evaluation can also be helpful to identify the potential location of pathology, as well as to begin swallowing therapy for the patient if needed. A modified barium swallow can also shed light on the dynamic process of swallowing and point to areas of concern.
- A preoperative contrast-enhanced esophagram may be helpful in diagnosing certain conditions, especially when dysmotility, mass effect, stricture, or diverticulum is suspected (Fig. 45.2). An esophagram can also identify foreign bodies not visualized on plain film.
- Barium is generally recommended as the contrast agent except when esophageal injury is suspected. In cases of suspected esophageal perforation, a water-soluble agent, such as gastrograffin, is recommended because it does not induce an inflammatory reaction with extravasation, which can be seen with barium. Barium is typically used if a perforation is not suspected because it does not induce the same inflammatory reaction as gastrograffin if aspirated into the lower respiratory tract.

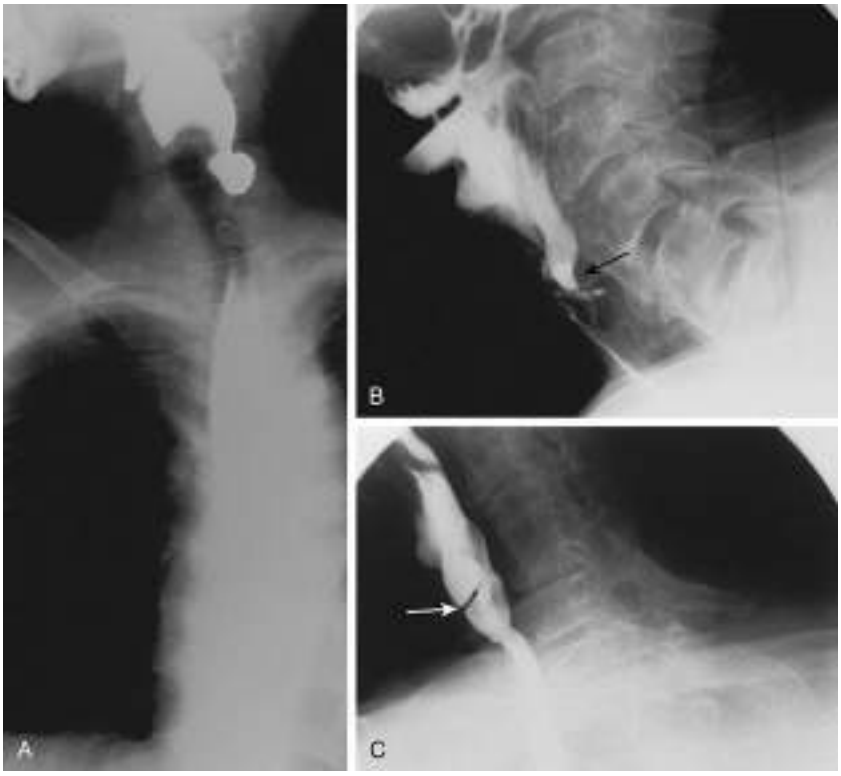

FIG. 45.2 **A**, Barium esophagram demonstrating a Zenker diverticulum. **B**, Barium esophagram of a patient with dysphagia and a large anterior cervical osteophyte *(black arrow)*. **C**, Barium esophagram demonstrating an esophageal web *(white arrow)*.

- Important to note that masses identified on esophagram may require computed tomography (CT) imaging for further characterization

Indications for Rigid and Flexible Esophagoscopy

- Rigid or flexible esophagoscopy can be a diagnostic tool for the evaluation of suspected masses, trauma, strictures, or inflammatory conditions. It allows for visualization and the ability to take biopsies if needed.
- In the case of esophageal foreign body, rigid esophagoscopy can be used to visualize and extract the foreign body.
- Rigid esophagoscopy can be used as a surgical approach for dilation of

strictures, placement of a stent, cricopharyngeal myotomy for diverticula, and laser procedures.

Contraindications

- Hemodynamic instability
- Poor general health
- Lack of patient and family understanding inhibiting informed consent
- Esophageal perforation

Preoperative Preparation

- The preoperative evaluation is minimal in these patients and typically requires only medical clearance to ensure safety for tolerating anesthesia. In some cases a cardiology clearance may be needed for patients with significant cardiopulmonary history.

Operative Period

The general condition of the patient, purpose of intervention, and patient compliance are three factors that determine whether patients should undergo rigid esophagoscopy or flexible esophagoscopy. Flexible esophagoscopy can be performed either transorally or transnasally. Flexible esophagoscopy allows for visualization of the gastroesophageal junction and improved instrumentation in patients with limited range of motion at the neck or obstructing osteophytes. Transoral esophagoscopy is typically performed under sedation and topical anesthesia, whereas transnasal esophagoscopy is performed with topical anesthesia only. Transnasal esophagoscopy is well suited for the office setting, is of minimal risk, and allows for patients to return home without need for observation. This procedure can be performed with relatively little patient discomfort and is associated with mostly minor complications, such as epistaxis. It is imperative that prior to any procedure, a full discussion of the risks and benefits be discussed with patients in a manner suited to their level of understanding. Overall, flexible esophagoscopy is a viable option for patients that cannot tolerate general

anesthesia; however, it is important to note that it has limitations and should be reserved for specific situations. According to recent studies, transnasal esophagoscopy can be helpful in changing the course of management in male patients, obese patients, and especially those patients with a history of dysphagia associated with head and neck cancer.

Rigid esophagoscopy is more advantageous in evaluating the hypopharynx, cricopharyngeal sphincter, and cervical esophagus. Oftentimes, redundant mucosal folds can hide pathology which can be readily missed with flexible esophagoscopy. Rigid instrumentation also confers the advantage of allowing larger suction cannulas and larger caliber instruments to be used for retrieval of foreign bodies.

Flexible Transnasal Esophagoscopy

- *Anesthesia*: topically sprayed 4% lidocaine and 0.05% oxymetazoline, followed by cotton pledgets with 0.5% tetracaine, followed by oral 2% lidocaine gel
- *Positioning*: patient kept sitting in the upright position or reclined
- *Antibiotics*: not needed on a routine basis
- *Monitoring*: no cardiac monitoring necessary if patient is not sedated

Instruments and Equipment to Have Available

- Transnasal esophagoscope (TNE)
- Video monitor
- Flexible suction
- Flexible biopsy instrument
- Flexible grasping instrument

Key Anatomic Landmarks

- Nasal passage, nasopharyngeal inlet, laryngeal inlet, piriform sinus, postcricoid area, endolarynx, superior esophageal constrictor, and

gastric inlet

Prerequisite Skills

- Transnasal endoscopy

Operative Risks

- Esophageal perforation, mucosal injury (less likely than with rigid)

Surgical Technique

- The patient is placed into the sitting position either upright or slightly reclined.
- Nasal cavity is sprayed with lidocaine and oxymetazoline spray. After decongestion, cotton pledgets with tetracaine are placed for further anesthesia. Patient is then given 2% lidocaine gel to gargle and swallow. At this time, the nasal cavity and pharynx should be well anesthetized.
- Under direct visualization, the TNE should be introduced into the larger nasal passage and advanced to the pharynx, taking the largest pathways with care not to injure the mucosa of the septum or turbinate.
- Prior to advancing into the hypopharynx, an overall view of the laryngopharyngeal complex can be appreciated.
- The scope is then used to examine each piriform sinus.
- The scope is then placed into the left piriform sinus and, while the patient swallows, is advanced into the esophagus through the cricopharyngeal inlet.
- As the scope is advanced, insufflation can be performed to evaluate the esophageal mucosa. The lower esophageal sphincter and gastroesophageal junction should be assessed before entering the stomach.
- After entering the stomach, the scope is used to evaluate the lining of the stomach. The scope is retroflexed to evaluated the gastric cardia.

- While the scope is being withdrawn, the walls of the esophagus are again examined.

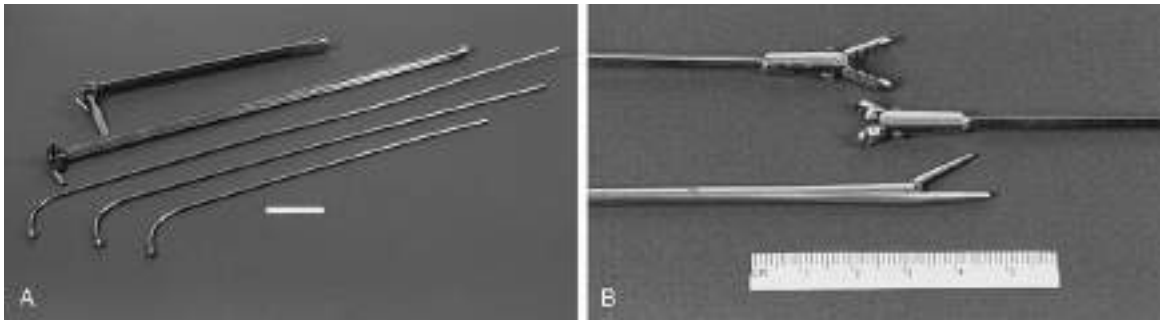

FIG. 45.3 **A**, Esophagoscopes and long suction cannulas; instruments available in variety of sizes. **B**, Esophagoscopy forceps. From top to bottom are forceps with serrated edges, cup forceps, and alligator forceps. A cup forceps is most suitable for biopsies, whereas the other two are most useful for the retrieval of foreign bodies.

FIG. 45.4 The thumb of the left hand is used as a fulcrum for the instrument to prevent pressure over the incisors and is used to advance the instrument while the right hand is used only to guide the esophagoscope by changing the angle of entry.

Common Errors in Technique

- Inadequate anesthesia leading to patient discomfort and poor cooperation
- Passing the scope through narrow portions of the nasal cavity, causing the patient significant pain
- Failure to evaluate the esophageal mucosa while withdrawing the scope

Rigid Esophagoscopy

- *Anesthesia*: General anesthesia with endotracheal intubation
- *Positioning*: Neutral position without head extension. Extension with techniques such as a shoulder roll can make passage of the esophagoscope more difficult
- *Antibiotics*: Not needed on routine basis
- *Monitoring*: standard cardiacpulmonary monitoring with pulse oximetry

Instruments and Equipment to Have Available

- Rigid esophagoscope
- Grasping forceps
- Biopsy forceps
- Cannula suction
- Camera head
- 0-degree long endoscope
- Optical forceps (Fig. 45.3)

Key Anatomic Landmarks

- Oropharynx, teeth, laryngeal inlet, piriform sinus, postcricoid area,

endolarynx, superior esophageal constrictor, and gastric inlet

Prerequisite Skills

- Direct laryngoscopy, manipulation of oral cavity structures, ability to avoid dental trauma

Operative Risks

- Esophageal perforation, mucosal injury

Surgical Technique

- Following anesthesia, the patient is positioned with the neck extended
- A tooth guard or wet sponge is used to protect the teeth
- Using a scissor-like maneuver, the mouth is opened and the endoscope is inserted into the oral cavity
- Endoscope held between thumb and index finger of the nondominant hand (Fig. 45.4)
- Scope advanced to posterior pharyngeal wall, and then follows posterior pharyngeal wall down to hypopharynx (Fig. 45.5)
- The scope is further advanced through the cricopharyngeal inlet. The nondominant hand always remains on the scope to stabilize it while the dominant hand can be used to change angle of movement.
- If resistance is met, muscle relaxants, deflation of the endotracheal tube, or the use of a smaller esophagoscope can circumvent the obstruction.
- The instrument is advanced to the gastroesophageal junction with care not to injure the esophageal mucosa. Care must be taken to never advance the scope when pressure is encountered because this could increase the risk of perforation.
- An esophageal suction can be used to remove secretions from the field.
- After scope reaches junction, it is slowly withdrawn while reinspecting the walls of the esophagus.

- It is best to biopsy lesions at the end of the procedure to prevent bleeding from obscuring the view. Multiple biopsies are often required to obtain a sufficient sample of the lesion.

FIG. 45.5 Insertion of the esophagoscope.

The tip of the instrument is advanced over the posterior pharyngeal wall. The base of the tongue and the larynx are displaced anteriorly until the axis of the endoscope is parallel to the longitudinal axis of the lumen.

Postoperative Period

Postoperative Management

- Usually performed as an out-patient procedure
- Patients generally observed for several hours, during which clear liquids can be administered
- Patients are monitored for signs of mediastinitis, such as fever, tachycardia, odynophagia, chest pain, and crepitus on examination of

the neck

- If recovery period is uneventful, patients can be discharged home with instruction to return promptly if any of the aforementioned symptoms occur.

Complications

- Dental trauma
  - Chipped tooth, avulsion of tooth
  - With a tooth fracture or avulsion, urgent consultation with a dentist or oral surgeon is warranted. Often, the tooth can be replaced with interdental wire fixation.
- Perforation of the esophagus
  - Most commonly occurs from aggressive movement from the scope against resistance, or from dilation or instrumentation during the procedure
  - The endoscopist can use a lumen finder or guidewire to help with finding the true esophageal lumen.
  - If a perforation is suspected, the patient should be admitted for intravenous broad-spectrum antibiotic care. A nasogastric tube should be placed and the patient should be kept NPO. Again, the patient should be closely monitored for signs of mediastinitis.
  - The surgeon and anesthesiologist should also evaluate for signs of pleural injury, such as diminished breath sounds, high ventilator peak pressure, and subcutaneous emphysema. A chest radiograph should be obtained if any of the signs are present.

FIG. 45.6 Gastrografin esophagogram, lateral view, demonstrating an esophageal perforation *(arrow)* with extravasation of contrast material into the mediastinum.

  - When the patient is awake and stable, a gastrograffin esophagram should be performed to evaluate for a leak (Fig. 45.6).
  - Large perforations should be explored and repaired as soon as possible. Small perforations can be managed conservatively by leaving a nasogastric tube, continuing intravenous antibiotics, using H_2 blockers, and keeping the patient NPO.
- Arrhythmia or hypotension
  - Usually from vasovagal reflexes and may be self-limited
  - Removal of instrument is helpful in returning arrhythmia to baseline rhythm
  - If arrhythmia is repetitive or if patient experiences hemodynamic compromise, an anticholinergic agent such as atropine can be administered.

Alternative Management Plan

- Imaging including esophagram and/or CT scan

Evidence-Based Question

What is the rate of esophageal perforation after esophagoscopy?

Esophageal perforation is a potentially devastating complication after either rigid or flexible esophagoscopy. According to the literature, the rate of esophageal perforation is approximately 1%; however, this rate can increase to up to 6% if patients are undergoing concurrent procedures, such as dilation of a stricture or removal of a foreign body. Most studies suggest a higher rate of perforation for rigid esophagoscopy compared with flexible procedures. In a study of 546 procedures by Tsao et al., a perforation rate of 2.6% was noted, all following rigid esophagoscopy. The authors suggest that patients for whom esophagoscopy was performed by junior residents may be most susceptible to injury and perforation. As such, close supervision is critical in academic training centers. Although esophageal perforation after esophagoscopy is rare, care needs to be taken to ensure meticulous technique during the procedure; excessive force and misapplication of pressure or direction need to be recognized in advance and avoided.

Editorial Comment

Endoscopy of the aerodigestive tract is an important component in the evaluation of certain patients with problems in the head and neck. Full evaluation of the mucosal extent of tumors helps to guide decision making. Imaging evaluation is often inadequate in determining the mucosal extent because there is often effacement of the air space of the pyrifom sinuses.

Ruling out synchronous primary cancers and other lesions of the esophagus is also important when evaluating patients with cancer of the hypopharynx and cervical esophagus. Drs. Kadakia and Chai have given the essential details for the different methods of esophagoscopy. Flexible esophagoscopy is both safer and more effective than rigid esophagoscopy for this purpose. In addition, many patients with cancer of the hypopharynx or cervical esophagus require prolonged enteral access, and careful placement of the flexible esophagoscope to facilitate percutaneous endoscopic gastrostomy is required.

Hypopharyngoscopy represents a special challenge and is a hybrid

procedure. Some specific things to keep in mind are that use of various laryngoscopes to displace the endotracheal tube anteriorly will help in visualizing the postcricoid area and esophageal inlet. These areas and the anterior, lateral, and medial walls and apex of the pyriform sinus are difficult to visualize with flexible scopes unless the larynx is displaced. Newer techniques used in the management of cancer of the hypopharynx, such as endoscopic and open partial laryngectomy, are available, and endoscopic assessment of exposure and tumor extent and accessibility using telescope and microscope helps in determining the feasibility for transoral laser surgery or transoral robotic surgery (TORS).

Telescopic visualization along with microlaryngoscopy for the better assessment of the mucosal extent of the cancer and documentation of the stage of the cancer for both early and advanced cancers is important for cancers in both surgical sites.

Laryngoscopes can also be used to facilitate exposure of the esophageal inlet for esophagoscopy when this access is difficult. In some cases the angle of approach or the cancer or even a cervical osteophyte will make access difficult. Videolaryngoscopy is often helpful to lift the tongue and provide this access. It is often helpful to have the surgeon place the laryngoscope and advance it while an assistant does the air insufflation, suction, and maneuvering. It is important to remove the air in the stomach on removing the scope, and the mucosa is best evaluated on the way out rather than on the way in.

For cancers of the hypopharynx and cervical esophagus, determination of the inferior extent of the cancer is important in determining resectability, particularly with reference to placement of vascularized tissue for circumferential reconstruction. For cancers that extend beyond the cervicothoracic inlet, consideration of total esophagectomy and gastric pull-up rather than free tissue transfer is advisable to avoid life-threatening leaks of saliva or gastric contents into the upper mediastinum.

Instrumentation has improved significantly over the past three decades, so when performed correctly, hypopharyngoscopy and esophagoscopy can be done very safely; however, in some cases, it is still better to avoid instrumenting the esophagus to avoid perforation. Unexpected pain and fever should be warnings of an unrecognized complication postoperatively. If there is any question of perforation after

an esophagoscopy, the patient should be kept under careful observation until complications have been excluded or managed. In general, antibiotics and analgesics are not required for patients undergoing endoscopy including esophagoscopy. An exception is percutaneous endoscopic gastrostomy, when prophylactic antibiotics are indicated.

Review Questions

1. All of the following are true regarding esophagoscopy except:

   a. The operator should be careful not to push the scope aggressively against areas of resistance

   b. **The operator should change the angle of the scope with the nondominant hand and guide the scope at the oral entry point with the dominant hand**

   c. Flexible and rigid endoscopy both have advantages and disadvantages

   d. Esophagoscopy can be a versatile tool for therapeutic and diagnostic intervention

2. Which of the following is a potential complication of rigid esophagoscopy:

   a. Esophageal perforation

   b. Dental trauma

   c. Mucosal trauma

   d. **All of the above**

3. If esophageal perforation is suspected postoperatively, which of the following are important measures to take?

   a. Intravenous antibiotics

   b. NPO status

   c. Nasogastric tube

d. **All of the above**

Dysfunction of the Upper Esophageal Sphincter

Bridget Hathaway, and Ricardo L. Carrau

Introduction

The cricopharyngeus muscle is the major component of the upper esophageal sphincter (UES). The cricopharyngeus muscle is innervated by the pharyngeal plexus, which is composed of contributions from the vagus and glossopharyngeal nerves. Increasing evidence suggests that contributions from the recurrent laryngeal nerve (RLN) also innervate the cricopharyngeus muscle. The origin of the parasympathetic innervation is vagal, whereas sensory branches are derived from the glossopharyngeal nerve. Sympathetic fibers arise from the superior cervical ganglion and also join the pharyngeal plexus.

In its normal resting state, the cricopharyngeus muscle is in tonic contraction. When a swallow occurs, the cricopharyngeus relaxes during pharyngeal contraction (mediated by the vagus nerve), and anterior-superior movement of the larynx opens the UES to allow passage of the bolus into the esophagus; the bolus itself causes further distention of the UES. Dysphagia related to dysfunction of the UES results from (1) failure of cricopharyngeal relaxation, which can be due to lack of vagal innervation or loss of the normal viscoelastic properties of the muscle; (2) discoordination between cricopharyngeal relaxation and pharyngeal contraction; or (3) weakness of the suprahyoid musculature with poor elevation (anterosuperior movement) of the laryngeal complex.

Cricopharyngeal myotomy is used for alleviating cricopharyngeal dysfunction caused by lesions of the central and peripheral nervous systems, which affect laryngeal and pharyngeal muscle activity and coordination, as well as for the treatment of postsurgical dysphagia.

One of the most widely recognized manifestations of UES dysfunction is Zenker's diverticulum. Although the first description of a pharyngoesophageal diverticulum is attributed to Ludlow in 1769, this entity became known as Zenker's diverticulum after it was described in Zenker and Ziemssen's *Krankheiten des Oesophagus,* a landmark compilation of esophageal pathology published in 1877. Killian clarified the anatomic site of origin as the space between the inferior constrictor muscle and the cricopharyngeus muscle—hence its name Killian's triangle. Zenker's diverticulum is a pulsion diverticulum that forms in the muscular dehiscence of Killian's triangle as the UES fails to open with pharyngeal contraction, thus raising pressure in the pharynx (Fig. 46.1). Other areas of weakness have been identified and can lead to variations of the site of origin of the diverticulum (Killian-Jamieson and Lamier triangles). Failure of UES opening may be the result of failure of cricopharyngeal relaxation or weakness of laryngeal elevation.

The standard treatment of a Zenker's diverticulum includes a myotomy of the UES, which may be combined with resection of the diverticulum through a left-sided cervical incision; however, other techniques are also in common use. Dohlman and Mattson described an endoscopic technique for cricopharyngeal myotomy that has been modified with the introduction of bivalved endoscopes to provide better exposure of the party wall between the diverticulum and esophagus (containing the cricopharyngeus muscle) and the use of lasers, staplers, and harmonic scalpels for its transection. Advances in endoscopic instrumentation enabled Collard and associates to perform the first esophagodiverticulostomy with an endoscopic stapler in 1993. This procedure involves endoscopic division of the cricopharyngeus muscle with marsupialization of the diverticulum into the pharyngoesophagus. Modification of the stapler as described by Lang and colleagues allows the division to extend as close as possible to the inferior aspect of the diverticulum. Alternative endoscopic approaches use the CO_2 laser or the harmonic scalpel to divide the party wall between the esophagus and diverticulum.

Key Learning Points

1. History of dysphagia and confirmation of upper esophageal dysfunction with imaging are essential in the diagnosis of dysfunction of

the UES.

2. Presence of normal or nearly normal pharyngeal function will optimize swallowing outcomes following cricopharyngeal myotomy.

3. Transcervical and endoscopic approaches are valid treatments for Zenker's diverticulum and multiple factors should be considered in selecting the best approach for each patient.

Preoperative Period

History

1. History of present illness
   a. Dysphagia to solids more than liquids
   b. Dietary restrictions related to dysphagia
   c. Regurgitation of undigested food
   d. Unintentional weight loss
   e. Recurrent pneumonia
   f. Gastroesophageal reflux symptoms and response to treatment
2. Past medical history and comorbid conditions
   a. Cerebrovascular accident
   b. Neurologic diseases (Parkinson's, amyotrophic lateral sclerosis [ALS]) or neuromuscular diseases (inclusion body myositis)
   c. History of head and neck surgery or radiation therapy to the neck

Physical Examination

1. Palpation of laryngeal elevation with swallowing
2. Flexible laryngoscopy
   a. Rule out other pathologies such as tumor or infection.
   b. Pooling of secretions in hypopharynx

3. Functional endoscopic examination of swallowing (FEES)
   a. Hypopharyngeal residue is suggestive of UES dysfunction.
   b. Evaluate for aspiration.
   c. Regurgitation (most commonly to the left piriform)

Imaging

1. Barium esophagram
   a. Prominence of the cricopharyngeus muscle on lateral view at the level of C5-C7 vertebral bodies
   b. Failure of relaxation of the cricopharyngeus muscle (Fig. 46.2)
   c. Presence of Zenker's diverticulum (Fig. 46.3)

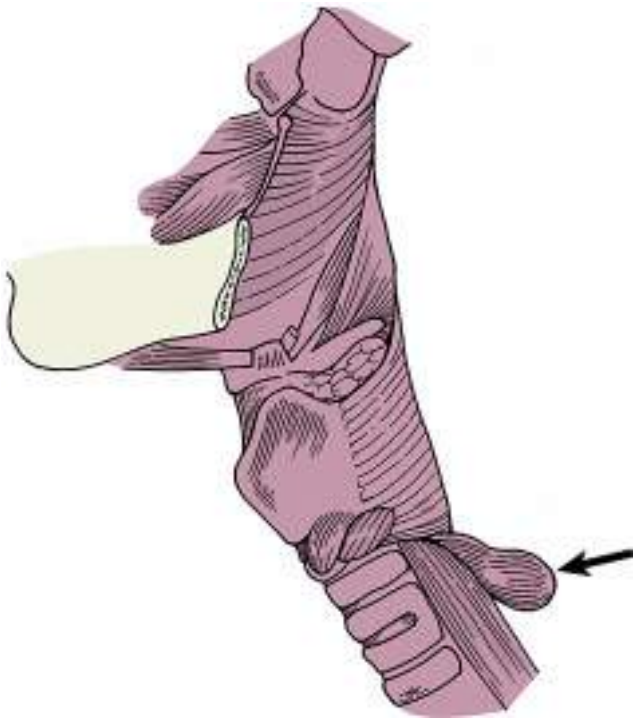

FIG. 46.1 Zenker's diverticulum posterior to the esophagus *(arrow).*

FIG. 46.2 Barium esophagogram (lateral view) demonstrating failure of relaxation of the cricopharyngeus muscle *(arrow).*

2. Modified barium swallow

   a. Identify and quantify laryngeal penetration and aspiration.

   b. Evaluate the coordination of swallow and laryngeal elevation.

3. High-resolution impedance manometry

   a. Allows for measurement of pharyngeal strength, UES relaxation, and intrabolus pressures

   b. During swallowing, normal pharyngeal contraction with elevated UES residual pressure is suggestive of UES dysfunction.

FIG. 46.3 Barium esophagogram demonstrating Zenker's diverticulum *(arrow).*

Indications

- Moderate to severe dysphagia symptoms with poor UES opening on Modified barium swallow MBS
  - Normal or nearly normal pharyngeal function, which is required for propulsion of the bolus
  - Adequate laryngeal elevation, which is required for opening of the UES
- Dysphagia causing significant weight loss
- Complications of aspiration (i.e., recurrent pneumonia)

Contraindications

- Medically unfit
- Diffuse pharyngeal motor abnormalities and poor anterosuperior

laryngeal elevation

- Comorbid conditions such as ALS, Parkinson's disease, or cerebellar atrophy that would contribute to diffuse pharyngeal motor abnormalities
- Conditions that affect the opening of the lower esophageal sphincter LES (achalasia, stricture)
- Severe esophageal dismotility with antegrade regurgitation
- Uncontrolled gastroesophageal reflux disease GERD

Preoperative Preparation

- Discontinue antiplatelet drugs and herbal medicines.
- Optimize GERD control.

Operative Period

Anesthesia

- General anesthesia is preferred.
- Local anesthesia can be used if the patient's condition does not permit general anesthesia (transcervical approach only).

Positioning

- Supine
- Shoulder roll facilitates exposure for transcervical approach

Perioperative Antibiotic Prophylaxis

- Antibiotics are administered during induction of anesthesia.
- Choices

  Clindamycin

Ampicillin-sulbactam

Cephalosporin and metronidazole

Monitoring

Routine anesthesia monitoring

Instruments and Equipment to Have Available

- Endoscopic approach for Zenker's diverticulum
  - Weerda diverticuloscope
  - Endo-GIA stapler
  - Endoscopic stitch or alligator forceps for retraction
  - Zero-degree and 30-degree endoscopes
- Transcervical approach
  - Rigid esophagoscope
  - Standard head and neck set
  - Bipolar cautery

Key Anatomic Landmarks

- Cricoid cartilage marks the level of the cricopharyngeus muscle
- Cricothyroid joint is the entry point of the RLN
- Cricopharyngeus muscle can be distinguished from inferior pharyngeal constrictor by the horizontal orientation of its fibers

Prerequisite Skills

- Rigid esophagoscopy
- Transcervical approach to the retropharyngeal space

- Closure of pharyngotomy

Operative Risks

- Injury to the teeth
- Contained salivary leak or salivary fistula
- Bleeding
- Mediastinitis

Surgical Technique

Cricopharyngeal Myotomy

- A nasogastric tube (NG) is placed.
- Transverse incision in a skinfold at the level of the cricoid cartilage
- Subplatysmal flaps are elevated inferiorly to the clavicle and superiorly above the thyroid notch.
- Sharp separation of the sternocleidomastoid (SCM) muscle from the strap muscles exposes the carotid sheath.
- The SCM and carotid sheath are separated from the strap muscles, thyroid gland, and laryngotracheal complex and retracted anterolaterally and rotated to the right to allow entry into the retropharyngeal-prevertebral space (Fig. 46.4).
- The middle thyroid vein and the omohyoid muscle may be divided to facilitate the exposure and decrease the need for retraction. A large double hook is placed in the posterior aspect of the midthyroid lamina, and the larynx, trachea, and thyroid gland are rolled medially. Care should be taken to avoid placing the retractor in the area of the cricothyroid joint in order to avoid injury of the RLN.

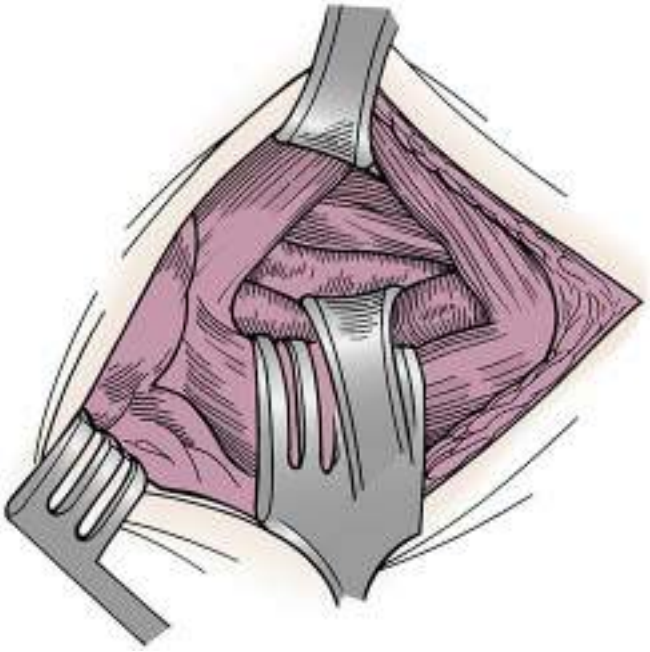

FIG. 46.4 The carotid sheath is retracted laterally to expose the prevertebral fascia.

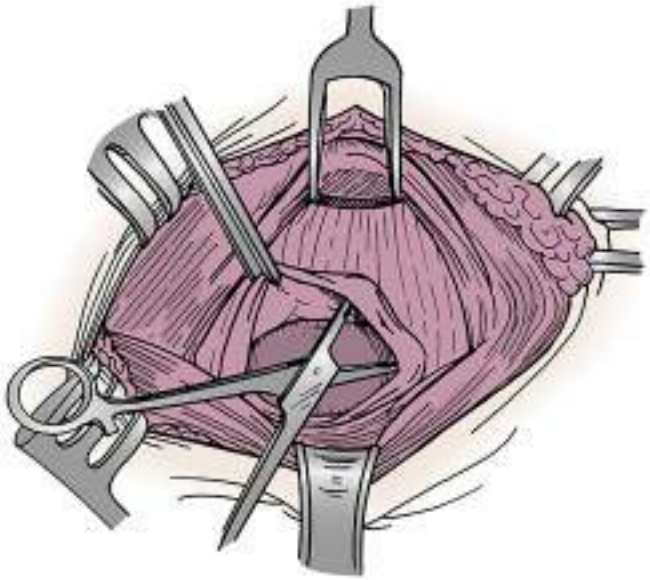

FIG. 46.5 Muscle fibers of the upper esophageal sphincter are separated from the hypopharyngeal mucosa in the midline with a hemostat.

- The nasogastric tube is palpated through the entrance into the retropharyngeal space. The NG tube is engaged into the lateral aspect

of the pharynx and grasped with Babcock clamps above and below the area of the cricopharyngeus, effectively isolating this muscle.

- This maneuver should be performed close to midline to avoid injury to the RLN. The cricoid cartilage will mark the level of the cricopharyngeal muscle; therefore, if the myotomy is performed at the level of the cricoid cartilage and extended above and below this level, it will be successful.
- Using a small hemostat, the oblique muscle fibers of the inferior constrictors are separated from the mucosa of the hypopharynx (Fig. 46.5). The muscle fibers are divided with a bayonet-type, insulated bipolar electrocautery as the hemostat is advanced along the plane between the muscles and mucosa. Change from an oblique to a horizontal direction of the muscle fibers marks the change from the inferior constrictor to the cricopharyngeal muscle.

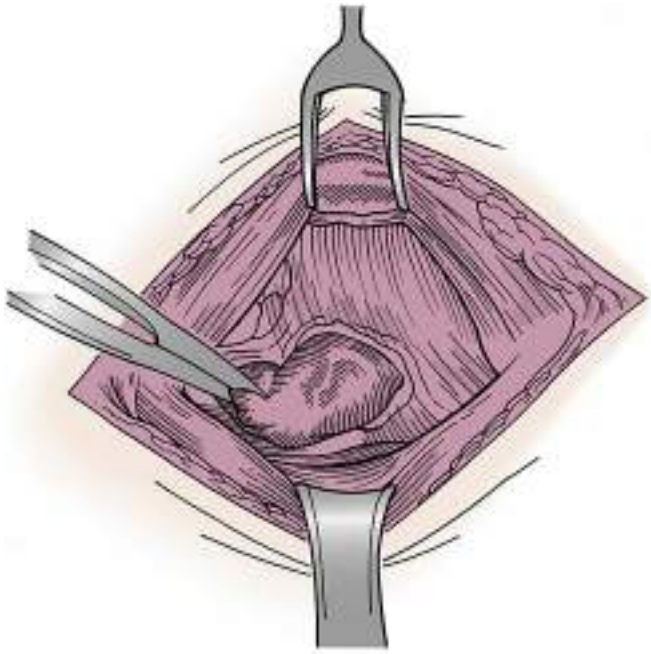

FIG. 46.6 The diverticulum is dissected from surrounding tissue.

- Extension of the myotomy to include 1 to 2 cm of esophageal musculature will also ensure that the myotomy is complete. These steps are repeated until the entire height of the cricopharyngeus muscle is divided. The Babcock clamps and the NG tube are removed.

- The wound is then irrigated with normal saline solution and closed in layers.
- If the pharynx is entered inadvertently, the nasogastric tube is left in place and secured to the nose with a suture. Any opening into the pharynx is closed with absorbable suture in an interrupted fashion. The wound is then irrigated and closed in layers over a suction drain, which is inserted into the area of the prevertebral fascia between the operative site and the carotid sheath.

Excision of Zenker's Diverticulum

Transcervical Approach

- The transcervical approach is preferable for diverticula that are too small to accommodate the endoscopic stapler (<3 cm) or when endoscopic visualization is precluded by anatomic factors.
- Direct laryngoscopy is performed and the contents of the diverticulum aspirated. The mucosal surface is thoroughly examined to rule out squamous cell carcinoma, which occurs in a small percentage of patients with Zenker's diverticulum.
- Cricopharyngeal myotomy is accomplished as described in the previous section. For most patients a myotomy suffices to alleviate symptoms caused by Zenker's diverticulum, especially when the diverticulum is small. Large pouches, however, are excised to prevent retention of secretions or food and regurgitation on assuming a recumbent position.
- The diverticulum is dissected from the surrounding tissue as the myotomy is performed (Fig. 46.6). If a diverticulectomy is to be performed, the neck of the diverticulum may be treated in one of two ways. The classic technique is to grasp the tip of the sac with a clamp and excise the sac (Fig. 46.7). Excessive traction on the sac may lead to overresection of hypopharyngeal mucosa and result in a stricture. A 3-0 or 4-0 gastrointestinal suture is then used to close the mucosa. Alternatively, a stapler may be used to excise the sac and repair the pharyngeal mucosa.

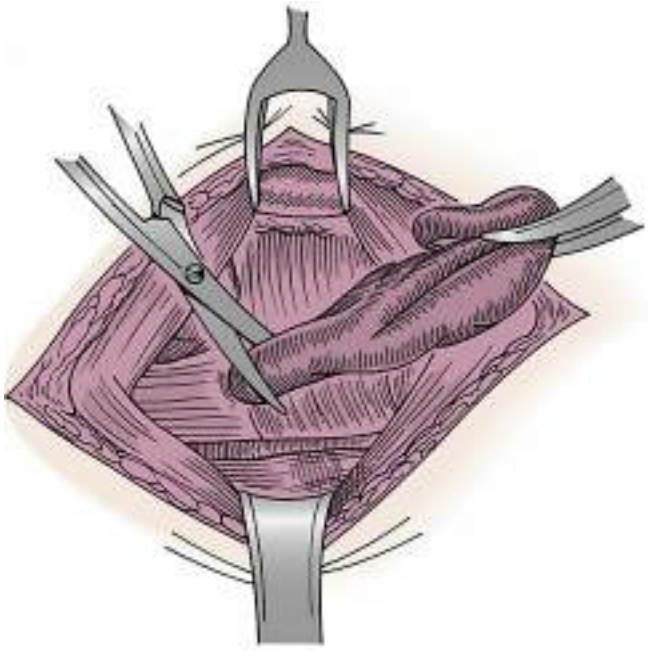

FIG. 46.7 Diverticulectomy is performed by excising the sac.

- The muscles should not be closed over the mucosa.
- Diverticulopexy was developed to avoid the risks inherent in entering the pharynx. When a diverticulopexy is to be carried out, the fundus of the diverticulum is inverted and sewn to the prevertebral fascia.
- The wound is then irrigated and closed in layers over a suction drain, which is inserted into the area of the prevertebral fascia between the operative site and the carotid sheath.

Endoscopic Approach

- A bivalved endoscope is inserted with one blade into the cervical esophagus and the other into the diverticulum (Fig. 46.8). The endoscope is suspended.
- Visualization is achieved with a 0-degree rigid endoscope.
- The "bar" between the pouch and the esophagus, which consists of the cricopharyngeus muscle, is stabilized by grasping it with alligator forceps or by using a stitch placed with an endoscopic stitching device.
- The Endo-GIA stapler is then used to divide the party wall between the

esophagus and diverticulum, with several rows of staples being deposited on each side in the process (Figs. 46.9 and 46.10). A modification of the Endo-GIA stapler as described by Lang and colleagues includes shortening the anvil so that it is as close as 1 mm to the metal clips. This allows the division of the party wall and marsupialization of the diverticulum to a level close to its fundus.

Common Errors in Technique

Incomplete transection of the muscle fibers comprising the UES can lead to persistent symptoms. If a pharyngeal closure is present, residual UES fibers can create a persistent high-pressure zone proximal to the UES, which can predispose to a pharyngeal leak in the postoperative period.

FIG. 46.8 Endoscopic view of the "bar" dividing the esophagus and pouch (the esophagus is anterior) *(arrow)*.

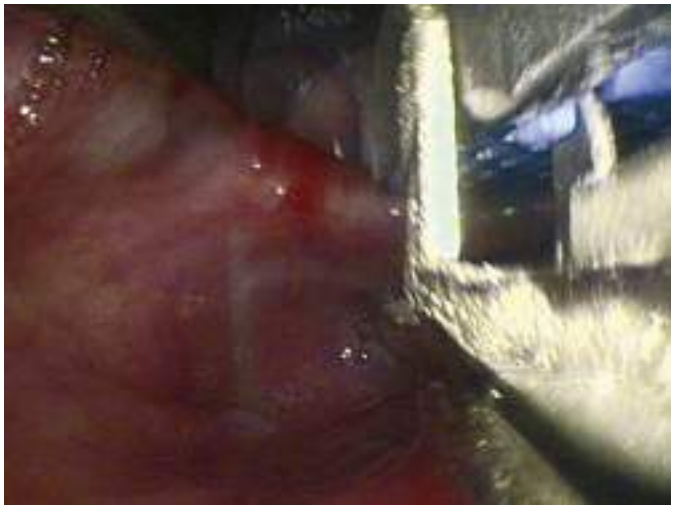

FIG. 46.9 The Endo-GIA stapler is positioned on the "bar" between the esophagus and pouch before stabilization with alligator forceps.

FIG. 46.10 The party wall between the esophagus and diverticulum has been divided and the resulting esophagostomy stapled in the process.

Postoperative Management

- Inadvertent entry into the pharynx is ruled out with a gastrografin esophagogram.
- For patients who have undergone primary cricopharyngeal myotomy

without pharyngeal entry, a soft diet is started and advanced to solid as tolerated; the patient is usually discharged the day of surgery. If a stapler diverticulectomy has been performed, the patient may be kept in the hospital overnight, and the suction drain is removed on the first postoperative day. Diverticulectomy repaired with traditional suture requires a longer hospital stay with no oral intake (3 to 7 days).

- If the pharynx was entered, a nasogastric tube should be passed to decompress the stomach over the first 48 hours and then be used for tube feeding. On the fifth day, the tube may be withdrawn after confirming the lack of a leak by a gastrografin esophagogram. The patient is given a soft diet for 1 week and then advanced to more solid food as tolerated.
- If the patient complains of a change in voice, laryngoscopy should be performed to rule out vocal cord paralysis/paresis from injury to the RLN.

Complications

- Contained salivary leak and salivary fistula should be treated with surgical drainage.
- Mediastinitis
- Injury of the RLN

Alternative Management Plan

- Botulinum toxin A (BTX A) has been used as an alternative to surgical cricopharyngeal myotomy in the treatment of a select group of patients with UES dysfunction.
  - BTX A may be injected transcutaneously under electromyographic guidance in the office or endoscopically in the operating room.
  - Given the preliminary nature of the studies, BTX A should generally be reserved for patients who refuse surgery or are not surgical candidates or when the diagnosis, prognosis, and expected response to myotomy are in question.
  - BTX A improves only UES relaxation; thus patients with poor

pharyngeal propulsion or weak elevation of the larynx, such as those with Parkinson's disease or ALS, are unlikely to benefit from BTX A injection.

- Dilation with balloons or bougies can also be employed in the treatment of UES dysfunction. While less invasive than surgical techniques, the results of dilation tend to be temporary.
- Observation is an option for any patient not amenable to surgical intervention.
- Enteral feeding access is an option for severe dysphagia, resulting in malnutrition and/or recurrent pneumonia.

Discussion

Reports of outcomes after cricopharyngeal myotomy are limited to retrospective reviews. Prognosis is generally related to the underlying cause of dysphagia, as well as the severity of dysphagia. As mentioned previously, those with focal neurologic deficits or isolated UES dysfunction are likely to have better functional outcomes than those with central neurologic processes or underlying oropharyngeal dysphagia.

With respect to the treatment of Zenker's diverticulum, transcervical and endoscopic techniques are both acceptable, and it is prudent to select a technique with which the surgeon is experienced that is best suited to the patient's needs. The endoscopic approach avoids potential RLN injury but has the potential complications of oral injury, dental injury, or laryngeal edema. Regardless of technique, complete myotomy is essential to minimize the persistence or recurrence of dysphagia.

Evidence-Based Medicine Question

Does the transcervical or endoscopic approach result in better outcomes in the treatment of Zenker's diverticulum?

Comparisons of endoscopic versus external approaches for the treatment of Zenker's diverticula have been retrospective. It is generally accepted that the endoscopic technique is associated with shorter operative time, length of hospital stay, and time to resume oral diet. A

recent systematic review by Verdonck and Morton found a higher success rate but more complications associated with external approaches.[1] Based on this, they advocate an external approach for younger patients with few comorbidities, as well as for those patients whose anatomy precludes endoscopic exposure.

Editorial Comment

Disorders of upper esophageal function are frustrating to patients. The authors have focused on Zenker's diverticulum, which is the most common indication for operative management of muscular dysfunction in this area. As described, Zenker's results at least in part due to lack of relaxation of the cricopharyngeus muscle. Most upper esophageal dysfunction is caused by this failure of relaxation of the muscle.

Dr. Hathaway and Dr. Carrau have done an excellent review of the pathophysiology and management of Zenker's. Prior to the development of the GIA stapler technique, most patients were treated with the open approach, but the endoscopic approach (Dohlman procedure) was employed safely using electrocautery or laser. Complications from violation of the retropharyngeal space can occur if the procedure is performed improperly.[2] As discussed, an open approach is probably ideal for younger patients and for patients in whom identification of the cricopharyngeus endoscopically is difficult due to exposure. Patients with smaller diverticulae seem to be more challenging from the endoscopic approach as well.

Cricopharyngeal denervation is an important technique, and the authors have discussed the utility of botulinum toxin injection. In addition to management of patients with Zenker's, this technique can be used for patients with dysphagia or strained voice following total laryngectomy as an alternative to pharyngeal plexus neurectomy. The reader is encouraged to discover the literature in this realm as well.

Review Questions

1. The best predictor of good functional outcome after criciopharyngeal myotomy is

   a. Age

   b. **Preserved pharyngeal strength**

   c. UES opening on MBS

   d. Preoperative diet

2. Which of the following is *not* a potential complication of endoscopic cricopharyngeal myotomy for Zenker's diverticulum?

   a. Pharyngeal leak

   b. Dental injury

   c. Mediastinitis

   d. **RLN injury**

3. Which of the following technical aspects is important in avoiding RLN injury during cricopharyngeal myotomy?

   a. Identification of inferior constrictor muscle fibers

   b. **Division of cricopharyngeus muscle fibers posteriorly in the midline**

   c. Retraction of the carotid sheath laterally

   d. Division of the omohyoid muscle

4. Which of the following factors can contribute to UES dysfunction?

   a. Vagus nerve injury

   b. Weakness of suprahyoid musculature

   c. Discoordination between pharyngeal contraction and cricopharyngeus muscle relaxation

   d. **All of the above**

Penetrating Trauma to the Hypopharynx and Cervical Esophagus

Trevor Hackman

Introduction

Penetrating trauma to the hypopharynx and cervical esophagus is a potentially life-threatening injury, which may be the result of iatrogenic injury, accidental impalement, or assault. Multiple routine procedures and surgeries (intubation, nasogastric tube placement, rigid and flexible esophagoscopy with or without dilation/biopsy/foreign body removal, Zenker's diverticulectomy, cervical spine surgery, and transesophageal echocardiography) carry a risk of visceral perforation, which if not recognized can quickly lead to patient compromise. Patients involved in major motor vehicle accidents, especially when ejected from the car, are at high risk for impalement injuries. Finally, the victims of violent crimes (stabbings and gunshot wounds) also may suffer aerodigestive tract injuries. Typically, the patients with potential noniatrogenic penetrating traumas have multiple confounding injuries (spinal instability, fractures, cranial injuries, vascular injuries), which may delay recognition of the visceral injury.

As perforations can quickly lead to life-threatening danger space infections, including mediastinitis, a high index of suspicion is necessary. The most critical factor affecting patient outcome is the time between the injury and the initiation of treatment.[2] Rapid diagnosis and treatment are paramount to patient survival, as a delay in treatment of more than 24 hours significantly increases morbidity and mortality.[3]

Many iatrogenic perforations and penetrating gun shot wound (GSW) or stab wounds can be managed conservatively with broad-spectrum antibiotics against upper aerodigestive tract flora (e.g., ampicillin-sulbactam, clindamycin), nasogastric tube placement, and nothing by

mouth status for 3 to 5 days.

Adequate nutrition is necessary for healing, and in cases where nasogastric tube placement is not feasible, laparoscopic gastrostomy tube placement can be performed.

Key Operative Learning Points

1. High index of suspicion is necessary to identify patients with penetrating trauma to the hypopharynx and cervical esophagus, as the early symptoms may be subtle, and delayed recognition may be life-threatening.

2. The most common cause of penetrating trauma is iatrogenic, accidental visceral injury during a procedure.

3. The signs and symptoms of a perforation include neck pain, dysphagia, odynophagia, new onset fever, tachycardia, chest pain, subcutaneous emphysema, or pneumomediastinum and should raise suspicion for pharyngeal perforation.

Preoperative Period

History

1. History of present illness

   a. Potential mechanisms of injury should be investigation

      1) Iatrogenic:

         a) Intraluminal instrumentation of the aerodigestive tract: Intubation, nasogastric tube placement, rigid and flexible esophagoscopy with or without dilation/biopsy/foreign body removal, Zenker's diverticulectomy, and transesophageal echocardiography

         b) External trauma—Cervical spine surgery, open Zenker's

      2) Traumatic; motor vehicle collision (MVC) ejection, gunshot, or stab wound

b. The stability of a patient should be assessed.

The ABCs of trauma (airway, breathing, circulation) should be assessed and addressed prior to further evaluation of a suspected perforation. In the cases of gunshot wounds and stabbings, the patient may also have life-threatening laryngeal and tracheal injuries, which may necessitate an immediate surgical airway.

c. The patient's symptoms should be assessed.

Neck pain, dysphagia, odynophagia, vocal pain, voice changes, and chest pain are all potential symptoms of a perforation, particularly after an at-risk procedure in the vicinity of the hypopharynx or esophagus.

d. Nil per os (NPO) status

Has the patient been eating? Is there pain with eating?

2. Past medical history

a. Prior treatment

b. Medical illness: ingestion of a foreign body

c. Surgery: recent surgical procedure involving the neck, spine, or aerodigestive tract Zenker's diverticulectomy

d. Family history

e. Medications

Physical Examination

1. Vital signs

As perforations can quickly lead to patient compromise, an assessment of vital signs and airway is critical. Fever, tachycardia, hypotension, tachypnea, and hypoxia can occur with perforation injuries. Airway symptoms, including dysphonia, hoarseness, and stridor, should alert the team to consider a surgical airway, such as a cricothyroidotomy or awake tracheostomy, depending upon the patient's stability.

2. Neck

Examination of the neck may reveal fluctuance, bruising, evidence of

recent surgical incision, or subcutaneous emphysema. Penetrating external trauma may also result in injury to the great vessels and airway.

3. Flexible fiberoptic laryngoscopy

Confirms a safe and patent airway and may reveal mucosal abnormalities and bleeding if the trauma is high in the hypopharynx. Vocal fold mobility can be evaluated, as well as whether the patient is a candidate for intubation or requires an awake tracheostomy.

Imaging

1. Chest radiograph
    a. Chest radiograph is an expedient method to assess for subcutaneous emphysema, pneumomediastinum, pneumothorax, or tracheal shift.
2. Esophagogram
    a. Esophagogram is the most sensitive test for detecting perforation, ranging from 75% to 100%. Water-soluble contrast, such as meglumine diatrizoate (Gastrograffin), is the preferred method for detecting perforations, as the extravasated contrast is quickly absorbed and cleared by the tissues, unlike barium. However, Gastrograffin is extremely damaging to pulmonary tissues and may lead to life-threatening pneumonitis and pulmonary edema due to powerful osmotic shifts. Therefore it should be avoided in patients at risk for aspiration or complex laryngotracheal injury. A negative esophagogram does not definitively rule out a perforation, and thus when the index of suspicion is high, patients should still be managed accordingly to clinical findings.
3. Computed tomography (CT) spine/neck/chest
    a. When concomitant spine, vascular, or laryngotracheal injury is suspected in the stable patient, a CT is useful for evaluating soft tissue damage. In the case of suspected perforation, especially with a negative swallow study, a CT scan of the neck will often demonstrate free air in the soft tissues, as well as the extent of fluid collection/infection in the danger space and mediastinum, leading to prompt exploration and drainage. Pneumomediastinum, pneumothorax, and pleural infections can also be more clearly seen

and prompt earlier intervention by a Thoracic Surgery (Fig. 47.1).

4. Angiography

   a. If zone 3 vascular injury is also suspected in the stable patient, angiography is useful for triaging management of the patient's problems.

Indications

1. Evidence of large perforation on esophagogram

FIG. 47.1 Axial computed tomography scan demonstrating free air in the deep planes of the neck, suggestive of an injury to the aerodigestive tract.

A large pharyngeal defect is unlikely to heal spontaneously and will require direct repair or soft tissue flap coverage.

2. Chest radiograph demonstrating significant (or increasing) subcutaneous emphysema, pneumothorax, or tracheal shift

In the case of expanding free air with airway shifting or pneumothorax, neck exploration with drain placement and likely chest tube insertion is necessary to prevent pulmonary compromise.

3. Progressive decline in patient stability despite conservative management

Patients with progressive fevers and cardiopulmonary instability require surgical intervention, as they are likely developing mediastinal fluid collections and mediastinitis requiring drainage.

Contraindications

1. Patients who respond to conservative management

2. Major airway, vascular, and spine injuries require stabilization prior to investigation for visceral injury to the pharynx.

The patient should be stabilized first from an ABC standpoint and be covered with broad-spectrum antibiotics if perforation is suspected, prior to diagnostic tests (esophagogram) being performed.

Preoperative Preparation

1. Confirm cervical c-spine clearance.

2. Confirm plan for airway management—intubation versus tracheostomy.

3. Discontinue antiplatelet drugs if possible.

4. Monitor Hb/Hct and transfuse if necessary.

Operative Period

Anesthesia

General: Surgery will require instrumentation of the pharynx and/or exploration with in the neck. To perform this safely, the airway must be secured and patient movement controlled.

Positioning

Supine: The patient is positioned the same as any neck exploration or

endoscopy with the head of the bed turned toward the surgeon.

Perioperative Antibiotic Prophylaxis

Ampicillin-sulbactam (3 grams IV)

Piperacillin/tazobactam (3.375 grams IV)

Clindamycin with ciprofloxacin if allergic to penicillin

Monitoring

Recurrent laryngeal nerve (RLN)—In cases of patients with a intact and functioning larynx, for whom intubation is feasible, real-time recurrent laryngeal nerve monitor (while not shown in the literature) may be used to aid in laryngeal nerve identification and preservation during exploration of a contaminated neck wound.

Instruments and Equipment to Have Available

1. Basic rigid panendoscopy set

2. Basic neck dissection set: scalpel, scissors, retractors (Army/Navy, Deaver, Richardson), fine dissecting forceps (McCabe, Jake's), needle drivers, and suture

3. Nasogastric tube

4. Drains: Penrose drain, Jackson-Pratt drain

5. Methylene blue

Key Anatomic Landmarks

1. Laryngeal framework: The thyroid ala is a thin wedge-shaped cartilage, which houses the arytenoids and false and true vocal folds, and is positioned on top of the cricoid. The cricoid cartilage is the only complete cartilaginous ring of the airway. Anteriorly the cricothyroid membrane bridges the two structures and is the site for placement of an

emergent airway (cricothyroidotomy).

2. Inferior pharyngeal constrictors: This muscle originates from the thyroid ala and cricoid cartilage in two separate bellies. Zenker's diverticulum develops between the two bellies of this muscle (thyropharyngeal and cricopharyngeal) in a small gap, known as Killian's triangle.

3. Recurrent laryngeal nerve: The recurrent laryngeal nerve courses from the thoracic inlet superiorly along the tracheoesophageal groove and enters the larynx at the posterior edge larynx between the thyroid ala and cricoid at the cricoarytenoid joint. The right recurrent laryngeal nerve has a more oblique course and in rare cases (retroesophageal subclavian artery) may be nonrecurrent.

4. Thyroid gland: A highly vascular horseshoe-shaped endocrine gland that bridges over the cricoid or upper trachea, overlies the esophagus, and occupies the bilateral central compartment (see Chapter 78).

5. Parathyroid glands: Small (3 to 5 mm) amber-colored endocrine glands deep to the thyroid lobe that control calcium absorption (see Chapter 84).

Prerequisite Skills

1. Upper aerodigestive tract endoscopy (see Chapters 18 and 45)

2. Neck dissection and exploration (see Chapters 64 and 75)

Operative Risks

1. Intraoperative injury to the recurrent laryngeal nerve

If initial attention is paid to nerve identification using the laryngeal landmarks listed previously prior to management of the visceral injury, the risk is significantly reduced. In some settings, nerve monitoring may be beneficial. In cases of bilateral injury, tracheostomy may be necessary.

2. Parathyroid injury

Leads to hypoparathyroidism and hypocalcemia. Preventable by performing meticulous dissection deep to the thyroid and identifying the glands, prior to addressing the perforation. In cases of recognized

parathyroid injury, the glands may be minced and reimplanted into neck musculature. Intraoperative parathyroid hormone testing can be used to predict parathyroid function postoperatively, when injury is suspected.

3. Bleeding

The common carotid artery, subclavian artery, thyrocervical trunk, jugular vein and superior thyroid vessels, and anterior jugular veins all course through this region and, depending on the location and trajectory of injury, may be involved. Meticulous dissection and high index of suspicion for preoperative trauma prevent injury to the major vessels.

4. Substernal extension

In cases where the injury or neck infection extends substernally a Thoracic surgeon should be consulted for intraoperative management.

Surgical Technique: Direct Repair—Small and Early-Recognized Defects

Endoscopy: (see Chapters 18 and 45)

Prior to neck exploration, endoscopy/esophagoscopy may be helpful for assessment of the perforation and guided placement of a nasogastric tube. Care should be taken to avoid further expansion of the perforation. Insufflation flexible esophagoscopy is not recommended, as this will increase subcutaneous free air.

A horizontal neck crease at the level of the laryngeal framework is marked and injected with local anesthesia between the anterior sternocleidomastoid muscle edges (Fig. 47.2).

The crease chosen depends on the level of the injury; esophageal injuries are best exposed with midline incision over the trachea, whereas high hypopharyngeal injuries are best approached through incision over the thyroid ala.

- Subplatysmal flaps are elevated superiorly to the hyoid and inferiorly to the clavicle.
- Dissect the outer tunnel between the sternocleidomastoid muscle and strap muscles.

- Identify a carotid sheath and retract its contents laterally (Fig. 47.3).
- Identify and preserve the superior laryngeal nerve.
- Identify and preserve the recurrent laryngeal nerve.

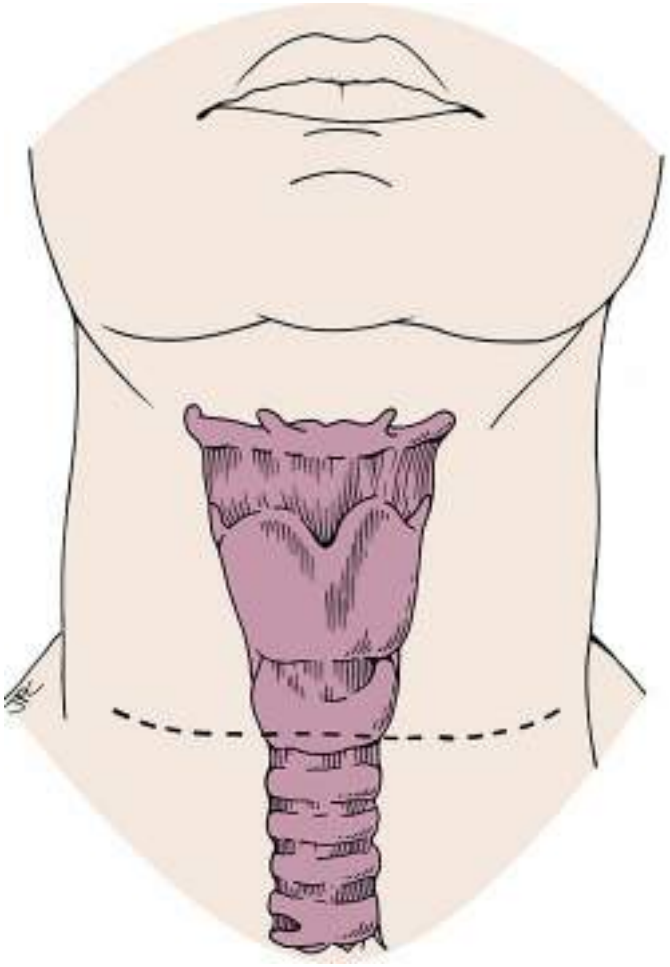

FIG. 47.2 A transverse cervical incision at the level of the inferior edge of the cricoid cartilage. This incision provides bilateral access to the pharyngoesophageal area. However, it can be adapted to a particular need according to the level of injury and laterality.

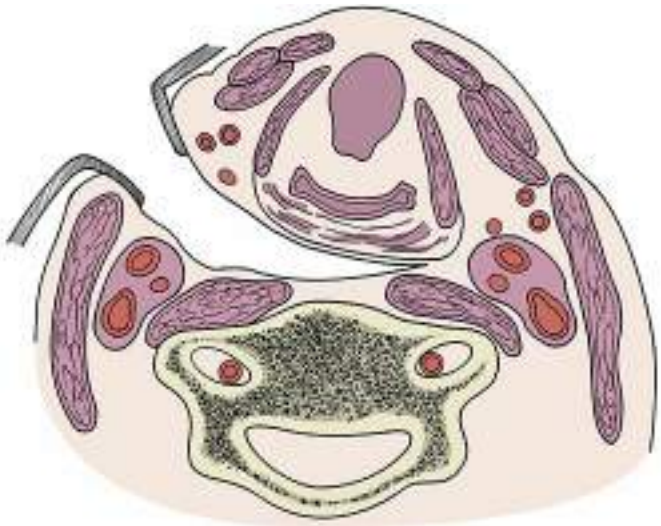

FIG. 47.3 Axial view of the surgical route to the pharyngoesophagus (retropharyngeal space). The retractor on the *left* is displacing the sternocleidomastoid muscle and the contents of the carotid sheath. The retractor on the *right* is rotating the larynx in an anteromedial direction.

- Blunt and sharp dissection are used to mobilize the laryngopharyngeal complex with the identified nerves off of the prevertebral fascia.
- Search for site of perforation—use of methylene blue-dyed saline irrigation of the oral cavity may aid in identification of the perforation.[4]
- The wound cavity is copiously irrigated with warm sterile saline.
- Perforation edges are freshened with a 15-blade scalpel and then closed in two layers: First an absorbable suture is used to invert and closed the mucosal injury; second the constrictor muscles or esophageal muscles are closed with interrupted suture.
- Blue dye irrigation of the oral cavity may be used to confirm watertight closure.
- The wound cavity is copiously irrigated with warm sterile saline.
- A suction drain is placed in the prevertebral space and extended into the chest as needed for pleural space contamination.
- For severe chest infection, mediastinitis, chest tube placement, and

thoracotomy are often required.

- The neck is closed in multilayer fashion; platysmal closure, followed by skin closure

Surgical Technique: Direct Repair—Large or Delayed Defects

For large defects, or defects older than 24 hours, direct repair is not feasible or recommended. In these cases, local or regional flaps may be necessary, depending on the surrounding tissue quality. In severe cases, temporary esophagostomy may be necessary.

- Follow the previous steps until the freshening of perforation edges.
- Myofascial strap or sternocleidomastoid transposition flaps may be elevated and rotated over the defect to either buttress a closure or patch a defect (Fig. 47.4).[5,6]
- For more contaminated wounds and/or larger defects not amenable to local muscle flaps, a pectoralis major flap or free tissue transfer may be performed.[7]

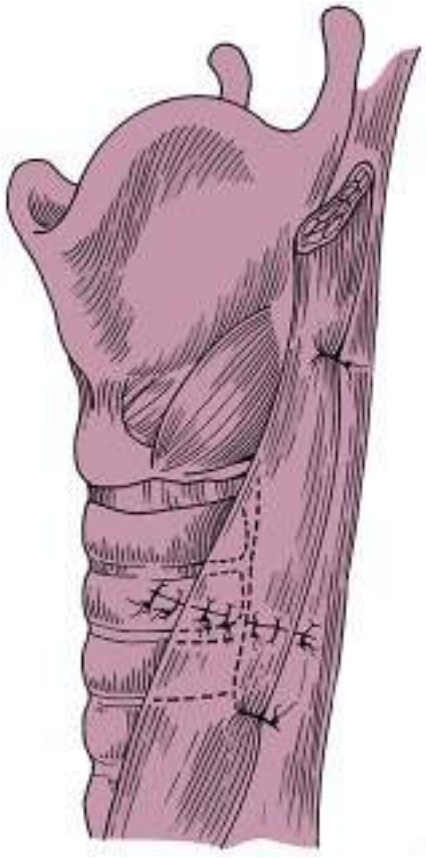

FIG. 47.4 Tracheoesophageal injury repaired primarily and reinforced with a strap muscle pedicle flap.

Surgical Technique: Diversion

In some cases (e.g., contaminated wounds, multiple sites of injury, complete esophageal transaction, or an unstable patient), a diverting esophagostomy is an efficient and safe method for salivary diversion, allowing time to stabilize the patient and develop a future surgical plan.

- Follow the previous steps until the perforation is identified.
- The cervical esophagus is mobilized inferiorly, and the injured segment is externalized and sewn to the cervical skin with Vicryl sutures as a controlled fistula (Fig. 47.5).

Surgical Technique: Special Circumstances

- In the case of concomitant tracheal injury, direct repair of the tracheal injury should be performed. The practitioner should have a low

threshold for performing a tracheostomy below the level of tracheal injury to prevent further free air in the mediastinum.

- If the esophageal and tracheal injuries overlap, an interpositional local myofascial flap should be placed to prevent tracheoesophageal fistula.
- In the case of vascular injury, after repair of the vessel, salivary diversion should be planned away from the vessel, and one should consider local muscle flap coverage of the vessel repair.

Common Errors in Technique

1. Improper neck incision placement for the level of the defectFailure to properly localize the fistula may result in an incision that does not offer easy exposure and thus requires further lateral extension of the incision, or risk operative in a poor visual field, increasing the traction on tissues and risk of injuries.

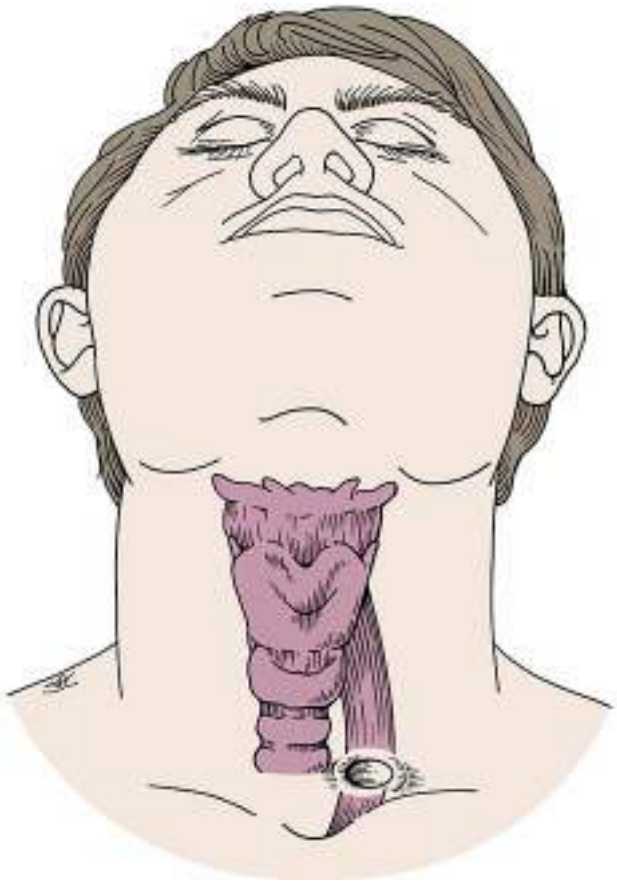

FIG. 47.5 Esophagostomy after completion.

2. Approaching prevertebral space too medially

After lateralizing the carotid sheath, the next step is to elevate the laryngopharyngeal framework off of the spine. Care must be taken to start far laterally on the spine to avoid inadvertent injury to the pharynx or esophagus, which are often off the midline. Palpation of the nasogastric tube and blunt dissection in this area are helpful techniques.

3. Failure to freshen wound edges, invert the mucosa, or recognize compromised pharyngeal tissue, which may lead to delayed nonviable tissue in the suture line and hence delayed leaks

The quality of the pharyngeal tissue and the closure technique (inverting the mucosal edges) are critical to success. If the exploration is delayed more than 24 hours and/or the tissue has discoloration (dusky quality), the wound edges should be freshened until healthy bleeding is seen, and secondary muscle patches should be utilized.

4. Attempts to force large wounds to closure primarily under tension

The pharyngeal tissues, even when healthy, are not robust in strength and therefore cannot withstand tension.

5. Ischemic suture line

Performing a running suture line (particularly locking fashion) with tension can lead to tissue ischemia and delayed leaks. The tissues and closure must be performed meticulously with gentle handling of the mucosa, adequate bites of tissue, and appropriately spaced sutures to avoid tissue ischemia.

6. Failure to adequately drain the space

Prompt and adequate drainage of the neck and prevertebral space are the most important factors affecting patient prognosis. Failure to recognize mediastinal extension of the process and drainage of the collection can be devastating. Suction drains are preferable to a Penrose drain, as the drainage cavity often extends below the sternum, resulting in a nondependent drain position.

Postoperative Period

Postoperative Management

1. Check hematocrit.

2. Closely monitor patient on telemetry.

3. Monitor drain output, and maintain drain until negative esophagogram.

4. Daily chest radiograph to assess free air status

5. Antibiotics for at least 24 hours after surgery

6. Continued NPO status for at least 1 week after repair. Resumption of an oral diet only after a negative esophagogram. Consideration for gastrostomy tube placement in patients with complex defects requiring muscle flap repair, esophagostomy, or associated laryngotracheal repair

7. Strict antireflux precautions (head of bead >30 degrees, proton pump inhibitor), as the presence of a nasogastric tube will promote reflux due to stenting of the lower esophageal sphincter and acid reflux will severely inflame the surgical site raising the risk of tissue damage/necrosis

Complications

1. Persistent salivary leak

Ensure adequate drainage of the space—CT scan of the chest can be used to confirm appropriate drain placement and identify loculated collections of fluid in the stable patient, if there is an index of suspicion. Robinul or scopolamine can be used to decrease secretions in the stable patient. Maintain adequate nutritional support to promote healing. In a clean wound, with good drainage and nutrition, the majority of salivary leaks should close spontaneously within 2 weeks.

2. Cellulitis/Abscess

Due to delayed treatment, inadequate drainage, or narrow antibiotic coverage. Early wound washout and broad-spectrum antibiotics are critical.

3. Mediastinitis

Due to delayed treatment, inadequate drainage, or narrow antibiotic coverage. A high index of suspicion for perforation and early

management is critical to a patient's prognosis. Without prompt treatment, this condition is universally fatal.

4. Recurrent laryngeal or superior laryngeal nerve injury, which can affect voice, airway, and swallowing

Discussion

Evidence-Based Medicine Question

Does the level of penetrating trauma to the pharyngoesophageal complex affect the success of conservative management?

A retrospective review of 70 patients revealed that the location of a pharyngoesophageal injury did impact the outcomes of patients, in particularly the successfulness of conservative management.[8] In this series of 70 patients (47 hypopharyngeal, 23 esophageal), no patient with a penetration injury into the hypopharynx above the level of the arytenoid cartilages developed a complication, regardless of management (observation versus exploration). However, 22% of the patients with a hypopharyngeal injury below this level and 39% of patients with a cervical esophageal injury developed either a deep neck infection that required drainage or a postsurgical salivary fistula. They therefore concluded that injuries located in the upper portion of the hypopharynx can be routinely managed without surgical intervention. Neck exploration and adequate drainage of the deep neck spaces are, however, mandatory for all penetrating injuries into the cervical esophagus and most injuries into the lower portion of the hypopharynx.

Editorial Comment

Dr. Hackman has done an excellent job of reviewing the key points regarding the management of penetrating trauma to the hypopharynx and cervical esophagus caused by iatrogenic or accidental causes. As he has thoroughly described, the management involves not only meticulous surgical technique but also keen diagnostic evaluation for other associated injuries and associated medical and surgical treatments required. Some injuries are quite subtle, and as stated in the chapter,

extremely careful observation for complications is required postoperatively. Because these injuries are relatively uncommon and present in numerous different clinical situations, a guide to the diagnostic evaluation and understanding of the indications for different aspects of surgical management are essential components of the operative strategy. It is important to expect the unexpected with these injuries.

Christopher H. Rassekh

Review Questions

1. All of the following are essential in the management of a pharyngoesophageal perforation, except:

   a. Broad-spectrum antibiotics

   b. NPO status

   c. **Steroid therapy**

   d. Enteral access

2. Which of the following is an absolute indication to perform surgical management?

   a. Pharyngeal leak on esophagogram

   b. Subcutaneous emphysema

   c. Perforation during removal of an esophageal foreign body

   d. **Mediastinal opacification on chest radiograph**

3. What is the most common cause of penetrating trauma to the pharyngoesophagus?

   a. Gunshot wound

   b. Stabbing injury

   c. Motor vehicle trauma

   d. **Spinal surgery**

Partial Pharyngectomy

Rebecca E. Fraioli, and Andrew Tassler

Introduction

The hypopharynx is the inferior-most portion of the pharynx, bounded by the oropharynx superiorly and the esophagus inferiorly. The hypopharynx is intimately related to the larynx, both anatomically and functionally. Anatomically, the hypopharynx extends from the base of the vallecula down to the apices of the piriform sinuses and the inferior border of the cricoid cartilage. For purposes of classification, the hypopharynx is divided into three subsites: the piriform sinuses, the posterior pharyngeal wall, and the postcricoid area. The mucosa of the hypopharynx is continuous with that of the larynx, and cancers that originate in one site frequently spread to the others. Functionally, the hypopharynx and larynx are responsible for coordinating the competing tasks of airway maintenance and deglutition.

Squamous cell carcinoma (SCCA) is the most common malignancy presenting in the hypopharynx and usually presents at an advanced stage. Alcohol and tobacco are strong risk factors, as with other cancers of the head and neck.

Due to the rich lymphatics of the pharynx, cervical metastases are common with hypopharyngeal primaries, and over two-thirds of patients present with stage III or IV cancer. Perhaps because of this, prognosis is often poor despite aggressive treatment—hypopharyngeal SCCA has the worst prognosis of SCCA at any subsite within the head and neck. The piriform sinus is the most common site for hypopharyngeal cancer.

Traditional treatment for hypopharyngeal SCCA included surgery, usually total laryngectomy with total or partial pharyngectomy, and was followed by postoperative external beam radiation therapy (XRT). However, following landmark studies using chemoradiation with

surgical salvage for laryngeal[1] and hypopharyngeal[2] cancers, which showed equivalent survival in the surgical and nonsurgical arms, the use of primary surgical treatment of hypopharyngeal cancer has decreased.[3]

Both surgical and nonsurgical treatments for hypopharyngeal cancers carry significant functional morbidity. Gastrostomy tubes are often required during and after treatment, and swallowing and sometimes airway function following chemoradiotherapy may be permanently compromised, despite a surgically undisturbed larynx (Fig. 48.1).

Given the low cure rates and high rates of functional sequelae, alternatives to laryngectomy and nonsurgical organ preservation continue to be of interest and evolve. Such operations as transoral laser microsurgery (TLM),[4] transoral robotic surgery (TORS),[5] and extended partial laryngopharyngectomy procedures such as SCHLP (supracricoid hemilaryngopharyngectomy)[6] provide palliation and cure rates that rival other treatments and are being revisited for selected lesions.

Key Operative Learning Points

Small cancers of the posterior wall of the pharynx may be resected transorally or through a suprahyoid pharyngotomy.

At least 2.5 to 3 cm of pharyngeal mucosa must remain in the transverse dimension after resection in order to close the pharyngeal mucosa primarily.

Cancer extension across the midline of the posterior hypopharyngeal wall or involving the postcricoid mucosa requires total laryngopharyngectomy with reconstruction.

Cancers extending to the esophagus cannot be excised and the wound closed primarily.

Failure to aggressively preserve uninvolved mucosa may preclude primary closure.

Wound closure under tension due to insufficient mucosa will predispose to wound breakdown, fistula formation, and postoperative dysphagia due to stricture formation.

Submucosal spread is common in hypopharyngeal cancers, and negative

margins must be confirmed by frozen section.

Patients must understand that although every attempt may be made to perform partial laryngopharyngectomy, intraoperative findings or frozen section pathology may make this impossible. Therefore, patients should be consented for a possible total laryngopharyngectomy.

Patients with prior radiation or chemoradiation should have pharyngeal closure performed with a vascularized flap either integrated into the remaining pharyngeal mucosa or tubed in the case of total pharyngectomy defect. A pectoralis major flap can be used for closure of the anterior pharynx over remaining mucosa, but a complete pharyngeal defect with discontinuity is best reconstructed with free tissue transfer.

Preoperative Period

History

History of Present Illness

Symptoms often occur late in the course of cancer of the hypopharynx.

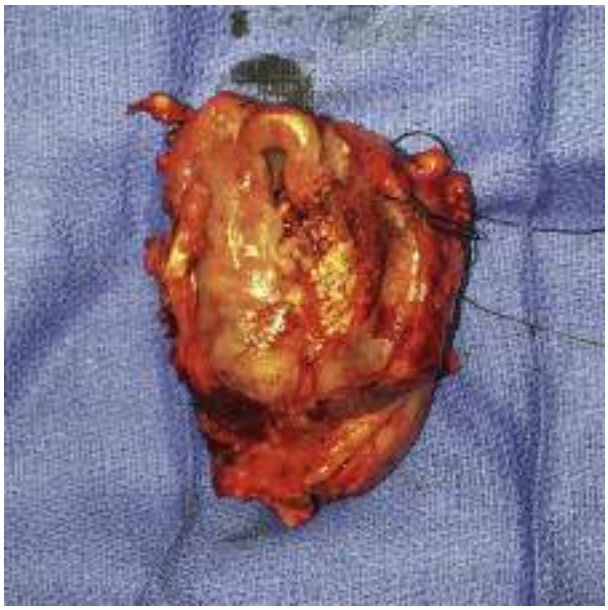

FIG. 48.1 A laryngopharyngectomy specimen removed

for persistent disease following primary chemoradiation treatment. The epiglottis is misshapen and thickened from the chemoradiation. This photograph demonstrates why organ preservation therapy with chemoradiation does not always lead to preservation of a functional larynx.

Symptoms vary significantly, depending on the location of the cancer.

Sore throat, blood in the saliva, weight loss, dysphagia, and odynophagia may all be symptoms of cancer of the hypopharynx. Referred otalgia is another frequent symptom. Malnutrition may be a major problem when patients present with an advanced stage cancer.

Dysphagia is often a late symptom but can occur earlier in postcricoid carcinomas.

Sore throat and odynophagia may indicate perineural spread and advanced disease.

Globus and foreign body sensation in the throat can be indicators of a hypopharyngeal mass.

Hoarseness, difficulty breathing, and stridor generally indicate advanced cancer with hemilaryngeal fixation.

Past Medical History

Medical Illness

Pharyngectomy is an extensive operation with an often difficult postoperative course. Patients must be medically stable to survive the surgery and postoperative period.

Insulin-dependent diabetics are at increased risk for wound breakdown and fistula formation.

Patients must have adequate pulmonary reserve to be considered for a partial pharyngectomy or a partial laryngectomy.

Iron deficiency anemia, along with hypopharyngeal webs (Plummer-Vinson syndrome), may be associated with cancer of the hypopharynx,

although the incidence of this syndrome appears to be decreasing with lower rates of iron deficiency anemia.

Gastroesophageal reflux is associated with esophageal cancer and may also be a major problem in cancer of the hypopharynx.

Surgical History

Prior thyroid or neck surgery may present surgical challenges and increase the risk of injury to the parathyroid glands.

A history of lung surgery or other pulmonary compromise may increase the consequences of aspiration and preclude partial laryngectomy.

Family History

Family history of cancer

History of adverse anesthesia reactions in family members

Social History

Tobacco and alcohol use are strong risk factors for the development of hypopharyngeal cancer.

Smoking also significantly impairs wound healing and is a risk factor for developing a fistula postoperatively.

Honest reporting of alcohol consumption is critical to provide adequate prophylaxis for postoperative withdrawal if alcohol dependence is present.

Medications

Anticoagulants and antiplatelet drugs should be discontinued if medically feasible.

Immunosuppressant medications may make the cancer more virulent.

Physical Examination

- A thorough examination of the oral cavity and oropharynx, including palpation of the tonsils and base of tongue, should be performed.
- Second primary cancers are not uncommon, even in patients with early-stage cancer.
- Trismus indicates involvement of the muscles of mastication.
- Fiberoptic examination of the pharynx and larynx is indicated to evaluate the extent of the cancer, assess for second primaries, and evaluate the mobility of the vocal folds.
- The Chevalier Jackson sign of saliva pooling in the piriform sinuses is also suggestive of hypopharyngeal carcinoma with distal obstruction.
- If partial laryngectomy is considered, pulmonary function must be evaluated, as patients undergoing these procedures must have excellent pulmonary reserve.
- Basic laboratory tests in the form of complete blood count (CBC) and metabolic profile are indicated. Liver function tests with measurement of serum albumin may also be useful to assess basic nutritional status.
- If open surgery is considered or the patient has a history of prior neck radiation or chemoradiation, thyroid function tests (thyroid stimulating hormone [TSH] and free T4) should be obtained.
- Examination under anesthesia with direct laryngoscopy, rigid esophagoscopy, and bronchoscopy must be performed prior to cancer resection.
- A biopsy should be obtained during the examination under anesthesia to provide a tissue diagnosis. Other benefits of endoscopy include evaluation of the size and extent of the cancer, palpation of the arytenoids to assess for fixation of the vocal folds, and identification of second primary cancers.

Imaging

- Barium swallow esophagram
  - Provides preoperative assessment of swallowing function, laryngeal penetration, and aspiration

- May reveal extension of the cancer into the cervical esophagus
- May demonstrate fixation of the cancer to the prevertebral fascia

- Computed tomography (CT) and/or magnetic resonance imaging (MRI)
  - Preoperative imaging is critical to assess the extent of the cancer and help plan the appropriate resection.
  - CT and MRI are both useful to assess the extent of the primary cancer.
  - MRI provides better assessment of the degree of invasion of the prevertebral musculature and may be preferable for cancers of the posterior pharyngeal wall.
  - CT is superior for assessment of invasion of the thyroid or cricoid cartilages.
  - Either CT or MRI should be performed with contrast whenever possible, as this better demonstrates the vasculature and areas of enhancement.
  - Given the high rate of cervical metastases at presentation, whichever imaging modality is chosen should include the neck. Cancer of the pharynx may involve the retropharyngeal nodes, which are usually not clinically apparent.
- Positron emission tomography (PET) CT
  - Indicated to identify synchronous second primaries as well as cervical lymph nodes and distant metastases
  - If PET/CT is not performed, a minimum of a chest CT should be performed.

Indications

- In properly selected patients, partial pharyngectomy with postoperative radiotherapy may be preferable to more extensive surgery or definitive chemoradiation therapy.
- A general stepwise paradigm for surgical excision of cancers of the hypopharynx is outlined in Table 48.1.

TABLE 48.1

Algorithm for Management of Hypopharyngeal Tumors

Extent of Surgery	Surgical Approaches	Indications	Reconstructive Options
Simple excision	• Transoral CO2 laser excision or transoral robotic surgery	• Small tumors of posterior pharyngeal wall • Small tumors of medial or lateral wall of piriform sinus	• None; wounds heal by secondary intent
Partial pharyngectomy	• Lateral pharyngotomy • Suprahyoid pharyngotomy	• Small tumors of posterior pharyngeal wall • Carefully selected larger tumors of posterior pharyngeal wall	• Suture mucosal edges to prevent dural fistula • Skin graft
Partial pharyngectomy with partial laryngectomy	• Supraglottic hemilaryngopharyngectomy • Vertical hemilaryngopharyngectomy	Cancer limited to: • AE fold • Medial wall of piriform sinus • Anterior wall of piriform sinus	• Primary closure of pharyngeal mucosa buttressed by remaining thyroid cartilage, pericardium, and infrahyoid musculature flap • Free flap reconstruction
Partial pharyngectomy with total laryngectomy	• Transcervical	Tumor involving piriform sinus with involvement of: • Larynx • Apex of piriform sinus • Lateral wall of hypopharynx	• Primary closure if ≤3 cm of pharyngeal mucosa remains
Total pharyngolaryngectomy	• Transcervical	• Postcricoid carcinoma • Large circumferential wall • Piriform sinus carcinoma with extension across midline	• Total Pharyngolaryngectomy will always require either flap reconstruction, gastric pull-up, etc. Primary closure will never be possible in this scenario.

- Partial pharyngectomy—no laryngectomy:
  - Small T1/T2 cancers of the posterior pharyngeal wall without extension to the cervical esophagus may be treated by excision using a transcervical (lateral or suprahyoid) pharyngotomy or transoral resection (Fig. 48.2).
  - Larger cancers of the posterior wall of the hypopharynx can sometimes be completely excised via suprahyoid pharyngectomy and/or lateral pharyngotomy approaches and reconstructed with a free flap. However, excision of large amounts of posterior pharyngeal wall sensate mucosa will have negative effects on swallowing function, and this should be taken into account when planning surgery.
- Partial pharyngectomy with partial laryngectomy
  - Patients undergoing these procedures must have adequate pulmonary function to tolerate partial laryngectomy.
  - Vertical hemipharyngolaryngectomy
    - Mainly indicated for cancers of the medial piriform sinus without extension to the piriform apex
    - Involvement of the ipsilateral arytenoid is acceptable.
    - The excision can be extended to allow resection of cancer extending to the supraglottis and a portion of the lateral wall of the piriform sinus.
    - The most extreme extension of this procedure is a full supraglottic

hemipharyngolaryngectomy, with resection of the epiglottis, vallecula/pre-epiglottic space, and a portion of the base of the tongue.

- SCHLP
  - Extends the previous procedure by also excising the ipsilateral piriform sinus and supracricoid larynx
  - Patients are likely to have aspiration postoperatively, and only patients with excellent pulmonary reserve are candidates for this procedure.
  - The indications for this procedure were traditionally for early pyriform and arytenoid cancers, but it has been used in experienced hands for more advanced cancers.

- Partial pharyngectomy with total laryngectomy
  - The most common indication is piriform sinus carcinoma that extends medially to the larynx, inferiorly to the apex of the piriform sinus, or laterally to the lateral wall of the hypopharynx.
  - Partial pharyngectomy is indicated if 2.5 to 3 cm in horizontal dimension of posterior pharyngeal wall mucosa remains following excision of the cancer. In such cases, primary closure of the pharyngeal mucosa can result in a functional swallowing mechanism postoperatively.

FIG. 48.2 Surgical photograph demonstrates the lateral

transcervical approach to the hypopharynx.

- Total laryngopharyngectomy
  - In addition to the indications for total laryngectomy listed previously, common indications for total laryngopharyngectomy include piriform sinus carcinoma that extends across the midline and postcricoid cancer. The hypopharynx is shaped like a funnel, and while there may be sufficient pharyngeal mucosa in the superior hypopharynx to close a defect, the total area of pharyngeal mucosa in the postcricoid area is so limited that direct closure is not possible following cancer resection.
  - Total pharyngectomy is necessary when less than 2.5 cm of posterior pharyngeal wall mucosa remains horizontally following cancer resection; therefore, large cancers of the posterior hypopharyngeal wall are a common indication for this procedure.
- Neck dissection of at least levels II to IV should be performed in all patients. Metastatic cancer is found in 60% to 80% of patients with cancer of the hypopharynx, and 20% to 40% will have occult neck metastases to the cervical lymph node. Bilateral selective neck dissection (or radiation to the contralateral neck) is indicated for cancers of the medial wall of the piriform sinus, which tend to behave more like supraglottic carcinomas.[7]

Contraindications

- Contraindications to partial pharyngectomy without laryngectomy
  - Cancer involving the larynx
  - Location of the cancer in the piriform sinus or postcricoid area
  - Extension of posterior wall cancer to the lateral pharyngeal wall
  - Large cancer of the posterior pharyngeal wall, although acceptable in certain carefully selected patients, is generally contraindicated, as the loss of large amounts of sensate mucosa severely impairs swallowing function and places the patient at risk for aspiration.
- Contraindications to partial pharyngectomy with partial laryngectomy

- Extension of the cancer to the apex or lateral wall of the piriform sinus
- Large cancers of the posterior pharyngeal wall
- Cardiopulmonary comorbidities with inability to tolerate postoperative aspiration require total laryngectomy.

- Contraindications to partial pharyngectomy with total laryngectomy
  - Insufficient pharyngeal mucosa to allow for a functional primary closure (Fig. 48.3)
  - Resection of the cancer at the following sites generally requires total pharyngectomy, due to insufficient mucosa remaining for primary closure:
    - Postcricoid carcinoma
    - Piriform sinus carcinoma with extension across the midline
    - Large cancer of the posterior pharyngeal wall
- Contraindications to total laryngopharyngectomy
  - Cancer spread to involve prevertebral fascia
  - Cancer involvement of carotid sheath
  - Involvement of the cervical esophagus by cancer will require esophagectomy in addition to total laryngopharyngectomy. Reconstruction is usually with gastric pull-up to minimize the risk of suture lines in the mediastinum with potential leak.

FIG. 48.3 Large carcinoma of the right pirifrom sinus.

There was not sufficient uninvolved mucosa to allow for primary closure of the hypopharyngeal mucosa; therefore, primary closure was not possible and free tissue transfer was performed for pharyngeal reconstruction.

Preoperative Preparation

- Patients should be evaluated for their overall health and fitness for general anesthesia. Advanced age is not a contraindication in an otherwise healthy patient.
- If the patient is not undergoing a total laryngectomy, careful consideration of his or her pulmonary function and ability to tolerate aspiration is of critical importance.
- Preoperative evaluation by a speech language pathologist to evaluate preoperative swallowing function as well as motivation and ability to rehabilitate swallowing postoperatively is of significant value.
- If the cancer causes airway obstruction, preoperative discussion and planning for airway management with the anesthesiology team are mandatory.

- If free tissue transfer is to be considered, preoperative consultation by a microvascular surgeon should be obtained. Vascular imaging to assess the quality of vessels can be performed as indicated.
- Repeat endoscopy to ensure that the cancer has not grown or changed is important and is often done just prior to surgery.

Operative Period

Anesthesia

- General anesthesia is required.
- Oral intubation is preferred unless significant airway obstruction is present, in which case initial tracheotomy may be the safest means of obtaining an airway. Some patients will have a pre-existing tracheostomy, and the tracheostomy tube can be removed and the patient intubated through the stoma.
- Continued communication with the anesthesiologist throughout the case is important for cranial nerve monitoring and regarding the use of vasopressors if microsurgical free flaps are planned.

Positioning

- The patient should be supine.
- Placement of a shoulder roll to extend the neck may help with exposure.
- Care should be taken to position the arms with adequate padding and protection.
- Sequential compression devices (SCD) should be placed on the lower extremities if possible. If a lower extremity is being used for reconstruction, a single SCD should be placed on the unprepped leg.
- The entire neck and lower face should be prepped, as access to the oral cavity may be helpful during an external approach to the laryngopharynx.

- The upper chest should be prepped into the field if there is a possibility that a regional flap such as a pectoralis major flap might be used.
- A thigh can be prepped for possible skin grafting.
- If a free flap reconstruction is possible, then the donor site should be prepped as well.

Perioperative Antibiotic Prophylaxis

- Partial pharyngectomy is a clean-contaminated procedure, and as such 24 hours of intravenous antibiotics covering oral flora is indicated.
- We prefer to use ampicillin/sulbactam. If the patient is allergic to penicillin, a combination of cefazolin and metronidazole can be used, as can clindamycin. If the patient has a pre-existing tracheostomy, it is often helpful to broaden the antibiotic coverage to include pseudomonas with an agent such as piperacillin/tazobactam.
- The first dose should be given prior to induction of anesthesia induction and redosed at the proper interval during the procedure.

Monitoring

- We prefer to limit the amount of paralytic agent given to facilitate monitoring of cranial nerves during the preliminary neck dissection.
- Nerves can be stimulated with either handheld nerve stimulators or electromyogram (EMG) based nerve monitoring and stimulation.

Instruments and Equipment to Have Available

- Head and neck surgical instrument set
- Head and neck endoscopy set
- Microvascular instruments and equipment if free flap reconstruction is planned

Key Anatomic Landmarks

- The hypoglossal nerve and lingual artery lie just adjacent to the greater cornu of the hyoid bone. Care must be taken when dissecting in this area to stay on the bone and avoid injury to these structures.
- The superior laryngeal nerve provides sensation that is important for the coordination of swallowing, and as such, effort should be made to preserve this nerve. However, if an extensive amount of sensate pharyngeal mucosa is resected, swallowing function will be severely compromised, even if the nerve is preserved.
- The recurrent laryngeal nerve is not routinely identified in partial pharyngectomy procedures, but postcricoid cancers may invade the nerve by direct extension into the tracheoesophageal groove.
- There is an area of weakness in the posterior pharyngeal wall in between the inferior constrictor muscle superiorly and the cricopharyngeus muscle inferiorly. This area is known as Killian's triangle, and this is a site where cancers of the posterior wall can spread to structures outside of the hypopharynx.

Prerequisite Skills

- Prior to attempting conservation laryngeal procedures, the surgeon should be adept at total laryngectomy.
- Free tissue transfer may be necessary for reconstruction. If the surgeon does not routinely perform free tissue transfer, a microvascular surgeon should be available.

Operative Risks

- Bleeding or hematoma
- Infection
- Permanent tracheostomy for airway compromise
- Swallowing dysfunction with the potential need for prolonged parenteral nutrition

- Potential for poor voice quality following partial laryngectomy
- Injury to the hypoglossal nerve
- Wound infection
- Pharyngocutaneous fistula

Surgical Technique

- Partial pharyngectomy—no laryngectomy
  - May be performed transorally, with endoscopy or robot, or transcervically via suprahyoid or transhyoid approaches
    - Transoral approaches
      - Typically performed for early (T1 or T2) cancers with limited or no laryngeal involvement. If significant laryngeal resection including the arytenoid is necessary, the functional outcome may be inferior to nonoperative treatment.
      - Perioperative tracheostomy should be strongly considered.
      - Preoperative endoscopy to assess the extent of the lesion and the endoscopic exposure is mandatory. This is particularly true in the salvage setting following prior radiation or chemoradiation.
      - Cancers with significant deep or lateral extension that will create communication with the lateral neck or retropharyngeal space are more appropriate for an open approach.
      - Endoscopic resection is commonly performed with either TLM technique, using either mounted or fiber-based CO_2 laser, or with TORS technique, which can use either monopolar cautery or fiber-based CO_2 laser.
    - Transcervical approaches
      - Transcervical pharyngotomy
        - Superiorly based apron flap incision
        - Tracheostomy
        - Subplatysmal flaps are elevated superiorly above the hyoid bone.

- Neck dissection as indicated
- Expose the posterior thyroid ala and divide the inferior constrictor attachments.
- View the piriform sinus mucosa, and excise the cancer of the posterior or lateral wall under direct vision.
- Frozen section margins are obtained.
- Direct closure, skin graft, or flap reconstruction is performed.

- Lateral transthyroid pharyngotomy
  - Steps through neck dissection given previously
  - Expose hyoid bone and thyroid cartilage
  - Thyroid perichondrium is incised superiorly and reflected inferiorly as an inferiorly based flap
  - Incisions are made through the lesser cornu of the hyoid bone and vertically through the posterior-lateral third of the thyroid cartilage.
  - The pharynx is entered through the vallecula, and incisions are made around the cancer under direct vision.
  - Frozen section margins are obtained.
  - Reconstruction with direct mucosal closure is reinforced by the perichondrial flap or by flap closure.
- Transhyoid pharyngotomy
  - Steps through neck dissection given previously
  - Expose the hyoid bone.
  - Enter the vallecula above, though, or below the hyoid bone.
  - Retraction of the base of the tongue provides visualization of the posterior pharyngeal wall.
  - Cancers of the posterior wall can be excised under direct visualization; deep margin is the prevertebral fascia.
  - Frozen section margins are obtained.
  - Defect can be covered with a split-thickness skin graft or left to heal

- Vallecular opening is closed primarily
- Perichondrial flap provides a second layer of closure

- Partial pharyngectomy with partial laryngectomy
  - Horizontal partial pharyngolaryngectomy
    - Superiorly based apron flap incision
    - Tracheostomy
    - Subplatysmal flaps are raised.
    - Bilateral neck dissections
    - The hyoid bone is skeletonized superiorly, and the infrahyoid strap muscles are released from the hyoid bone.
    - The perichondrium is elevated off of the thyroid cartilage and left attached as an inferiorly based pedicle flap.
    - The thyroid cartilage is incised horizontally, halfway between the thyroid notch and the inferior border. The greater cornu is excised on the side of the cancer.
    - The vallecula is entered on the side ipsilateral to the cancer.
    - Grasp and retract the epiglottis, visualize the cancer, and excise the epiglottis and ipsilateral aryepiglottic fold, including the false vocal fold but not the true vocal fold.
    - The ipsilateral arytenoid can be included in the specimen if involved by cancer.
    - Excision can be extended to remove the mucosa of the medial, the anterior, and a portion of the lateral piriform sinus walls.
    - Frozen section margins are obtained.
    - If the arytenoid has been resected, the true vocal fold must be sutured back into the midline to the cricoid.
    - A cricopharyngeal myotomy should be considered.
    - Depending on the size of the resection, closure may be performed primarily or with regional flap or free tissue transfer.
- Vertical partial laryngopharyngectomy

- Steps through neck dissection as noted previously
- Expose the larynx from the hyoid bone down to the trachea.
- Incise the thyroid perichondrium vertically from the thyroid notch down over the cricothyroid membrane to the cricoid cartilage.
- Perichondrial flaps should be elevated laterally on both sides of the vertical incision. Often the strap muscles will still be attached, creating composite flaps.
- Use a saw to cut through the thyroid cartilage, maintaining a 3-mm posterior strip.
- Incise through the petiole of the epiglottis, thereby exposing the vocal cords.
- Incise the cricothyroid membrane just superior to the cricoid cartilage to ensure that this area is free of tumors.
- Cut through the vocal cord at the anterior commissure or 3 mm past the tumor if it crosses the midline.
- Use hooks to open the larynx like a book.
- Excise the remaining cancer under direct vision, and confirm the margins with the frozen section.
- Cancers of the medial wall of the piriform sinus can be included in this resection.
- Reconstruct the contralateral vocal cord by suturing it to the remaining cartilage or perichondrium.
- If 3 cm or more of mucosa remains in the transverse direction, primary closure may be performed over a nasogastric tube. The remaining pharyngeal mucosa is sutured to the vallecula and remaining portion of the larynx.
- Closure is reinforced by suturing the previously reflected thyroid cartilage mucoperichondrium and strap musculature.

- Partial pharyngectomy with total laryngectomy
  - Steps through neck dissection as noted previously
  - Incise the constrictor muscles along the posterior lamella of the thyroid cartilage on the side contralateral to the cancer.

- Enter the larynx in the vallecula contralateral to the cancer, and dissect the piriform sinus mucosa free from the larynx on the side opposite the cancer.
- Mucosal incisions should be made with the tumor under direct vision in order to maintain an adequate (1.5 to 2 cm) mucosal margin around the tumor while preserving as much mucosa as possible.
- Dissect from the lateral edge of the epiglottis to the arytenoid.
- Frozen section assessment of surgical margins must be obtained.
- If 3 cm or more of mucosa remains in the transverse direction, primary closure may be performed.

- Total laryngopharyngectomy (see Chapter 17 for details)

Common Errors in Technique

- Attempts to perform primary closure of the pharyngeal defect when less than 2.5 cm of mucosa remains
- Failure to adequately visualize the cancer while making mucosal incisions may result in a total laryngectomy due to failure to preserve adequate mucosa.

Postoperative Period

Postoperative Management

- The pharyngeal reconstruction is performed over a nasogastric tube, which is used to provide enteral nutrition until oral feeding can sustain the patient's nutritional requirements.
- Oral feeding is generally initiated 10 days postoperatively.
- Speech pathology evaluation and possibly a formal swallowing study should be performed before initiating oral feeding in patients whose risk of aspiration is high.
- For patients undergoing partial laryngectomy, early and aggressive pulmonary toilet must be maintained due to the high likelihood of

aspiration. In these patients, the tracheostomy tube can often be capped a week after the surgery, and early initiation of phonation is encouraged. The tracheostomy tube is not removed until oral feeding is established.

- Flexible nasolaryngoscopy may be performed to assess healing of the reconstructed laryngopharynx.

Complications

- Attempts at primary closure of the pharyngeal defect when insufficient mucosa remains following tumor excision place the suture line under excessive tension and predispose to wound fistula (pharyngocutaneous fistula).
- Closure of the pharyngeal defect with insufficient mucosa also predisposes to esophageal stricture, and esophageal dilation procedures and even placement of a surgical feeding tube may be necessary. Postoperative radiation therapy may also contribute to esophageal stricture and dysphagia.
- Postoperative aspiration is essentially guaranteed in patients undergoing partial laryngectomy, but it may also occur in patients where the entire larynx is preserved due to disruption of the swallowing mechanism and loss of sensate mucosa following pharyngectomy. Aspiration may lead to postoperative pneumonia and may be severe enough to necessitate permanent tracheostomy or secondary laryngectomy or laryngotracheal separation.
- Fever or back pain in the early postoperative period can be an indicator of retropharyngeal abscess.

Alternative Management Plan

Treatment with primary chemotherapy and radiation is a reasonable option for hypopharyngeal SCCA. Survival rates are comparable to surgery.

Discussion

Evidence-Based Medicine Question

Has the trend toward chemoradiation therapy for organ preservation in hypopharyngeal cancer changed survival?

The landmark European Organization for Research and Treatment of Cancer (EORTC) study using chemoradiation for larynx preservation in hypopharyngeal cancer[2] began a paradigm shift in the treatment of hypopharyngeal cancer, with many patients who would formerly have been treated with primary surgery being treated with definitive chemoradiation therapy instead. Recent studies have suggested that in the case of laryngeal cancer, the shift to nonsurgical therapies may have reduced survival.[8] By contrast, in the case of hypopharyngeal cancer, a 2015 study of the SEER database by Newman and colleagues[8] showed an improvement in overall survival in the time period between 1990 and 2003, a time frame that corresponds to the shift in the treatment paradigm toward chemoradiation as definitive therapy.

There are several factors that may contribute to this increase in survival. First, the increase in overall survival in the study was mostly attributable to the increased survival in patients receiving radiation and no surgery. Therefore the study does not address the question of when primary surgery is indicated over primary chemoradiation therapy. Additionally, chemotherapy data were not available in this study, so the study does not directly address whether the addition of chemotherapy to treatment regimens could be responsible for the increased survival. However, temporal therapy trends suggest this as a possible explanation. It is also notable that studies in laryngeal and oropharyngeal carcinoma have demonstrated a survival benefit of chemoradiation therapy when compared with radiotherapy alone.[9]

Newman and colleagues also note that other changes have occurred during the studied time frame, including the adaptation of intensity modulated radiation therapy (IMRT), which in a study by Mok and colleagues[10] was shown to improve locoregional control in hypopharyngeal carcinoma when compared with conventional radiotherapy.

Another possible factor is the development of cetuximab, a monoclonal antibody to the epidermal growth factor receptor (EGFR), which was

approved by the FDA in 2006 for use in advanced SCCAs of the head and neck. As a whole, cetuximab has fewer side effects and is better tolerated than platinum-based chemotherapies, and its availability may have increased the number of patients who are able to receive systemic therapy.[9]

There are many questions still to be answered regarding the treatment of hypopharyngeal carcinoma, especially regarding the relative roles of surgery and chemoradiation therapy, but data suggest that chemotherapy may play an important role.

Editorial Comment

This chapter by Dr. Fraoli and Dr. Tassler demonstrates the complexity of evaluating and managing cancer of the hypopharynx. The wide range of presenting symptoms and physical signs varies from minimal to profound. Many patients present only with neck metastasis or when the cancer is very advanced. The topic is covered very comprehensively but with an attempt to limit any redundancy with other related chapters on management of different aspects of cancer of the pharynx. However, as the authors have detailed, there is considerable overlap in the management of cancer of the hypopharynx, because cancers that arise in the hypopharynx commonly impact the larynx and oropharynx. Similarly, cancers of the oropharynx and larynx often are complicated when there is extension to the hypopharynx. Many of the surgical approaches for cancer of the hypopharynx are relevant in oropharyngeal and laryngeal cancer as well.

Partial pharyngectomy (sometimes referred to as "limited pharyngectomy") applies to both hypopharyngeal and oropharyngeal lesions. The management of cancer of the oropharynx is covered in detail elsewhere, but the armamentarium of surgical approaches includes transoral, transpharyngeal, and even combined laryngectomy/hypopharyngectomy operations. Technical nuances in these procedures are critically important when providing optimal oncologic and functional outcomes.

In order to be comprehensive, a surgeon must be familiar with all of these approaches. The authors have taken a very difficult and important topic and condensed it into a valuable reference, which is an excellent

starting point. Readers are encouraged to look at the references to other chapters and refer back and forth to the chapters that overlap with this one to maximize the educational value and help master the critical elements in patient care.

Review Questions

1. Regarding imaging for hypopharyngeal tumors, which of the following statements is *true?*

   a. Magnetic resonance imaging (MRI) is superior to computed tomography (CT) for assessment of the primary extent of the tumor.

   b. CT is superior to MRI for assessment of the primary extent of the tumor.

   c. **MRI is superior to CT for assessment of prevertebral muscle invasion.**

   d. CT is superior to MRI for assessment of prevertebral muscle invasion.

2. Which of the following is a contraindication to partial pharyngectomy?

   a. 1 cm cancer involving the medial wall of the piriform sinus

   b. **1 cm cancer involving the postcricoid area**

   c. 1 cm cancer of the posterior pharyngeal wall

   d. 1 cm cancer of piriform sinus extending to ipsilateral arytenoid

3. Which of the following is a contraindication to partial laryngectomy in combination with partial or total pharyngectomy?

   a. **Patient with severe chronic obstructive pulmonary disease (COPD)**

   b. Patient with Plummer-Vinson syndrome

   c. Laryngeal involvement by cancer

   d. Cancer located on medial wall of piriform sinus

4. How much pharyngeal mucosa must remain following tumor resection in order to perform direct pharyngeal closure?

   a. 1 cm in horizontal dimension

   b. 1.5 cm in horizontal dimension

   c. 2.0 cm in horizontal dimension

   d. **2.5 cm in horizontal dimension**

5. Which of the following is *not* a reasonable treatment option for cancer of the hypopharynx?

   a. Cisplatin and intensity modulated radiation therapy (IMRT)

   b. Cetuximab and IMRT

   c. **Cisplatin and cetuximab**

   d. Surgery and IMRT

Reconstruction of Hypopharyngeal Defects

Jason I. Kass

Introduction

The hypopharynx is a complex anatomic region that begins at the level of the hyoid and terminates at the esophageal inlet. It is adjacent to, but distinct from, the larynx and is the functional conduit that carries food from the oropharynx to the esophagus. Three anatomic subsites are included: paired pyriform sinuses, posterior pharyngeal wall, and postcricoid pharynx (Fig. 49.1).

Key Operative Learning Points

- There are many reconstructive options for creating a neopharynx, and decision making depends on the following four general criteria: (1) size of the defect (laryngectomy with partial pharyngectomy, total laryngopharyngectomy, and total laryngopharyngectomy with cervical esophagectomy), (2) surgeon's experience with regional and free tissue transfer, (3) available donor sites that will provide sufficient tissue to reconstruct the defect, and (4) donor site morbidity that may help to select among multiple tissue flaps.
- A pharyngeal leak is the primary complication that carries a risk of significant morbidity/mortality for the patient. A leak not only puts a free tissue reconstruction at risk but also leads to fistula, wound healing complications, and infection leading to possible carotid blowout. This will prolong the postoperative care and delay oral intake and rehabilitation of speech.
- Stricture resulting from an inadequate pharyngeal circumference will

impact the quality of deglutition but will also predispose patients to developing a pharyngeal leak.

Preoperative Period

In preparing for reconstruction of hypopharyngeal defects, it is critical to anticipate the size of the defect and the remaining adjacent healthy tissue. With small lesions that can be removed via a transoral approach no reconstruction may be necessary, and the tissue can be left to heal by secondary intention. Unfortunately, hypopharyngeal cancer usually presents late and requires not only resection of the hypopharynx but also the larynx. This is, in part, from their late presentation. In general, tumors of the hypopharynx, more than 95% of which are squamous cell carcinoma, carry very high overall mortality rates (65% of patients die within 5 years of presentation). These cancers are characterized by submucosal spread with invasion of surrounding structures that lack barriers for spread, metastases to the neck or distant metastases at presentation, and a higher rate of synchronous second primary cancers.

Understanding the variety of surgical approaches for tumor resection can be helpful when anticipating the size of the defect required for reconstruction (Table 49.1). They can generally be divided into approaches that spare the larynx and those that require a laryngectomy. Laryngeal sparing procedures include transoral endoscopic approaches to the hypopharynx, as well as open approaches that resect a portion of one or more hypopharyngeal subsites, but preserve the larynx. Examples include well-circumscribed cancers of the posterior pharyngeal wall or small cancers in the pyriform sinus that can be excised along with a portion of the aryepiglottic fold. Open approaches with partial resection of the larynx can carry higher morbidity, particularly if the patient has had prior radiation of the neck. Laryngeal-sparing open approaches include a midline pharyngotomy with or without mandibulotomy, lateral pharyngotomy, and partial resection of the larynx with partial pharyngectomy. More commonly, a laryngectomy is required for patients with advanced cancer at presentation or persistent cancer following chemoradiation. Achieving a negative margin may require partial pharyngectomy or total circumferential pharyngectomy (Fig. 49.2). When the cancer extends to the cervical esophagus, a cervical or total esophagectomy is required.

There are many options when evaluating the reconstruction of a hypopharyngeal defect, and many decisions are based on the surgeon's preference and experience. A defect-oriented approach can be helpful when deciding reconstructive options (Table 49.2). The simplest reconstruction is none at all—and this can be achieved with many defects following endoscopic resection because there is a lower risk for pharyngocutaneous fistula and the wound can be left to granulate. After an open approach is used to do a partial pharyngectomy, reconstruction is required. In the rare case of a small defect and no prior neck radiation, a primary closure with a local muscle flap (strap muscle or sternocleidomastoid muscle) can be used. More likely a cutaneous or fascial patch is required. A number of regional flaps can be elevated with a cutaneous skin paddle and rotated to close the pharyngectomy defect. The choices include the pectoralis major (PM) myocutaneous, deltopectoral (DP) fasciocutaneous, island deltopectoral (island-DP) fasciocutaneous, and supraclavicular (SC) flaps. Free tissue transfer is also an option and a thin pliable radial forearm (RFFF) or small anterolateral thigh free flap (ALT) can be used. With a total laryngopharyngectomy, the regional or free flap must be tubed to replace the entire pharynx. There are well-described series of reconstruction of the pharynx using tubed PM or DP flaps. In addition to the RFFF and ALT, the jejunum and gastro-omental free flaps are options. The jejunum is harvested as a tube so that there is one less suture line to leak. With each reconstructive option, there are limitations, and the problem with the jejunum is that it has an inferior voice outcome that sounds "wet" and food may be retained in the conduit, giving the patient significant halitosis. If the cervical esophagus is resected along with the larynx and pharynx, there are fewer options available for reconstruction. The gastric transposition (or "pull-up") is one way to recreate a pharyngeal conduit and requires collaboration with general surgeons.

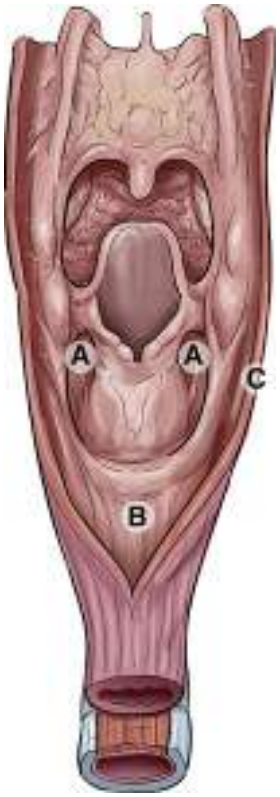

FIG. 49.1 Hypopharynx viewed posteriorly with the pharynx incised at the midline. The three subsites are identified. Paired pyriform sinuses *(A)*, postcricoid mucosa *(B)*, and posterior pharyngeal wall *(C)*.

TABLE 49.1

Surgical Approaches for Resection/Reconstruction of the Hypopharynx

- Laryngeal sparing:
- Transoral resection subsite (either laser or robotic)*
- Transhyoid midline pharyngotomy
- Lateral pharyngotomy
- Mandibulotomy with or without midline division of the tongue
- Partial laryngeal surgery with hypopharyngectomy

- Laryngeal sacrifice:
- Laryngectomy with partial pharyngectomy
- Laryngectomy with total circumferential pharyngectomy
- Laryngectomy with total circumferential pharyngectomy and cervical esophagectomy

* No reconstruction typically required—defect left to granulate.

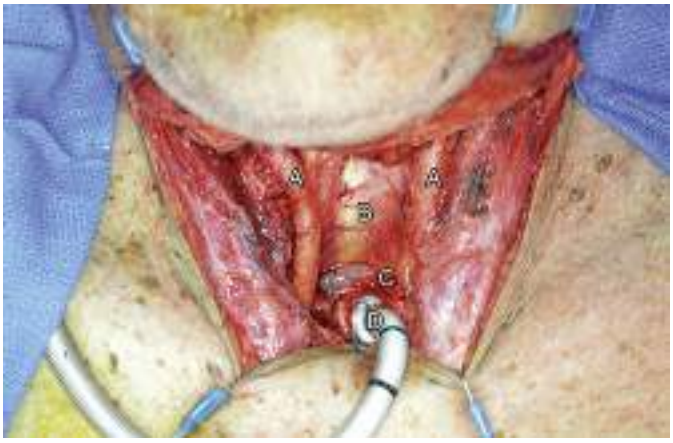

FIG. 49.2 Defect following total laryngopharyngectomy. Common carotid artery *(A)*, prevertebral fascia *(B)*, esophageal inlet *(C)*, and trachea with endotracheal tube in place *(D)*.

For purposes of illustration, reconstruction of a total circumferential laryngopharyngectomy without cervical esophagectomy is described here using an ALT free flap. Other chapters describe the harvest of regional and free tissue transfer that can easily be translated to reconstruction of hypopharyngeal defects.

TABLE 49.2

Defect-Orientated Reconstructive Options of the Hypopharynx

- Hypopharyngeal defect following resection via endoscopic transoral approach
- Healing via secondary intention with granulation and no reconstruction
- Partial laryngectomy with partial hypopharyngectomy (open approaches)
- Primary closure with overlay local muscle flap (rare circumstance with no prior radiation and small defect)
- Regional flaps
- Pectoralis major myocutaneous flap
- Deltopectoral fasciocutaneous flap
- Island-deltopectoral fasciocutaneous flap
- Supraclavicular fasciocutaneous flap
- Free flaps
- Radial forearm free flap
- Anterolateral thigh flap
- Laryngectomy with partial pharyngectomy
- Regional flaps
- Pectoralis major myocutaneous flap
- Deltopectoral fasciocutaneous flap
- Free flaps
- Radial forearm flap
- Anterolateral thigh flap
- Laryngectomy with circumferential pharyngectomy
- Regional flaps
- Tubed pectoralis major myocutaneous flap
- Tubed deltopectoral fasciocutaneous flap
- Free flaps
- Tubed radial forearm flap

- Tubed anterolateral thigh flap
- Jejunum free flap
- Gastro-omental free flap
- Laryngectomy with total circumferential pharyngectomy and cervical esophagectomy
- Gastric pull-up

History

1. History of present illness
   a. Dysphagia—able to tolerate solids/liquids
   b. Mass in the neck
   c. Change in voice
   d. Hemoptysis/hematochezia
   e. Weight loss, nutritional status
   f. Fatigue
   g. Otalgia
   h. Functional status
2. Past medical history
   a. Prior head and neck treatment: any prior history of chemotherapy or neck radiation
   b. Comorbid medical illnesses—particularly pulmonary status if considering partial laryngeal surgery
   c. Surgical history: prior neck surgery? Prior surgery at potential donor sites (e.g. wrist, forearm, groin, or thigh)
   d. Family history: Disorders of bleeding/clotting are particularly important when considering free tissue transfer
3. Medications
   a. Antiplatelet drugs
   b. Herbal products

c. Alcohol (consider risk of withdrawal)

d. Allergies to antibiotics

4. Mental and social status

a. Coexisting or new situational depression

b. Ability to give consent

c. Social support structure

Physical Examination

1. Complete examination of the head and neck looking for synchronous second primary cancers and regional lymphadenopathy; incidental thyroid disease may be noted and inform which lobe of the thyroid to save or perform a total thyroidectomy at the time of the resection

2. Flexible fiberoptic examination—The cancer may not be visible so evaluate for effacement of the pyriform, visible blood or a friable mass, lack of vocal fold mobility, distortion of the larynx and pooling of saliva.

3. Potential donor sites for flaps

a. Radial forearm free flap

1) Evaluate for scars from prior surgery or injury.

2) Perform an Allen test by occluding the radial and ulnar artery and asking the patient to squeeze a closed fist until the hand is pale. Release of the ulnar artery should result in brisk return of blood and normal color to the hand through the palmar arch. Delayed or no return indicates a radial dominant hand, which should not be used as a donor site.

b. Anterolateral thigh free flap—Obesity may make the skin paddle too thick if making a tube; this is less of an issue if using it as a patch.

c. Regional flaps—Evaluate for scars from prior surgery.

4. General health

a. Nutrition

b. Cardiovascular

c. Respiratory

d. Mental

Imaging

1. Chest radiograph
   a. Identify metastases.
   b. Synchronous lung cancer
   c. Pulmonary and cardiac status
2. Computed tomography (CT) of the neck with contrast
   a. Laryngeal erosion
   b. Esophageal involvement
   c. Metastasis to the neck
   d. Thyroid disease (consider ultrasound for characterization)
3. Magnetic resonance imaging (MRI)
   a. Not required in all cases
   b. Can be helpful to evaluate for preservation of adipose tissue planes
4. Chest CT
   a. Not required in all cases
   b. Can exclude pulmonary metastases
5. Positron emission tomography (PET)-CT
   a. Not required in all cases
   b. Excludes distant metastases; identifies second primary cancers
6. Modified barium swallow and cervical esophagram
   a. Functional status of the larynx
   b. Involvement of the mucosa of the esophagus
   c. Invasion of prevertebral fascia

Indications

1. Failure of nonoperative management with persistent cancer

2. In the setting of a nonfunctional larynx or advanced cancer it is reasonable to offer the patient a laryngectomy. In rare cases of limited cancer, partial resection of the hypopharynx with or without a partial laryngectomy can be considered.

Contraindications

1. Patient factors
   a. Medically unfit
   b. Unable to give informed consent
   c. Inadequate social support structure
2. Tumor factors
   a. Unable to obtain clear margins
   b. Invasion into the prevertebral fascia and spine
   c. Circumferential encasement of the carotid artery
3. Surgical factors
   a. Inadequate expertise available for reconstruction or postoperative complications

Preoperative Preparation

1. Optimize nutrition when possible with either nasogastric tube or gastric tube if the patient is not taking adequate nutrition by mouth.

2. Laboratory tests: preoperative prealbumin, albumin, thyroid stimulating hormone (TSH), white cell count, hematocrit, hemoglobin, and platelet count

Operative Period

Anesthesia

1. Patients with cancer of the hypopharynx can usually be intubated without difficulty unless the cancer has eroded into the larynx, exerts mass effect, or extends superiorly to distort/obstruct the supraglottis.

2. At the time of reconstruction the patient should already have a tracheostomy in the case of laryngeal preservation approaches or via a tracheostoma following laryngectomy.

Positioning

1. Position the patient so that the ablative and reconstructive teams can work simultaneously to limit surgical time.

2. The patient is in the supine position with a shoulder roll for neck extension. This shoulder role may be removed following flap inset to facilitate the re-draping and closure of the skin of the neck.

Perioperative Antibiotic Prophylaxis

1. Clean-contaminated surgery with antibiotics during induction and continued for 24 hours

   a. First-generation cephalosporin + metronidazole

   b. Cefuroxime if allergic to penicillin

   c. Clindamycin alone provides inadequate antibiotic coverage in the setting of free tissue transfer.

Monitoring

1. Routine anesthesia monitoring

2. Arterial line for precision monitoring of blood pressure and access for intraoperative blood draws

3. During the resection, important cranial nerves, including CN X-XII, have typically been identified. Patient can be paralyzed at this point to allow the anesthesiologist greater control of blood pressure and respiratory status.

Instruments and Equipment to Have Available

1. Anterolateral thigh free tissue transfer
   a. Standard head and neck instrument set
   b. Harmonic scalpel can be helpful for dissecting through the vastus lateralis muscle
   c. Large Deaver retractor to aid with exposure when dissecting the proximal portion of the pedicle
   d. Microvascular instruments for vessel preparation and anastomosis
      1) Microvascular 9-0 nylon suture
      2) Microclips
      3) Heparin-injectable saline solution (1:200)
      4) Operating microscope or operating loupes
      5) Implantable Doppler (optional)

2. Montgomery salivary bypass tube (minimum 10- to 12-mm outer diameter) to assist with creation of the neopharynx

Key Anatomic Landmarks

1. PM, DP, and SC (see chapter on regional flaps)

2. Anterolateral thigh myocutaneous free tissue transfer
   a. A line drawn between the anterior superior iliac spine and lateral patella approximates the septum between rectus femoris and the vastus lateralis.
   b. Neurovascular anatomy
      1) The skin of the lateral thigh is typically supplied by two to three perforators from the descending branch of the lateral circumflex femoral artery (LCFA) and associated *venae comitantes.*
      2) The LCFA joins with the femoral artery (FA), and there are two *venae comitantes* that empty into the femoral vein.

3) There is anatomic variation of the LCFA, and three types of cutaneous perforators have been described:

a) Type I (70%): arise from the descending branch of the LCFA; 90% of them are musculocutaneous, and 10% are septocutaneous

b) Type II (5% to 10%): arise from the transverse branch of the LCFA and travel a long distance though the vastus lateralis muscle

c) Type III (1% to 5%): arise directly from the FA and are very small, take a long intramuscular course, and are usually too small for anastomosis

4) The nerve to the vastus lateralis travels with the descending branch of the LCFA. This is a motor nerve, and when reconstructing the pharynx is not typically neurotized.

Prerequisite Skills

1. Pedicled flap harvest and inset—PM, DP, island-DP, and/or SC flaps

2. Free tissue transfer—ALT, RFFF, or alternative harvest sites that offer thin pliable tissue for inset (groin, lateral arm, jejunum, gastro-omental). For intra-abdominal donor sites, coordination with a general surgeon is essential.

Operative Risks

1. Related to duration of the procedure

a. Intraoperative cardiac events

b. Decubitus ulcers

2. Related to resection

a. Aspiration—Ensure that there is no significant air leak and that the endotracheal tube is sufficiently inflated to protect the airway.

b. Airway fire—Maintain oxygen saturation below 30% when using electrocautery near the airway. Maintain good communication with the anesthesia team regarding risks of a fire.

Surgical Technique

1. Anterolateral thigh free tissue harvest for a total laryngopharyngectomy defect (see Fig. 49.2)

a. Choice of left or right thigh for flap harvest

1) Avoid a side with prior surgery or injury at the donor site. Preoperative imaging is not required before harvest. If there are no scars or history of surgical intervention, then for the right-handed surgeon dissection toward the pedicle is easier from the right side. In cases of severe peripheral vascular disease, consider a different flap choice or angiography if there is no palpable popliteal pulse.

b. Skin paddle design:

1) Mark out a line drawn from the anterior superior iliac spine to the lateral patella.

2) At the midpoint of this line, draw a circle with a 3-cm radius. Within this circle the vast majority of perforators can be found.

a) Many surgeons use a Doppler to estimate the location of the perforators. A 5-0 Prolene suture can be used to mark the perforators.

3) The skin paddle can be designed in either a spiral or horizontal configuration.

a) Spiral configuration

i) A long elliptical skin paddle is drawn with 8 cm at its largest width, centered at the midpoint of the circle. This can typically be closed primarily and evaluated by pinching the skin together.

b) Horizontal configuration

i) A trapezoid is drawn with an 8- to 14-cm width at one end for the base of tongue and 6 to 7 cm (the width of the cervical esophagus) at the other end. If the proximal portion of the neopharynx is longer than 8 cm, it may not be possible to close the donor site primarily.

c) For pharyngeal reconstruction, a tube with a 3-cm distal radius is adequate for near-normal swallowing.

c. Harvesting the flap

1) The anterior incision is made through the skin, subcutaneous adipose tissue, and fascia down to the rectus muscle.

2) The fascia and skin are gently retracted laterally to find the lateral edge of the rectus muscle and perforator vessels to the skin. The incision may need to be extended both superiorly and inferiorly to allow for identification of the perforator(s).

3) Rarely there is an inadequate perforator (type III) to the lateral thigh (<5%) and either the other leg must be explored or a medial-thigh or free-style flap based on the medial system must be harvested.

4) Two perforators from the descending branch of the LCFA are typically identified as either fasciocutaneous or musculocutaneous perforators.

5) After the perforators are identified, mark their location by placing clips on the edges of the skin paddle fascia so they can be readily identified as the dissection proceeds.

6) Proximal separation of the rectus femoris from the vastus lateralis will allow for direct visualization of the main pedicle and palpation of the FA.

7) Careful proximal dissection from the distal perforator to the pedicle is important to ensure continuity of the perforator with the descending branch of the LCFA.

8) There are two *venae comitantes* that travel with the artery as well as the motor nerve to the vastus lateralis.

9) After the perforators have been traced to the pedicle, the proposed skin paddle is reexamined and shifted, if necessary, to ensure that they are included in the flap design. Care must be taken to correlate the site of the perforator with the location on the skin paddle. Mark this location on the skin so that the lateral incision will not injure the perforator.

10) The lateral incision of the skin paddle can now be made with

confidence of the location of the perforator and continuity of the perforator with the pedicle.

11) The skin paddle should now be elevated, and the remainder of the dissection along the pedicle can be performed. It is helpful at this point to let the skin edges of the paddle bleed to ensure the viability of the flap.

12) A portion of the vastus muscle around the perforator and distal pedicle is typically harvested with the flap. This ensures that the vessels are protected. The harmonic scalpel can be helpful for efficient dissection through the muscle, particularly if the patient has not been paralyzed (i.e., if the ablative team prefers no paralysis during simultaneous harvest and neck dissection).

13) If the pedicle is under tension or twisted, it will go into spasm, and the edges of the flap will stop bleeding.

d. After the flap has been completely elevated, but still attached, check for adequate perfusion before clamping the pedicle and starting ischemic time period. The edges of the flap can be checked for bleeding, which should be bright red and flow readily. Abrading the skin edge with a sponge should initiate bleeding if the edges have been cauterized. If the flap bleeds slowly or is in question, then let it stay undisturbed for 10 minutes wrapped in a warm moist sponge and ensure that the pedicle is neither twisted nor under any tension. Temporarily secure the skin paddle to the leg in its anatomic position with a staple or a suture and let it warm up while ensuring that the recipient vessels are prepared in the neck.

2. Preparation of recipient vessels in the neck

a. Arterial

1) Any of the major branches of the external carotid (facial, lingual, and superior thyroid arteries) can be used. Alternatives that are preserved even in the setting of a previously operated field include the transverse cervical artery and internal mammary artery. The external carotid artery itself can also be used.

2) The selected artery should be dissected free so that is it not

tethered to the surrounding fascia. Small branches, particularly with the facial artery, should be clipped and divided.

3) Minimal electrocautery (bipolar if necessary) should be used in proximity to the vessels. The vessels should be picked up only by their adventitia. Gentle handling of the vessels will minimize the chance of intimal injury and risk for thrombosis.

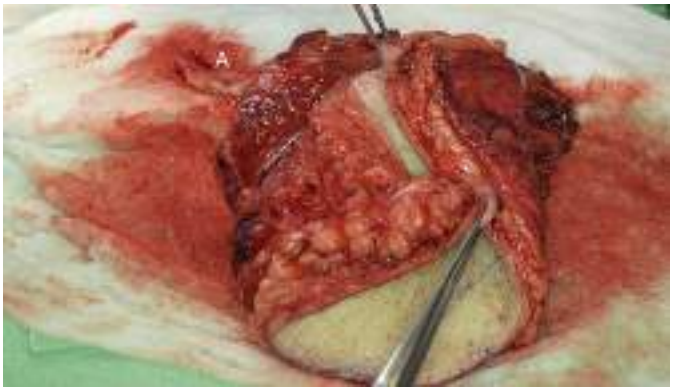

FIG. 49.3 Harvested anterolateral thigh free flap. The elliptical flap is brought together with a spiral suture line to create a neopharynx. The flap pedicle is lateral to the reconstruction for anastomosis with recipient neck vessels *(A)*.

4) After the artery has been dissected so that there is enough length to reach the free flap, a microvascular clamp is temporarily placed across the artery. The vessel should have brisk pulsatile flow with enough force to support the flap.

5) Always have a second choice for an arterial input in case there are any problems with the artery after the ALT has been harvested and the ischemia window has started.

b. Venous

1) The external jugular vein and branches of the internal jugular vein are typically adequate to drain the flap. Transverse cervical and internal mammary veins can be used when the paired artery is dissected.

3. ALT inset

a. Typically the majority of the flap is inset while ischemic to minimize edema of the flap.

b. A tube is created by twisting the elliptical flap over a Montgomery pharyngeal stent (salivary bypass tube).

c. This creates a spiral suture line that reduces the risk of postoperative stricture (Fig. 49.3).

d. A distal portion of the skin paddle is de-epithelialized so that a monitoring portion can be incorporated externally (Figs. 49.4 and 49.5).

e. Either a running Connell stitch or interrupted horizontal mattress sutures are used to close the pharynx

4. Revascularization of the flap

a. Ask the anesthesiologist to maintain mean arterial pressure greater than 70.

b. Under the microscope or with loupes using 9-0 suture, sew the artery. Evenly spaced interrupted sutures placed with care not to injure the intima will result in a successful anastomosis. Use heparinized saline to ensure complete visualization of proper placement of the sutures.

c. Use a coupler for the venous anastomosis. If a coupler is not available or malfunctions, be prepared to sew the veins together. Irrigation of the vein with heparinized saline will keep the vein from collapsing and improve visualization of the edges of the vessel.

d. After it is revascularized, use warm saline irrigation to warm up the flap.

e. Perform a strip test on the vein to ensure adequate venous outflow.

f. Palpate an arterial pulse on the flap pedicle.

g. Turn the head in both directions to ensure the artery and vein do not become kinked.

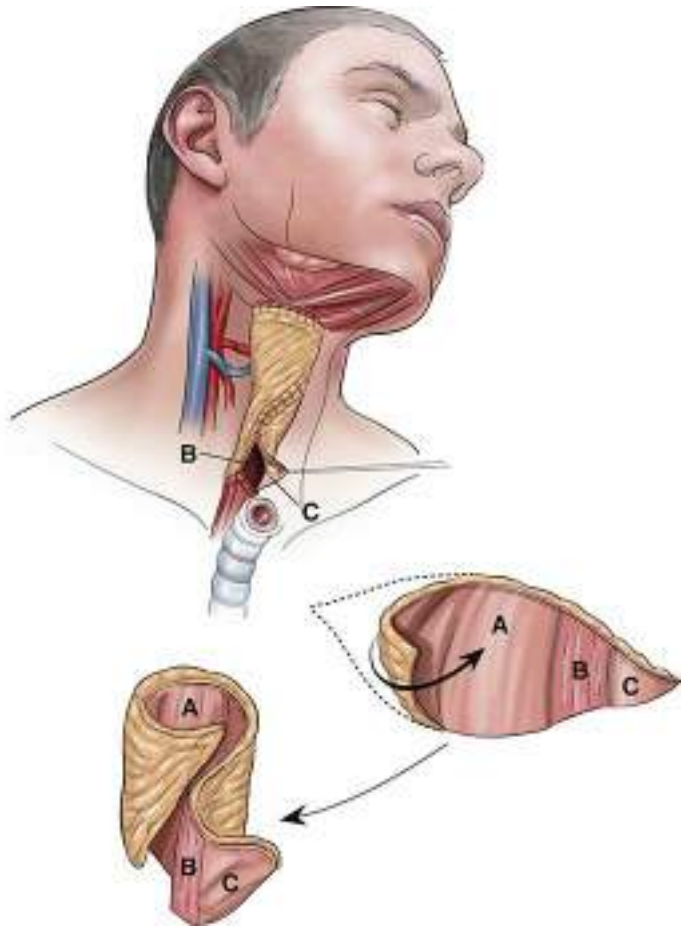

FIG. 49.4 A schematic detailing of one method of flap inset that allows for an external monitoring skin paddle. The skin paddle that will become the neopharynx *(A)*, de-epithelialized portion in the neck *(B)*, and triangular external monitor *(C)*.

FIG. 49.5 Final reconstruction of total laryngopharyngectomy with external skin paddle for monitoring. The flap shows bleeding with

either pinprick or scratch. This monitor can be excised at a later time for better cosmesis.

h. Check the externalized portion of the skin paddle. Prick the flap with a 25-gauge needle and expect bright red bleeding after a slight delay.

5. PM inset

a. The design and inset of the skin paddle are essentially the same as with the ALT; however, a monitoring skin paddle is not necessary.

b. The flap should be elevated so that the distal edge of the skin paddle is not under tension, particularly when the patient turns his/her head.

Common Errors in Technique

1. General

a. Creation of an inadequate tracheostoma—Half-mattress sutures should be used to bring the edges of the trachea to the skin (refer to chapter on total laryngectomy). Small distances should be between tracheal sutures, with wider distances on the skin flaps. This will stretch out and create a wide tracheostoma. The clavicular attachments of the sternocleidomastoid muscle can also impinge on the stoma. Partial medial division of these muscle fibers can allow for a larger stoma.

2. Reconstruction using regional pedicled flaps

a. Tension on the proximal suture line—This usually occurs either as a result of poor planning of the skin paddle or inadequately releasing the pedicle so it can reach the most proximal inset on the contralateral side without tension.

1) During flap design, accurately mark the pivot point for flap rotation. For the PM, the pivot point is where the thoracoacromial artery reaches the clavicle. At this point the flap will rotate over the clavicle. Use a large laparotomy towel and measure the distance from the most proximal inset point (on the contralateral side) to the pivot point. To gain maximal rotation the lateral and medial muscle attachments must be released.

3. Reconstruction using ALT

   a. Internal rotation at the ankle can distort the position of the septum medially. This can result in a miscalculation of the medial incision for the skin paddle and result in injury to the perforators.

Postoperative Period

Postoperative Management

1. Reconstruction using regional pedicled flaps

   a. Antibiotics for 24 hours

   b. Monitor for hematoma—Distinguish between the normal appearance of the bulky pedicle overlying the clavicle.

   c. Early ambulation—postoperative day 1

2. Reconstruction using free tissue transfer

   a. Aspirin, subcutaneous heparin

   b. Flap monitoring—Methods and duration vary widely based on surgeon training and preference. Every four hours for the first two days, then every six hours for 1 day, and then twice daily until discharge works well.

      1) Clinical examination (color, capillary refill, skin turgor, bleed to pinprick with 25-gauge needle)

      2) Doppler signal

      3) Invasive methods (implantable Doppler around artery or vein)

Complications

1. Early

   a. Hypocalcemia—most common complication (45% in one series)

   b. Migration of the salivary bypass tube—if it is left in place during healing

   c. Fistula—a major cause of prolonged hospitalization, delayed oral

intake, and delays in adjuvant therapy

1) Recognize new or worsening tenderness, erythema, fever, wound breakdown, change in the drain output, or loss of stable suction drains.

2) Confirm with bedside blue dye leak test, barium esophagram, or amylase in the drains.

3) Establish a safe tract with a Penrose drain and then shift to local wound care, nutrition status, and general measures to help to close wounds.

4) Ensure that the carotid artery is protected to prevent carotid blowout. A pharyngostome can be created to protect the carotid and divert saliva. This can then be closed at a later time.

d. Flap failure

2. Late

a. Permanent feeding tube

b. Stricture

c. Stomal stenosis

d. Small bowel obstruction (those who have a laparotomy for reconstruction)

Alternative Management Plan

1. Primary nonoperative chemoradiotherapy for cancer of the hypopharynx

2. Alternative donor sites for regional and free tissue transfer (see Table 49.2)

3. Delayed reconstruction

a. No reconstruction—oversew esophagus with planned salivary fistula

b. Wookey flap—creating a neopharynx using the external cervical skin healed directly to the prevertebral fascia

1) Two-step procedure with minimum 2- to 3-week delay between

steps

Discussion

Evidence-Based Medicine Question

What are the reported morbidity and mortality outcomes following reconstruction? How are the functional outcomes with regard to speaking and swallowing?

A number of retrospective series from individual institutions have looked at oncologic and functional outcomes after resection and reconstruction of the hypopharynx.[1] Here are the results of a representative series that reported on 136 patients treated over a 14-year period.[2]

Morbidity

Surgical and medical complications were 29% and 8%, respectively. Pharyngocutaneous fistula was the most common in this series. Of note, the rate of postoperative hypocalcemia, which had been previously found to be more common than fistula,[3] was not reported. Common complications included postoperative hemorrhage and cardiovascular events. Late complications reported in other series include stricture, stomal stenosis, permanent feeding tube, and small bowel obstruction (in patients who had a laparotomy for flap harvest).

Mortality

Perioperative mortality was 3% in this series. In general, the outcome was poor, with 5-year overall survival (OS) of 35% and disease-specific survival (DSS) of 49%. There was no difference in OS with respect to the size of the defect; however, disease free survival (DFS) was lower for partial pharyngectomy versus circumferential pharyngectomy. This suggests that the mucosa at risk may be greater than indicated by mucosal appearance and frozen section.

Speaking

Tracheoesophageal puncture (TEP) was performed in 38% (44% to 60% in other studies). Patients who were reconstructed with pedicled flaps were more likely to have a prosthesis placed. The authors note that those who had free flap reconstruction were more likely to have circumferential defects and were less amenable to voice prosthesis placement. Primary versus delayed TEP placement remains surgeon and institution dependent despite evidence that free flap reconstruction generally does not interfere with TEP placement and voicing. The jejunum free flap is associated with a "wet voice."

Swallowing

More than 80% of the patients in this series resumed full oral diet, and the remaining had a gastrostomy tube for partial or complete nutritional supplementation. There are no randomized studies evaluating the impact of type of reconstruction with swallowing. In this study the authors note that a bulky ALT may not be appropriate for reconstruction of a posterior pharyngeal defect with preservation of the larynx.

Editorial Comment

Hypopharyngeal defects may result from localized resections or from total laryngectomy with partial or total (circumferential) pharyngectomy. Optimal reconstruction of complex hypopharyngeal defects requires special expertise and experience. Dr. Kass has divided the subject into laryngeal preservation and laryngeal sacrifice and provided the surgical armamentarium that is needed to reconstruct defects from relatively simple to extremely complex. As emphasized in the chapter, many hypopharyngeal defects require microvascular expertise. Historically, the jejunal free flap and radial forearm fasciocutaneous flaps were preferred for reconstruction of circumferential defects. The jejunal free flap had significant donor site morbidity and resulted in some problems with succus production and sometimes a very "wet" postlaryngectomy voice. The radial forearm free flap also has donor site morbidity, and stricture was sometimes a problem. Many surgeons now prefer the anterolateral

thigh free flap. The larger volume of soft tissue makes it more versatile for insetting into defects that may involve not only the entire circumference of the hypopharynx but extension into the oropharynx, nasopharynx and cervical esophagus, and/or skin. In addition, the donor site morbidity is considerably less than either the jejunum or radial forearm. Although dilation of the pharyngoesophageal segment is sometimes required after ALT free flap reconstruction, stricture formation may be more manageable because of the volume of tissue in the flap.

Review Questions

1. What is the most common late postoperative complication following total laryngopharyngectomy?

   a. Salivary fistula

   b. Hypocalcemia

   c. **Pharyngeal stricture**

   d. Flap failure

2. When considering how to reconstruct the hypopharynx what factor is most important?

   a. Defect size

   b. Surgeon experience

   c. Prior surgery at potential donor sites

   d. **All of the above**

3. What is the most common arterial blood supply to the anterolateral thigh free flap?

a. Septocutaneous and musculocutaneous perforators from the profunda femoris, a branch from the femoral artery

b. Only septocutaneous perforators from the descending branch of the lateral circumflex femoral artery

c. **Septocutaneous and musculocutaneous perforators from the descending branch of the lateral circumflex femoral artery**

d. Only musculocutaneous perforators from the profunda femoris, a branch from the femoral artery

Cancer of the Cervical Esophagus

Anastasios Maniakas, and Apostolos Christopoulos

Introduction

Cancer of the cervical esophagus has long been known as one of the most difficult neoplasms to treat and cure surgically. It is relatively uncommon, representing less than 5% of all esophageal cancers, themselves representing 5% of all digestive system cancers.[1] In 2010 in the United States there were an estimated 16,640 new cases of esophageal carcinoma, with 14,500 deaths, thus explaining the paucity of data with cervical esophageal carcinoma.[1] Patients often present with advanced-stage cancer and several comorbidities. The aggressive clinical course of this disease is influenced by the high incidence of submucosal spread, ipsilateral or bilateral lymph node metastasis, and the high rate of a second primary cancer in the esophagus.[2] Involvement of the larynx and trachea is often encountered, as a distant metastasis. The surgical defects are often quite significant and most of the time circumferential, necessitating challenging reconstructive planning. A multidisciplinary team is therefore required for the proper management of patients with cancer of the cervical esophagus, including a head and neck surgeon, thoracic surgeon, reconstructive surgeon, medical oncologist, radiation oncologist, speech language pathologist, nutritionist, and physiotherapist. As such, the patients' treatment remains personalized and tailored to their needs, with the main goal being that of curing while attempting to allow for functional rehabilitation to maximize the patients' quality of life.

Squamous cell carcinoma is the most frequent histologic type of cancer found in the cervical esophagus. Primary adenocarcinoma of the cervical esophagus is rare and may arise from Barrett esophagus. Less common are tumors that arise from heterotopic gastric mucosa without evidence of Barrett disease. Benign lesions occur infrequently, the most common

being pedunculated hyperplastic or fibrovascular polyps. Benign lesions are most often removed by endoscopic excision.

Key Operative Learning Points

- Cancer of the cervical esophagus is a rare disease and may be a direct extension of a hypopharyngeal lesion.
- Early diagnosis is one of the most important factors for survival.
- Posttreatment quality of life, in association with functional outcomes, should be a key discussion point before choosing to move ahead with extensive surgery.
- Computed tomography (CT) is essential in the preoperative evaluation of a patient.
- Invasion of the prevertebral fascia must be ruled out before, or at the beginning of, any surgical intervention.
  - Any level of invasion is a strict contraindication to surgery.
- Encasement of the carotid artery is a strict contraindication to surgery.
- The presence of distal cervical esophageal or proximal thoracic esophageal cancer involvement is an indication for total esophagectomy.

Preoperative Period

History

1. History of present illness
   a. Patients with cervical esophageal cancer often have vague and nonlocalizing symptoms, while also being known as long-term smokers and drinkers, thus requiring a thorough head and neck oncologic questionnaire, including the following signs and symptoms:
      1) Sore throat
      2) Hoarseness

3) Gastroesophageal reflux

4) Heartburn/chest pain

5) Difficulty swallowing: dysphagia, odynophagia, aspiration, globus sensation

6) Hemoptysis

7) Weight loss; often associated with advanced disease

8) Dyspnea

9) Referred otalgia

10) Mass in the neck

b. A clear timeline of the signs and symptoms is important to collect because it often provides a preliminary idea of the evolution and progression of the cancer.

c. More than one-third of patients with early-stage cancer will be asymptomatic at presentation.[3]

2. Past medical history and associated risk factors

a. Medical illnesses

b. Surgeries: oropharyngeal, laryngeal, or hypopharyngeal

c. Previous head and neck radiation

d. Family history of cancer

e. Risk factors: tobacco (cigarette or pipe smoking), alcohol abuse, Plummer-Vinson syndrome, lower socioeconomic class, and lower educational levels. Heavy alcohol and tobacco abuse increases the risk of cancer of the head and neck.

Physical Examination

1. Appearance: Patients will often seem malnourished, dehydrated, and with poor oral hygiene.

2. The oral cavity and oropharynx should always be examined to avoid overlooking any asymptomatic second primary cancer or direct extension from a large cancer.

3. Mirror examination and flexible endoscopy

   a. Evaluation of the base of the tongue with proper protrusion of the tongue

   b. Vallecula

   c. Hypopharynx: requires a thorough evaluation reviewing bilateral vocal cord mobility, any extension into the pyriform sinuses (using a puffed cheek maneuver), postcricoid region, and/or the posterior pharyngeal wall. Pooling of secretions is often encountered as a result of distal obstruction by the cancer.

4. Palpation of the neck is performed to rule out regional metastasis. Paratracheal nodes are a common site of metastasis from cervical esophagus cancer.

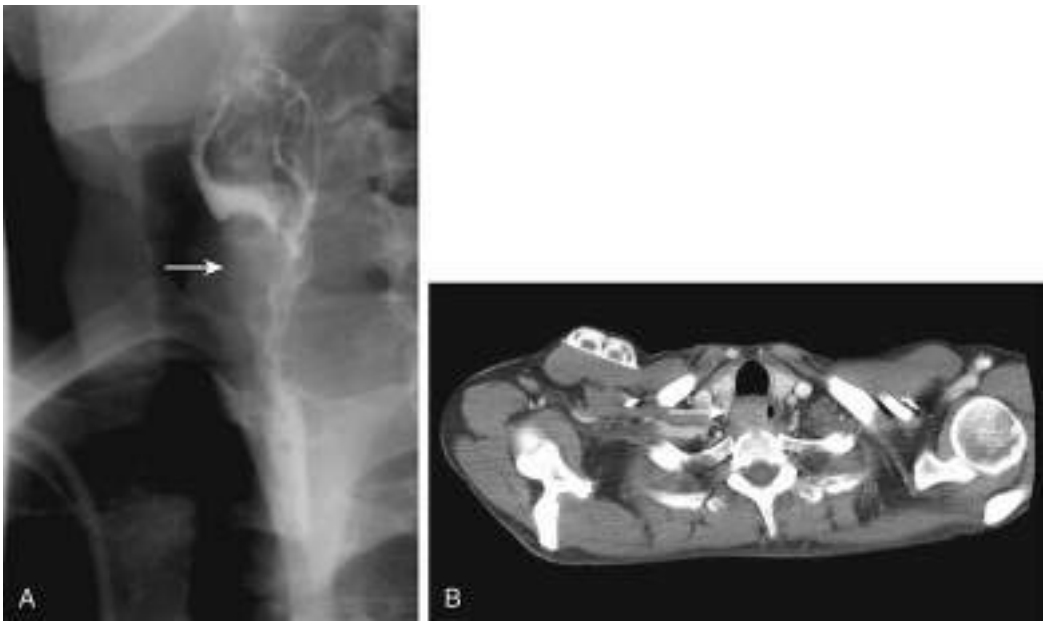

FIG. 50.1 **A,** Barium esophagogram demonstrating carcinoma of the cervical esophagus *(arrow)*. **B,** Computed tomography scan of same patient demonstrating the cancer with narrowing of the lumen of the cervical esophagus *(arrow)*.

Imaging

Imaging studies contribute to the diagnosis and staging while giving information about whether the cancer appears to be technically operable. Although flexible endoscopy provides a direct visualization of the mucosa, it is the imaging that will be most helpful in staging the cancer.

1. Esophagography (barium esophagogram)

   a. Used to determine the extent of mucosal involvement and to establish the presence of a second primary cancer in the more distal aspect of the esophagus (Fig. 50.1A)

   b. The most valuable aspect of this imaging modality is the evaluation of invasion of the posterior wall of the esophagus.

   c. Obliteration of the retropharyngeal and retroesophageal space or invasion of the prevertebral fascia can be estimated through dynamic fluoroscopic evaluation.

   d. In the presence of aspiration, it would be prudent to carry out a diatrizoate meglumine (Gastrografin) esophagogram rather than a barium esophagogram because less reaction occurs if the patient aspirates Gastrografin into the lungs than if barium is aspirated.

2. CT scan with intravenous contrast enhancement of the head, neck, and chest. All newly diagnosed cancers of the head and neck require at the least a CT of the chest before staging (see Fig. 50.1B).[4]

   a. Most widely used imaging technique for cancer of the cervical esophagus

   b. CT of the neck should be performed using maximum 3-mm slice thickness, whereas chest CT can be done with 5- to 7-mm slice thickness.

   c. Goal: accurately evaluate the location and size of the primary cancer and determine whether there is direct extension of tumor into the neck, especially posteriorly into the retropharyngeal and esophageal space, prevertebral fascia, or vertebral column (Fig. 50.2)

   d. Key points:

      1) An anteroposterior diameter of the cervical esophagus greater than 24 mm must be considered abnormal.

      2) The average thickness of the wall is 4.8 mm laterally and 3.8 mm posteriorly.

3) Thickening of the esophageal wall and effacement of the adipose tissue plane are the two criteria with the best sensitivity.

4) Presence of a circumferential mass surrounding the esophagus greater than 180 or 270 degrees has a reported sensitivity of 100%.

e. Cancer of the cervical esophagus most often metastasizes to paratracheal, jugular chain, recurrent laryngeal nodes and superior mediastinal lymph nodes.

3. Magnetic resonance imaging (MRI) may provide greater soft tissue delineation and insight toward prevertebral fascia invasion; however, it does not provide additional staging information than does a CT scan. Some surgeons may prefer this modality to CT scan for initial staging.

4. Positron emission tomography (PET)-CT scan is an imaging tool that is now routinely used for staging cancer of the head and neck, as well as for evaluation of metastatic disease. It should be considered in the workup of cervical esophageal cancer, as well as in monitoring active response in treated patients. Having a trained radiologist or nuclear medicine specialist reviewing the PET-CT images is of utmost importance due to their complexity and the high rate of false-positive readings.

5. Ultrasonography (US) may be used to provide complementary information to the aforementioned imaging techniques via a transesophageal evaluation of the tissues. A US assessment of cervical lymph node metastasis can be made coupled with fine-needle aspiration biopsy to provide valuable information in the staging process.

6. Endobronchial US (EBUS) with fine-needle aspiration for more difficult to attain suspicious lymph nodes (paratracheal, subcarinal, paraesophageal) is often used in our center and allows for a more accurate staging of the disease.

Indications

1. The cancer is resectable with only regional metastases.

2. Patient fit for extensive surgical procedure with challenging and lengthy postoperative recovery period

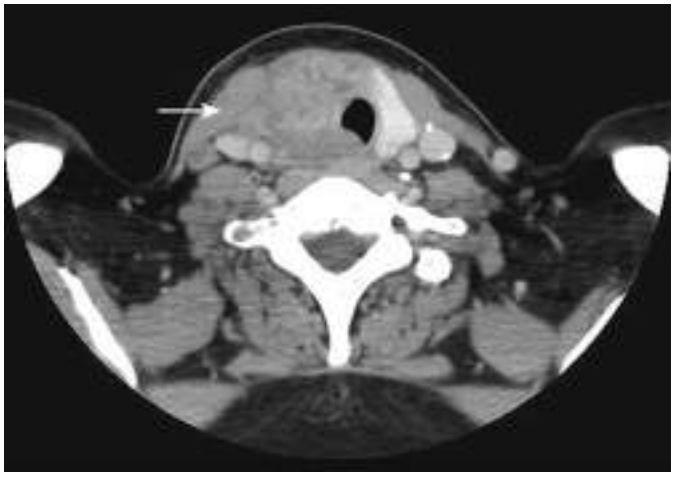

FIG. 50.2 Squamous cell carcinoma of the cervical esophagus with extensive invasion of surrounding structures in the neck *(arrow)*.

BOX 50.1 Staging of Cervical Esophageal Cancer

Tx: Unable to assess the primary tumor

T0: Unable to find the primary tumor

Tis (HGD): High-grade dysplasia (HGD) is abnormal cells that have not invaded deeper cell layers. This term has replaced the term carcinoma in situ for columnar mucosa in the gastrointestinal tract.

T1a: Tumor invades into the lamina propria or muscularis mucosa

T1b: Tumor invades the submucosa

T2: Tumor invades the muscularis propria

T3: Tumor invades the adventitia

T4a: Resectable tumor invading the pleura, pericardium, or diaphragm

T4b: Unresectable tumor that invades other structures, such as aorta, spine, trachea

Nx: Neck lymph nodes cannot be assessed.

N0: No evidence of any spread to nodes

N1: 1 or 2 cancerous nodes in the region

N2: 3 to 6 cancerous nodes in the region

N3: 7 or more cancerous nodes in the region

M0: No evidence of distant spread

M1: Evidence of spread outside of the head and neck (lungs, bone, brain)

Contraindications

1. Severe medical comorbidities rendering the patient unfit for surgery (poor nutritional status, medically unstable)

2. Encasement of the carotid artery visualized in the preoperative imaging is a definite contraindication to surgery. However, if the surgeon unexpectedly finds encasement of the carotid arteries intraoperatively, the extirpative part of the procedure should be completed with the understanding that it will be palliative rather than curative surgery.

3. Involvement of the prevertebral fascia or vertebral column. This should be assessed clinically at the beginning of surgery by using finger dissection of the hypopharynx and esophagus from the prevertebral fascia. If the cervical esophagus cannot be separated easily from the prevertebral fascia, cure is unlikely.

4. Distant metastases

Preoperative Preparation

1. Complete medical preoperative evaluation, including an electrocardiogram, complete blood count, liver function, and renal function tests is required. As previously mentioned, patients often present with severe comorbidities, such as advanced chronic obstructive pulmonary disease secondary to long-term cigarette smoking or cirrhosis of the liver due to chronic alcoholism. Preoperative evaluation by the internal medicine team is essential.

2. Before surgery, patients should be optimized accordingly:

a. Patients with low hemoglobin should undergo transfusion.

b. Nutritional status should be evaluated with a referral to a medical nutritionist, if deemed severe.

3. A diagnostic endoscopy and biopsy should be performed under general anesthesia, although some of these patients may also have upper airway obstruction or an unstable airway because of bilateral vocal cord paralysis, in which case the endoscopy should be preceded by a tracheostomy under local anesthesia. Tracheoscopy is also performed to evaluate the integrity of the tracheal wall.

4. Staging of the cancer should be performed after the physical examination, imaging, and biopsies are available. Staging for a cancer of the cervical esophagus does not resemble that of cancers of the hypopharynx and instead follows the latest National Comprehensive Cancer Network published clinical practice guidelines (Box 50.1).[5]

5. Percutaneous gastrostomy should be avoided preoperatively in the patient with severe dysphagia because this could jeopardize gastric transposition. Instead, a nasogastric feeding tube should be used if necessary. A percutaneous gastrostomy tube may be placed for nutritional replenishment before surgery but only after the reconstructive team has eliminated gastric transposition as an option.

Operative Period

Anesthesia

All surgical procedures are conducted in the operating room under general anesthesia and endotracheal intubation.

Positioning

Patients are positioned in a dorsal decubitus (supine) manner, along with a shoulder roll and adequate headrest retraction to ensure maximal neck extension. The patient is then prepared and draped in such a way to have proper access to the head and neck, as well as the chest and abdomen for reconstruction purposes.

Perioperative Antibiotic Prophylaxis

A combination of a first-generation cephalosporin and metronidazole intravenously should be given preoperatively and for a minimum of 5 to 7 days postoperatively.

Monitoring

No special intraoperative monitoring is required.

Instruments and Equipment to Have Available

1. Standard neck dissection set

2. Tracheostomy set

3. Reconstruction set according to reconstruction team, including microvascular instrument set and sutures

Key Anatomic Landmarks

1. Refer to the chapter on neck dissection and laryngectomy landmarks.

2. The cricopharyngeus muscle represents the transition between the hypopharynx and cervical esophagus.

3. The retropharyngeal and retroesophageal spaces, along with the prevertebral fascia, are key sites that need to be evaluated and cleared of tumor invasion, as no surgical resection can ensure clear margins.

4. The cervical esophagus extends from the esophageal orifice, found at the lower border of the cricoid cartilage, to the sternal notch.

5. The carotid arteries must be cleared of any encasement by the cancer.

Prerequisite Skills

1. Surgery of the cervical esophagus should be performed by an

oncologic surgeon with proper training in extensive neck procedures. The surgeon should be prepared for a complex resection that can include esophagectomy, laryngectomy, hypopharyngectomy, thyroidectomy, tracheal resection, and neck dissection including level 4 nodes.

2. Knowledge of meticulous margin assessment by the surgeon and his pathology team is of paramount importance.

3. A team well trained for all reconstructive options must be available for the surgery.

Operative Risks

1. Pneumothorax

2. Pneumomediastinum

3. Neck abscess

4. Fistula

5. Hemorrhage

6. Mediastinitis

7. Refer to neck dissection, thyroidectomy, and tracheostomy chapters for respective operative risks.

Surgical Technique

1. Total laryngopharyngoesophagectomy (LPE): Due to the typical presentation of advanced-stage disease, a laryngopharyngectomy is required to obtain proper surgical margins and avoid postoperative aspiration. Because the cancer often extends distally in the esophagus, a total esophagectomy is required. Ong and Lee were the first to describe this technique more than 50 years ago as a single-stage, three-phase operation involving cervical and abdominal incisions and a thoracotomy.[6] Thoracotomy was then replaced by a transhiatal esophageal mobilization and finally by the more recent thoracoscopic approach.

a. *Apron flap elevation*

b. *Evaluation of prevertebral fascia:* The sternocleidomastoid muscle is retracted laterally and the larynx medially. The carotid sheath is identified and retracted laterally. The prevertebral fascia is identified by blunt dissection. Finger palpation is then used to determine whether the cancer has infiltrated into the retropharyngeal or retroesophageal space or into the prevertebral fascia. If cancer is present in the retropharyngeal or retroesophageal space, the surgery should be terminated because it is impossible to get a clear margin of resection posteriorly when invasion of the prevertebral fascia is present. In such cases, a gastrostomy and possibly a tracheostomy should be carried out to provide a means of nutrition and maintenance of the airway. If the retropharyngeal space is clear, surgery should proceed.

c. *Bilateral selective neck dissection:* If the patient has an N0 neck, levels II, III, IV, and VI are dissected. (For more information on Neck Dissection refer to Chapters 64 and 66.)

    1) Dissection of level VI is mandatory because multiple lymph nodes in the tracheoesophageal groove may be involved.

d. *Tracheal resection:* The extent of tracheal resection is dictated by the imaging studies and tracheoscopy. If there is no involvement of the trachea, the usual transection of the trachea between the second and third tracheal rings is appropriate. However, if cancer has extended into the trachea, more of the distal trachea may need to be resected.

e. *Laryngopharyngectomy: (For more information on laryngectomy refer to* Chapter 16*).* A transhyoid pharyngotomy is carried out (Fig. 50.3), and the retropharyngeal fascia is separated from the prevertebral fascia in the retropharyngeal space up into the level of the transhyoid incision. Scissors are used to cut through the posterior wall of the pharynx. After this is carried out, the specimen containing the larynx and pharynx attached to the cervical esophagus is then elevated by sharp and blunt dissection down as far as possible into the anterior mediastinum (Fig. 50.4). Ligation of the superior laryngeal arteries and veins is carried out during this procedure. The adjacent lymph nodes, including the retropharyngeal group, should be taken.

f. *Thyroid and parathyroid glands:* Inspection of the thyroid gland will determine whether the thyroid gland should be left intact or be

totally or partially removed. If the thyroid has been infiltrated by cancer, it must be removed along with the specimen (see Fig. 50.2). Parathyroid glands should be preserved and/or re-implanted if necessary. *(For more information on thyroidectomy and parathyroidectomy refer to* Chapters 78 and 84*, respectively.)*

g. *Superior surgical margin:* Specimens should be taken from the superior margin of resection of the pharynx and sent to the pathology department for frozen section examination to make certain that the margins of resection are free of cancer. If not, the surgeon must take additional specimens until clear margins are obtained. The specimen remains attached until the stomach is mobilized.

h. *Total esophagectomy:* The stomach is then mobilized in the abdomen. Blunt dissection in the mediastinum from the abdomen into the neck allows the specimen to be delivered and the stomach to be delivered into the neck by applying gentle traction to each (Fig. 50.5). The esophagus is separated from the stomach at the gastroesophageal junction, the lumen of the pharynx and esophagus is opened, and the edges of the specimen are checked microscopically for tumor clearance (Fig. 50.6).

i. *Partial esophagectomy:* In certain cases in which limited proximal cervical esophageal cancer is encountered, a partial esophagectomy can be undertaken, ensuring a minimum of 2-cm margins, followed by reconstruction with tissue transposition or free tissue flap. Esophageal stay sutures should be placed because tissue retraction into the mediastinum can occur following partial cervical esophagectomy.

2. Reconstruction: In most patients undergoing an esophagectomy, reconstruction is performed using a gastric conduit with the ultimate goal to replicate the esophageal tract as close as possible. The options for reconstruction can be subdivided into pedicled enteric conduits, enteric free flaps, pedicled myocutaneous flaps, and myocutaneous free flaps, each demonstrating their own advantages and disadvantages.

a. *Gastric transposition (pull-up):* This reconstruction technique following LPE for cancer of the cervical esophagus was popularized by Sir Donald Harrison.[7] It is a single-stage method of reconstruction

and allows for rapid re-establishment of deglutition. A two-layer closure with nonabsorbable suture is carried out, anastomosing the stomach to the remaining walls of the hypopharynx and the base of the tongue (Fig. 50.7). Other authors have described the use of a single-layer technique with a 4-0 absorbable monofilament with the knots tied in the lumen.[8] Mucosal inversion is ensured using a modified Gambee technique. Several nonabsorbable sutures are then placed between the stomach and the left diaphragmatic crus to prevent herniation of the stomach back into the thorax. Overall, a gastric transposition offers a simple reconstructive solution with adequate length and robust blood supply. Postoperative chest radiography will show the stomach widening the mediastinal shadow (Fig. 50.8).

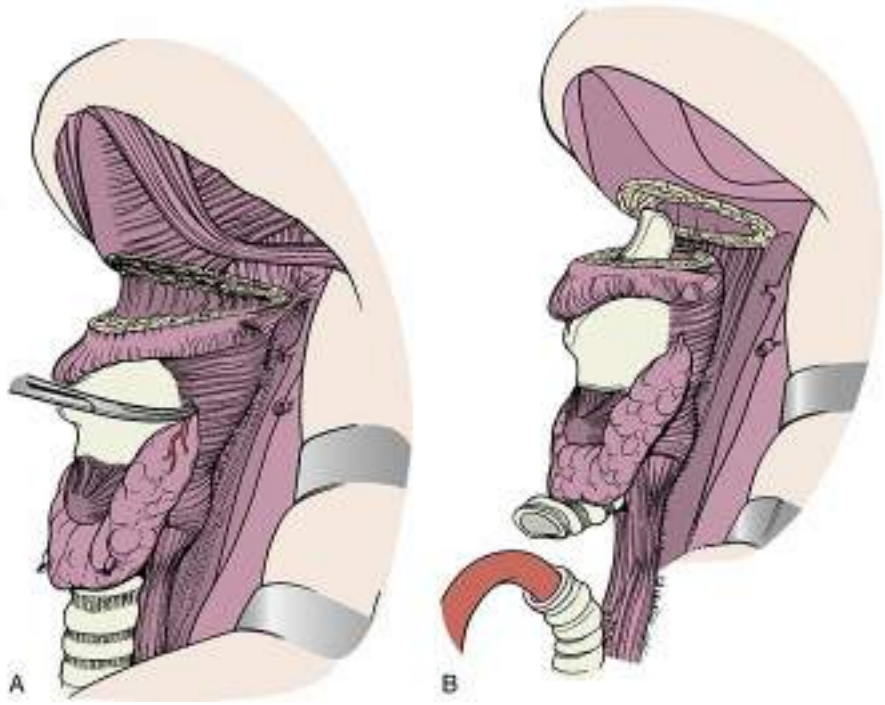

FIG. 50.3 **A,** Transhyoid pharyngotomy is carried out, and the pharyngeal lumen is explored. **B,** The incision is carried through the lateral and posterior pharyngeal wall to separate the pharynx from the base of the tongue. From Silver CE. Surgery for Cancer of the Larynx and Related Structures. New York: Churchill Livingstone; 1981, pp 198–199.

FIG. 50.4 The specimen is elevated off the prevertebral fascia by finger dissection as far inferior as the superior mediastinum, where it is pedicled on the cervical esophagus.

FIG. 50.5 Using gentle traction on the specimen and the stomach allows the specimen to be delivered and the stomach to be brought into the neck to complete the pharyngogastric anastomosis.

b. *Colonic interposition:* This procedure is usually reserved for the rare situation in which either a gastric transposition or a free tissue

transfer is not possible. Preparation of the bowel with a pure liquid diet and oral intake of antibiotics directed at colonic flora is instituted 48 hours before surgery. The left colon is usually the preferred segment for esophageal replacement because it has a more stable blood supply, and its size is more closely associated to that of the esophagus, although all three segments can be used. Because it preserves its active peristalsis, it may offer a superior functional substitute to the esophagus compared with the more passive gastric transposition. Lastly, this reconstructive technique requires multiple anastomoses, thus increasing the risk of anastomotic leaks.

FIG. 50.6 Laryngopharyngoesophagectomy specimen. It will be opened lengthwise to inspect the mucosa of the pharynx and esophagus and to be certain that tumor clearance is macroscopically adequate. Frozen sections will be carried out to confirm the adequacy of the margins.

FIG. 50.7 Diagram of gastric transposition with pharyngogastric anastomosis (Drawn by Dr. Ilyes Berania, MD).

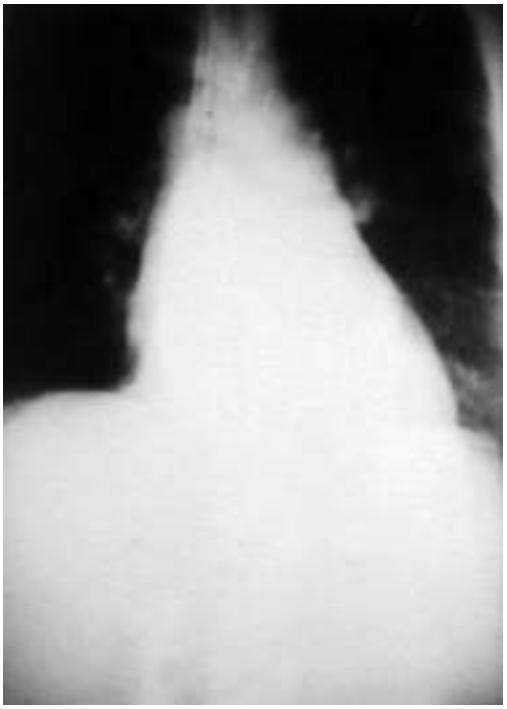

FIG. 50.8 Postoperative chest radiograph demonstrating the stomach widening the mediastinal shadow.

c. *Jejunal free flap:* This free tissue flap was the first use of a free tissue transfer in humans, reported by Seidenberg et al. in 1959.[9] It currently remains the abdominal organ used most frequently as a free tissue transfer for cervical esophageal reconstruction.[10] It is readily available and does not require a bowel preparation, and its diameter is an adequate replacement to the esophagus. Furthermore, its preserved peristalsis may help with the transport of the food bolus, and therefore care must be taken to insert the flap in an isoperistaltic orientation. We recommend having an exteriorized monitoring segment of jejunum based on the same pedicle that may be excised 5 to 7 days postoperatively. Finally, the jejunum has also shown strong tolerance to postoperative radiotherapy and will often allow for decreased rates of xerostomia due to its robust secretory surface.

d. *Gastro-omental free flap:* First reported in 1979 this free flap has the advantage of including a large omental apron that can be used to fill large dead spaces or cover the anastomosis and previously or potentially irradiated vessels. Mucus secretion is also found in this flap and aids in deglutition, although its composition is significantly

more acidic, and mucosal ulceration of adjacent tissues is possible. Furthermore, unlike in the jejunal free flap, patients are left with a gastric staple line.

e. *Deltopectoral or pectoralis major myocutaneous flaps:* These myocutaneous flaps provide a large volume of well-vascularized tissue used to cover the newly reconstructed cervical esophagus and exposed major vessels after exenteration of the central compartment. Their pliable nature allows suturing of the trachea to the skin edge without tension and avoids intraluminal prolapse of excess soft tissues, thus maintaining patency of the tracheostoma. However, they remain too bulky to create a tubularized conduit.

f. *Radial forearm free flap:* A group from Detroit described the successful use of a radial forearm free flap for reconstruction of an esophageal defect following resection of a localized squamous cell carcinoma of the cervical esophagus. This patient had previously undergone definitive chemoradiation (CRT) for a T4N2c of the base of the tongue and therefore was not eligible for CRT or an esophagectomy with a proximal anastomosis. This free flap may also be rolled into a tube in an effort to replace a short circumferential defect after a cervical esophageal excision. However, longer defects should be reconstructed with an alternative free flap.

g. *Anterolateral thigh free flap:* This free flap may be raised as a cutaneous, fasciocutaneous, or myocutaneous graft and provides a longer length than the radial forearm free flap. Yu described a novel technique performed in 10 patients for reconstruction of combined pharyngoesophageal, tracheal, and anterior neck defects with a single anterior thigh flap. The skin paddle was divided into two islands based on cutaneous perforators. One paddle was tubed and used for esophageal reconstruction and the other for repair of cutaneous defects. This technique provides good cosmetic and functional results with minimal morbidity and quick recovery.

3. Tracheoesophageal puncture can be completed postoperatively, as described in Chapter 83, to achieve phonation with a reasonable degree of success; a "tracheogastric" puncture in patients in whom reconstruction involves gastric transposition and "tracheojejunal" puncture in those in whom repair is accomplished with a jejunal interposition flap can be made. This procedure is simple and safe, and a

puncture into the jejunum produces a rather "moist" voice but one that is understandable. Puncture through the posterior wall of the trachea into the transposed stomach also produces a suboptimal, although understandable, low-volume voice.

4. Occasionally, patients may present with small lesions where a limited resection of the cervical esophagus with preservation of the larynx and the function of the cricopharyngeus muscle and vocal cords may be possible. Interesting findings in laryngeal preservation surgery have been reported from a group in Japan, where 33 patients with cervical esophageal squamous cell carcinoma had a cervical esophagectomy followed by reconstruction with a jejunal free flap. Recurrence rates, complications rates, and overall survival were all comparable with the non–larynx-preserving group (25 patients), as well as with the current literature on cervical esophageal cancer surgery. Initial nodal status and the use of neoadjuvant therapy were comparable between the two study groups, although more than 50% of the larynx-preserving group had a T1 or T2 lesion, compared with the non–larynx-preserving group that had primarily T3 or T4 lesions. In another study by Mizobuchi et al., a Weerda laryngoscope was used to remove an early esophageal cancer in a single patient where the lesion was limited to the mucosa. Apart from mucosal resection, endoscopic therapy has evolved to include photodynamic therapy, argon plasma coagulation, multipolar electrocautery, laser therapy, cryotherapy, and radiofrequency ablation,[8] showing comparable long-term survival rates to surgical resection, although these therapies are only applicable to patients with mucosal lesions and for whom lymph node metastases are rare.

Common Errors in Technique

1. Failure to adequately assess the extent of the cancer preoperatively will often result in inadequate resection of the cancer.

2. Attempts to resect the cervical esophagus while maintaining an intact laryngotracheal tract are challenging and require a nearly perfect combination of tumor location, stage, surgical, and reconstructive skills.

3. Previous gastric surgery or placement of a gastrostomy tube to correct malnutrition may make gastric transposition impossible.

Postoperative Period

Postoperative Management

1. A chronic alcoholic who continues to drink heavily before surgery is at high risk for delirium tremens.

2. Antibiotic therapy, as discussed in the section "Perioperative Antibiotic Prophylaxis." Any fistula formation or anastomosis leak/breakdown requires continuous antibiotic therapy.

3. Strict nil per os for 24 to 48 hours followed by nasogastric or percutaneous gastrostomy feeding

4. Thyroid hormone replacement therapy for patients whose thyroid gland has been removed at the time of the surgery with the specimen

5. Calcium levels should be monitored closely followed by adequate replacement therapy.

6. Gastroesophageal reflux disease precautions should be taken, and every patient should receive proton pump inhibitors in the postoperative period.

7. Drain (cervical, thoracic, abdominal) management is often variable from one center or subspecialty to the next.

8. Such surgical procedures often lead to severe psychologic distress due to the mutilating aspect of the defect. Close follow-up with a psychologist or psychiatrist is highly recommended.

9. Adjuvant or neoadjuvant CRT should be considered in patients having undergone a total LPE.

10. An anastomotic leak with a gastric transposition should be aggressively treated because the acidity of gastric secretions may result in severe bleeding from neck vessels.

Complications

1. Nonspecific complications: pneumothorax, pneumonia, pleural effusion, fluid shifts, hemorrhage, pulmonary atelectasis, intrathoracic

chyle leak, ischemia or necrosis of reconstruction tissue, peritonitis or gastrointestinal perforation (for gastric conduit reconstructions), tracheobronchial injury, wound dehiscence, hypocalcemia

2. Gastric pull-up
    a. Gravity will instill an important tension on the anastomosis and may increase rates of anastomosis leaks (10% to 37%), which can rapidly evolve to mediastinitis, sepsis, and death.
    b. Early satiety, postprandial discomfort, dysfunctional propulsion/dumping syndrome
3. Colonic interposition
    a. Short term: anastomotic leaks and strictures, as well as ischemia
    b. Long term: redundancy, leading to delayed emptying, stasis, and dysphagia
    c. Ulceration of the distal colonic interposition due to gastric reflux—can lead to stricture or perforation
4. All free flaps
    a. Stricture: treated by direct surgical revision, balloon dilatation, or placement of a stent
    b. Fistula formation: often treated by secondary intention. Chronic fistulas can be treated with a pedicled myocutaneous flap
5. Study specific outcomes
    a. Triboulet et al. reported a total mortality rate of 4.8% and an overall morbidity rate of 38.3% in a series of 209 patients, including 78 with cancer of the cervical esophagus. Reconstruction was carried out via gastric transposition, colonic transposition, or a jejunal free flap. Gastric transposition is the most frequent cause of respiratory complications. The survival rate without dysphagia is better in patients with gastric transposition than in those with jejunal grafts. The authors found no significant difference in survival between the techniques of reconstruction. However, better results were obtained with gastric transposition because of fewer postoperative complications, faster re-establishment of oral feeding, and better quality of life.

b. Podrecca et al., in their review of 346 patients who underwent free flap reconstruction in the head and neck, found that poor preoperative condition, previous treatment, and requirement for a vein graft were significantly associated with an increased risk for flap failure and other morbidities. Fistula formation occurs in 7% to 37% of patients. Necrosis and fistula rates are higher in jejunal free flaps compared with gastric transposition. Murray et al. reported no fistula development in the 14 patients reconstructed with a combination of anterolateral thigh free flap and salivary bypass despite the fact that some had been treated previously. In one of their patients a stricture developed that was successfully treated by dilatation.

Alternative Management Plan

1. Treatment of cancer of the cervical esophagus has also been undertaken in certain centers by primary radiation therapy (RT), in an attempt to preserve laryngeal function. In a 224-patient retrospective study by Cao et al., 2-year local, regional, distant, and overall disease-free survival were comparable with primary surgical therapy. Further long-term (5-year) survival rates and quality of life reports are required to truly understand the advantages and potential complications of primary RT.

2. As advances in CRT continue to emerge, patients with advanced, unresectable cancer of the cervical esophagus are now being treated, with an increasing population reaching long-term status follow-ups. Studies are now showing that definitive CRT in advanced, unresectable cancers of the cervical esophagus show comparable 3- and 5-year overall survival rates to that of surgery. Gkika et al. treated 55 patients with cervical esophageal cancer with definitive CRT, and at 2 months 35 (64%) had a complete response, 28 biopsy-proven. Survival rates at 2, 3, 5, and 10 years were 35%, 29%, 25%, and 10%, respectively. All patients still alive at their last follow-up had normal swallowing and no or mild esophageal symptoms.

Discussion

Evidence-Based Medicine Question

The management of unresectable cancer of the cervical esophagus remains a significant challenge. What role does primary CRT or RT alone play for unresectable cancer of the cervical esophagus, and what are the survival benefits?

- Refer to the section "Alternative Management Plan."

Editorial Comment

This chapter provides an important summary of the literature on cancer of the cervical esophagus. The prerequisite knowledge for management of this extremely difficult disease is contained in the other chapters in this section. In other words, it is important to understand all the principles of diagnosis and management of the entire hypopharynx, larynx, and upper esophagus to take on the challenge of cancer in this difficult location.

Comorbidity is the rule rather than the exception, and treatment failure is common due to the high incidence of regional failure. Although surgery may not be curative, it is often the only way to effectively palliate patients.

Reconstruction is covered not only here but also in other chapters, and the method of choice depends not only on tumor extent but also on coexisting conditions. The tolerance of visceral flaps, fasciocutaneous flaps, and the stomach to the high doses of radiation required to manage this cancer is an area of current and future investigation as improved methods of radiation delivery and new targeted drug therapies become available.

The authors have done an excellent job of adding important material from the recent literature to the chapter from the prior edition.

Review Questions

1. Which of the following is an absolute contraindication to a surgical

intervention in cervical esophageal cancer?

a. Unilateral cervical lymph node metastasis

b. Bilateral cervical lymph node metastasis

c. **Prevertebral fascia invasion**

d. Thoracic esophageal disease

2. Which of the following is FALSE in cervical esophageal cancer?

a. **Imaging tools are highly sensitive in ruling out prevertebral fascia invasion.**

b. Ultrasound-guided fine-needle aspiration is a helpful tool in disease staging.

c. A chest computed tomography (CT) or positron emission tomography-CT should be completed to evaluate distant metastasis.

d. Endobronchial ultrasound may be used to evaluate intrathoracic lymph node metastasis.

Office-Based Snoring Procedures

Amy Schell, and Andrea Lewis

Introduction

"Primary snoring" can be described as a symptomatic, sleep-related, respiration-dependent acoustic phenomenon with an apnea-hypopnea index (AHI) of less than 5 and without complaints of daytime sleepiness.[1] Snoring is common; it is estimated that 35% to 45% of men and 15% to 28% of women snore regularly. Current evidence regarding the medical morbidity of snoring is inconclusive. Population-based studies have been contradictory regarding the effect of snoring on mortality, cardiovascular disease, metabolic syndrome, and stroke.[2] Like mild obstructive sleep apnea (OSA), treatment of snoring is still commonly considered elective and optional depending on the implications on the patient's sleep and that of his or her bed partner. Snoring is the most common presenting symptom in sleep-disordered breathing patients, and therefore otolaryngologists should be aware of the proper workup as well as procedures and therapies available to treat this condition.

Numerous medical therapies are available for snoring, including various over-the-counter (OTC) options. Several common OTC choices, such as lubricating oral spray, nasal dilator strips, and snoring pillows, were not shown to be individually beneficial in a randomized, blinded clinical trial. Oral appliances have been shown to significantly reduce snoring, theoretically by increasing the size of the pharyngeal airway in both the lateral and the anterior-posterior dimensions.[1,3] If oral appliances are used, follow-up is necessary to monitor the occlusion and dental health long term.[4] Like available OTC snoring aids, oral appliance therapy is also limited by the requirement of regularly nightly use of the device.

Snoring is caused by the vibration of soft tissues in the upper airway

during respiration; these vibrations are exacerbated by sleep-related relaxation of upper airway dilator muscles. The source of vibration is typically the flutter of the soft palate but can theoretically be anywhere along the upper airway.[1] Surgeries addressing the patency of the nasal airway may help snorers who complain of nasal obstruction. The details of such procedures are discussed in detail elsewhere in this text. As a majority of snoring originates at the soft palate, the focus of the remainder of this chapter will be on awake, office-based palatal procedures. All of these procedures have the end goal of stiffening and/or reorienting the palate such that inhalation-induced vibration will be less likely to occur.

Key Operative Learning Points

1. Snoring procedures must minimize morbidity and preserve function, especially as snoring is generally considered to be medically benign.

2. When choosing the appropriate snoring procedure, the patient's upper airway anatomy as well as social and financial concerns should be taken into consideration.

3. Long-term follow-up after any of these procedures is necessary in order to monitor for return of snoring symptoms or signs of progression to OSA.

Preprocedure Period

History

1. History of present illness

   a. Quality, quantity, and intensity of the snoring itself: A visual analog scale (VAS) can be helpful in quantifying the subjective intensity of snoring and can help assess the effect of treatment over time.

   b. Aggravating factors

      1) Position

      2) Medications

3) Alcohol consumption

4) Weight gain

c. Presence of symptomatic nasal obstruction

d. Sleep history: A full sleep history is warranted to assess for possible underlying and/or accompanying sleep disorders.

1) Nocturnal apneas

2) Daytime sleepiness

3) Insomnia symptoms

4) Morning headaches

5) Restless sleep

6) Nocturia

2. Past medical history

a. Prior medical or surgical treatment for snoring or sleep-disordered breathing

b. Medical illness: The patient must be healthy enough to tolerate an in-office procedure.

c. Social history

1) Nicotine use: Abstaining from nicotine may help maintain a regular overall sleep-wake cycle.

2) Alcohol use: This can affect quality of sleep directly and can increase snoring by reducing upper airway muscle activity.

d. Medications

1) Sleep aids, benzodiazepines, and other sedating medications that impact central or peripheral control of breathing during sleep

2) Anticoagulant drugs that may increase the risk of bleeding during the procedure

3) Allergies to antibiotics

Physical Examination

1. Nasal cavity, including nasal endoscopy
    a. Septal deviation
    b. Turbinate hypertrophy
    c. Nasal polyposis
    d. Adenoid hypertrophy
2. Oral cavity
    a. Dentition, including width and depth of the dental arches
    b. Occlusion
3. Oropharynx
    a. Length of the soft palate
    b. Size of the uvula
    c. Hypertrophy of the tonsils
    d. Hypertrophy of the lateral oropharyngeal wall
4. Craniofacial morphology
    a. Retrognathia
    b. Maxillary retrusion

5. Overall body habitus, including body mass index (BMI): Weight reduction is often accompanied by a reduction in snoring and should be recommended for every overweight patient presenting with snoring.

6. Flexible laryngoscopy
    a. Sagittal configuration and length of the soft palate
    b. Size and compliance of the lateral oropharyngeal walls
    c. Size and position of the base of the tongue
    d. Shape and collapsibility of the epiglottis
    e. Muller's maneuver, an attempted inspiration with closed nose and mouth, may help identify problem areas with a tendency to obstruct.

Imaging/Testing

1. Sleep laboratory testing: A sleep study, either via home portable monitoring or in-lab polysomnography (PSG), is required to rule out the presence of OSA and other sleep disorders in those seeking treatment for snoring.

2. Drug-induced sedated endoscopy (DISE): DISE refers to flexible endoscopy performed on the sedated patient during spontaneous respiration. Sedation is typically achieved with propofol infusion. DISE may be considered if there is confusion regarding the anatomic source of snoring after clinical examination and flexible endoscopy. DISE may improve surgical success rates compared to clinical bedside examination in cases of snoring and OSA.

3. Allergy testing: In snoring patients with symptomatic nocturnal nasal obstruction and symptoms of allergic rhinitis, allergy testing may indicate a reversible cause. A trial of medical therapy for allergy may also be beneficial to determine the impact of the rhinitis and nasal resistance on the patient's snoring.

4. Lateral cephalometric radiograph: Imaging is not routinely indicated for primary snoring but may be helpful in cases of skeletal abnormalities.

Indications

1. Primary snoring in the setting of significant burden on the patient or bed partner

Contraindications

1. Patient factors
   a. Inability to tolerate awake, office-based intervention
   b. Allergy to local anesthetic
   c. For palatal procedures, pre-existing velopharyngeal insufficiency (VPI) or cleft palate
   d. Trismus or other oral anatomy (e.g., large torus palatinus) precluding adequate awake access to the soft palate
   e. Relative contraindication: Obesity is associated with lower success

rates for snoring procedures; this should be discussed preoperatively.

2. Disease factors

   a. Underlying OSA: Procedures for primary snoring are not appropriate management in the setting of untreated moderate to severe OSA.

   b. Comorbid sleep disorders should also be addressed prior to procedures for primary snoring.

Preprocedure Preparation

Discontinue anticoagulant drugs if possible; however, the use of anticoagulants is not an absolute contraindication to these procedures.

Procedures

Anterior Palatoplasty

When uvulopalatopharyngoplasty (UPPP) was first introduced and became widespread in the 1990s, the procedure involved relatively radical tissue resection that often resulted in common and bothersome adverse side effects. In the ensuing years, several less invasive, functional versions of the procedure were developed.[1] One of these UPPP descendants, the traditional cautery-assisted palatal stiffening operation (CAPSO), has been employed for snoring and involves the removal of a midline strip of palatal mucosa in the anterior-posterior direction. Though this procedure served to successfully stiffen the palate, the resulting scar was shown to narrow the distance between the tonsillar pillars laterally.

The modified CAPSO, or anterior palatoplasty, involves a horizontally oriented mucosal excision in the proximal soft palate. Resultant scarring and fibrosis not only stiffens the palate but also serves to pull the palate anteriorly and superiorly with healing (Fig. 51.1). This procedure seems to be especially suited for patients with obstruction at the genu of the soft palate.[5]

Anesthesia

- Local: If the patient requires only soft palate and uvula interventions, this procedure may be carried out under local anesthesia in the office setting.
- General: If a patient is noted to have large tonsils, a tonsillectomy may be simultaneously indicated. When tonsillectomy is required, the anterior palatoplasty may be carried out under general anesthesia at the time of tonsillectomy.

Positioning

- Seated: The patient should be sitting upright, at a level where the surgeon can comfortably visualize the oral cavity and oropharynx.
- Tongue depressor(s) are typically required to visualize the soft palate. The cooperative patient may assist with exposure by holding his or her own tongue depressor(s).

Perioperative Antibiotic Prophylaxis

- Anitbiotics are recommended prior to incision. Cefprozil 500 mg may be given orally 1 hour before procedure, or clindamycin may be used for patients who are penicillin-allergic.

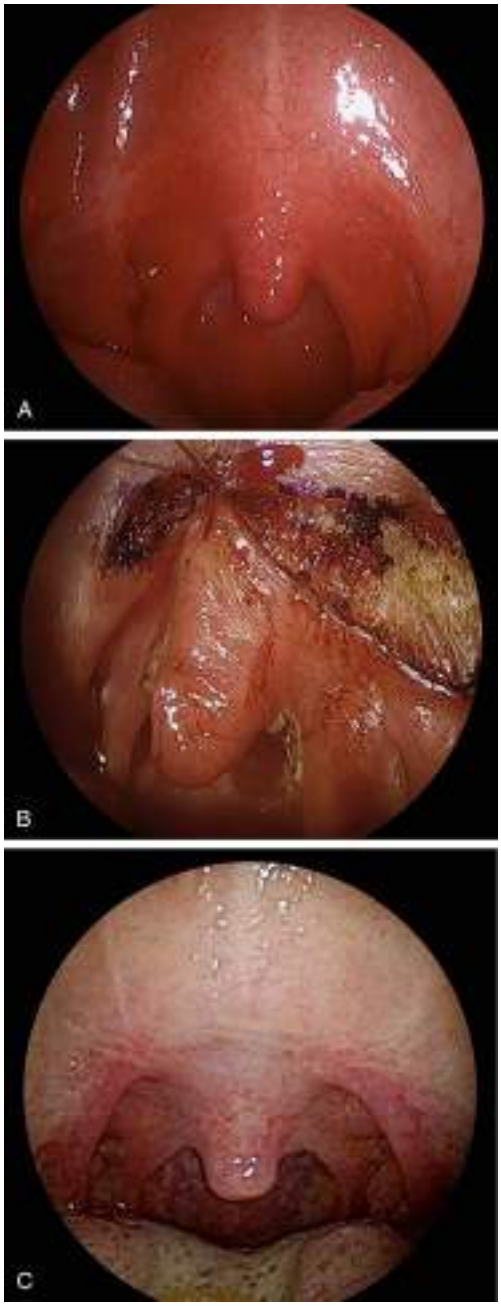

FIG. 51.1 **A,** Preoperative, **B,** intraoperative, and **C,** postoperative appearance of anterior palatoplasty.

Instruments and Equipment to Have Available

- Needle-tipped monopolar cautery on a setting of 10 to 15
- Suction for oral secretions, bleeding, and electrocautery fumes

FIG. 51.2 Planned excision area for anterior palatoplasty.

Surgical Technique (Fig. 51.2, Video 51.1)

- Oral cavity prepped with chlorhexidine mouth rinse
- Apply benzocaine spray (or equivalent topical anesthetic) to the oropharynx
- Inject local anesthetic: Inject a total of 2 to 4 cc 1% lidocaine with 1:100,000 epinephrine (or equivalent) into the soft palate in three sites, midline and approximately 1.5 cm on either side of midline.
- Perform partial uvulectomy, if uvula elongated. The redundant mucosa may be grasped with forceps and truncated at the distal aspect of the musculus uvulae.
- Perform parauvular incisions, if necessary: If prominent palatal arch webbing is noted, full-thickness vertically oriented cuts may be made on either side of the uvula. This step may serve to widen the distance between the tonsillar pillars laterally.
- Remove a strip of mucosa: A horizontal strip of mucosa from the proximal soft palate, approximately 4 to 5 cm in length and 7 to 10 mm in width, is removed down to muscle.
- Suture the defect: Approximately 5 to 10 interrupted 4-0 Vicryl sutures

are used to close the defect, effectively transposing the palate anteriorly and superiorly with closure.

Operative Risks and Common Errors in Technique

- Over-resection of the uvula: It is prudent to leave the muscular aspect of the uvula intact for maximum preservation of function.

Radiofrequency Ablation of the Soft Palate

Radiofrequency ablation (RFA) is a process that delivers thermal energy to submucosal soft tissues via a needle applicator, creating controlled, elliptical lesions and eventually inducing fibrosis and contracture. RFA gives the advantage of tissue volume reduction as well as stiffening. Thus this procedure may be particularly advantageous for the patient with a thick soft palate. Additionally, the safest area to treat is at or near the midline, where the palatal bulk is the greatest. A preprocedure lateral cephalogram can be used to measure the thickness of the soft palate in the midline when the safety of the procedure is in question. Though the soft palate is the chief focus here, RFA has been applied at various levels of the upper airway, including the nasal turbinates and tongue base. RFA seems to be especially well tolerated from a discomfort standpoint; however, multiple sessions are typically required to achieve the desired levels of snoring reduction.

For information on anesthesia, positioning, and perioperative antibiotic prophylaxis, see section "Anterior Palatoplasty."

Instruments and Equipment to Have Available

- Commercially available handpiece: Two options include the Somnus temperature-controlled device (Somnus Medical Technologies, Sunnyvale, California) and the Coblation system with ReFlex Ultra 55 Plasma Wand (Smith & Nephew PLC, London, UK).
- Flexible laryngoscope

Surgical Technique (Fig. 51.3)

- Prepare oral cavity with chlorhexidine mouth rinse.
- Apply benzocaine spray (or equivalent topical anesthetic) to the oropharynx.
- Choose and mark treatment sites: A variety of soft palate RFA lesion patterns have been described, including one midline lesion, one midline lesion with two lateral lesions, and two paramedian lesions with two lateral lesions. Lesion pattern may be tailored to the patient's palatal size and thickness; one midline lesion with two lateral lesions seems to provide an acceptable balance between efficacy and morbidity in most patients. The first mark should be placed in the midline 1 cm below the border of the hard palate; the lateral lesions should each be placed approximately 1 cm away from the initial mark, just above the superior pole of the tonsil on either side. Adjacent radiofrequency applications should be placed a minimum of 8 mm apart to avoid lesion overlap and subsequent mucosal damage.
- Inject local anesthetic: Inject approximately 4 cc 1% lidocaine with 1:100,000 epinephrine (or equivalent) among the marked lesion sites. Generous local injection serves to increase interstitial volume and thus decrease the risk of tissue damage.
- Create lesions at marked treatment sites: In an anterior-posterior direction, insert the handpiece needle submucosally into the muscular tissue of the soft palate. The maximum depth of insertion should be 1 cm. The superior surface of the soft palate can be visualized with a flexible scope during lesion generation; any mucosal blanching during ablation indicates that the needle is too deep and should be withdrawn. There are two genres of ablation devices: those that use temperature-controlled RFA and those that employ plasma-mediated ablation (coblation). For the temperature-controlled devices, an energy level of 400 to 700 joules should be used for midline/paramedian lesions; 300 to 350 joules will suffice for lateral lesions, where the palate is typically thinner. The device should be kept at a maximum of 85°C. When using plasma-mediated ablation, 10 to 15 seconds of coblation at a power setting of 6 is appropriate for each lesion.[6]

Operative Risks

- Palatal anatomy should be evaluated critically prior to the procedure. The soft palate is thickest in the midline, and bulk drops off significantly more laterally. The risk of mucosal injury is higher in these lateral areas, especially in the patient whose palate is thin at baseline.

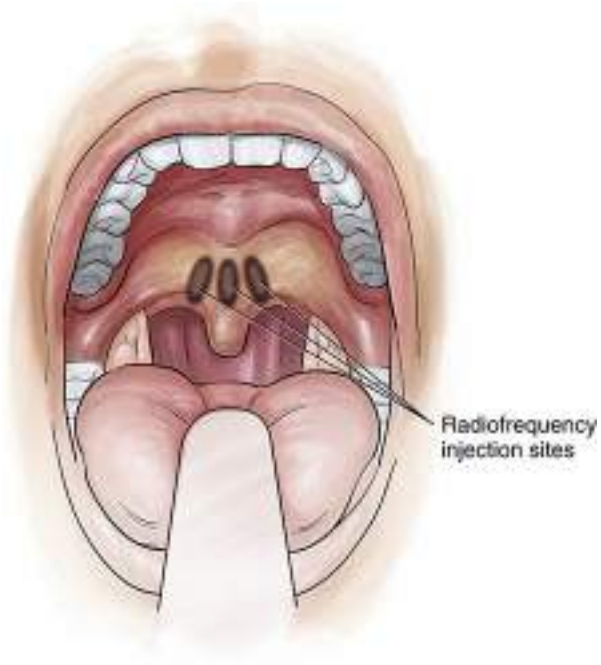

FIG. 51.3 Radiofrequency ablation sites.

Common Errors in Technique

- If RFA delivery sites are not adequately spaced, the surgeon runs the risk of lesion overlap. These areas of overlap may be at higher risk of mucosal injury.
- A lesion site too close to the base of the uvula may lead to uvular necrosis and sloughing.

Palatal (Pillar) Implants

This procedure, which was FDA approved for snoring in 2002, involves the insertion of cylindrical polyethylene terephthalate implants into the soft palate. The implants themselves as well as associated scarring serve

to stiffen the soft palate.[7] Each implant is 18 mm in length by 2 mm in diameter. Three to five implants are commonly used.

There are some anatomic preprocedure considerations for patients undergoing palatal implantation. The patient's soft palate should be between 2 and 4 cm in length with a uvula less than 1.5 cm in length. If the palate and/or uvula is too long, palatoplasty and/or partial uvulectomy could be considered. If the soft palate is too short, this tissue may not be able to safely house the implant.[8] Palatal implants may be safely used after prior UPPP or other palatoplasty technique, as long as the patient has residual soft palate at least 2 cm in length and no evidence of nasopharyngeal stenosis.

For anesthesia, positioning, and perioperative antibiotic prophylaxis, see section "Anterior Palatoplasty."

Instruments and Equipment to Have Available

- Commercially available insertion device with implants (Pillar Palatal LLC, Texas)
- Flexible endoscope

Surgical Technique (Fig. 51.4)

- Oral cavity prepped with chlorhexidine mouth rinse
- Mark implant sites: Implants should be inserted just anterior to the hard-soft palate junction and should be placed within the muscular layer of the palate. The first implant should be inserted at the midline. The other two should be inserted approximately 3 mm to the left and right of the initial implant, such that there is approximately 2 mm of space between each implant. More than three implants may be inserted at the discretion of the surgeon. This is mostly dependent on width of the soft palate.

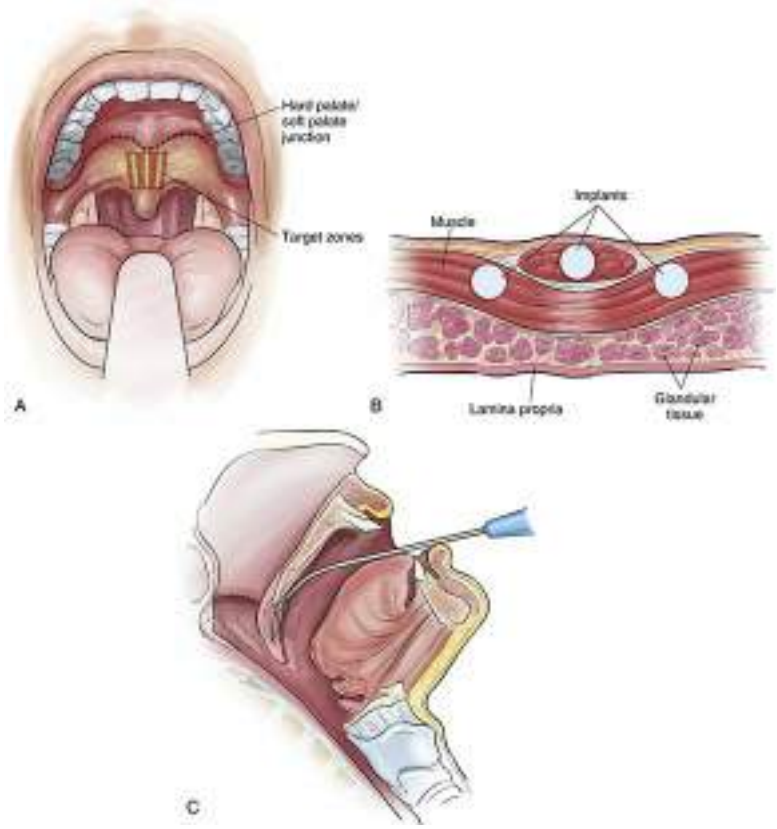

FIG. 51.4 **A,** Target zone for palatal implants. **B,** Implants within the muscular layer of the soft palate. **C,** Depth markings on the implant handpiece.

- Inject local anesthetic: Inject approximately 0.5 cc 1% lidocaine with 1:100,000 epinephrine (or equivalent) into each insertion site.
- Insert implants: The handpiece has three markings. Introduce the applicator tip to the third marking in a curvilinear fashion, taking care not to bypass the soft palate. The author prefers to have an assistant look into the nasopharynx with a flexible endoscope at this time to make sure the applicator tip is not visible in the nasopharynx. Withdraw the applicator to the second mark and deploy the implant.
- Confirm placement with a flexible endoscope.

Operative Risks

- If placed in an incorrect trajectory, it is possible to come through the soft palate and enter the nasopharynx with the implant. The surgeon may avoid this by viewing the soft palate from above with a flexible

laryngoscope.

Common Errors in Technique

- Prior to deploying the implant, it is also prudent to move the handpiece from side to side to ensure the implant is in the muscular layer.

Injection Snoreplasty

Injection snoreplasty involves the instillation of a sclerosing agent into the midline of the soft palate in order to induce scarring and stiffening of the tissue. Though this procedure might not offer as much control as RFA or palatal implantation, it is very low cost, technically very simple, and does not require specialized equipment. Various sclerosants have been used in the literature, including a 50:50 mix of 2% lidocaine and 99% dehydrated ethanol, 1% to 3% sodium tetradecyl sulfate, and polidocanol.

For anesthesia, positioning, and perioperative antibiotic prophylaxis, see section "Anterior Palatoplasty."

Instruments and Equipment to Have Available

- Sclerosing agent, approximately 2 mL total
- Twenty-seven gauge needle and syringe for injection

Surgical Technique

- Prep oral cavity with chlorhexidine mouth rinse.
- Apply benzocaine spray (or equivalent topical anesthetic) to the oropharynx.
- Place 2% viscous lidocaine (or equivalent) on the end of a tongue depressor and hold against the central soft palate for 5 to 10 minutes.
- Inject sclerosant: Inject approximately 1.5 to 2 mL of the sclerosant into the soft palate approximately 1 cm above the proximal edge of the soft

palate in a submucosal plane. Do not place in the uvula due to the risk of edema of the uvula.

- Watch for appropriate effects: When using sodium tetradecyl sulfate, a clear bulla of fluid is visible immediately after injection. Within about 2 minutes, the area takes on a purple, ecchymotic appearance.[9] If using ethanol, the palate will take on a blanched appearance in the area of injection. Either way, the resulting scar will evolve during the following weeks.
- Consider delayed, repeat injection: If the patient is not experiencing adequate snoring reduction, the surgeon may consider a repeat injection at a minimum of 6 weeks. If repeat injection is to be performed, sclerosant is typically placed just laterally to the initial site of scar; approximately 1 mL of sclerosant is injected on either side (Fig. 51.5).

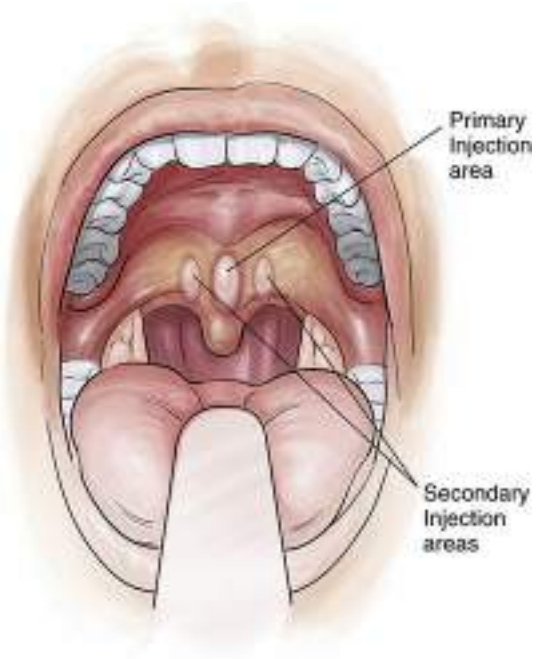

FIG. 51.5 Snoreplasty injection sites.

Operative Risks and Common Errors in Technique

- Similar to RFA, the thin palate is at a higher risk of mucosal breakdown and fistula when undergoing injection snoreplasty. A smaller volume

of injection may need to be considered in this situation.

Postprocedure Period

Postprocedure Management

- Observation: Patients should be observed for 20 to 30 minutes following these office-based upper airway procedures.
- Pain medication: Patients generally do well with 2 to 3 days of OTC analgesics. Anesthetic sprays and/or lozenges may be used as an adjunct. Some patients, including most who undergo anterior palatoplasty, will require narcotic medications.
- Antibiotics: 5 to 7 days of postoperative antibiotics should be prescribed following palatal implantation.
- Steroids: As scar and fibrosis are the desired outcomes for snoring procedures, postprocedure steroids are generally not recommended.
- Diet: Most patients can resume a normal diet postprocedure but may have less discomfort with a soft diet for 24 to 48 hours.

Complications

- Pain: Some discomfort should be expected with all of these procedures and will vary on a patient-to-patient basis. OTC pain medication should be adequate for most patients undergoing palatal implants, RFA, and injection snoreplasty. Of the previously noted procedures, anterior palatoplasty is generally associated with the greatest discomfort; these patients may require narcotics for several days.
- Edema: Mild to moderate soft palate and uvular edema can occur following any of these procedures. This is typically self-limited and does not require treatment, but the patient and surgeon should be aware of this potential complication and its impact on the airway.
- VPI: This is a theoretical risk (although very rare given the lack of excision of the velum) of most of these procedures, which serve to shift, shrink, and stiffen the palate.

- Mucosal blanching and erosion: These minor mucosal changes are commonly seen with RFA of the soft palate and are self-limited; rates have been quoted at 15% to 45%. The mucosal breakdown rate seen with injection snoreplasty is 12.5%.[9]
- Palatal fistula: Palatal fistulas are rarely seen following RFA, palatal implantation, and injection snoreplasty. All reported cases were noted to heal spontaneously, with or without antibiotics.[7] Those with thinner soft palates and/or risk factors for poor wound healing, including diabetes, vascular disease, and cigarette smoking, may be at higher risk and should be counseled as such.
- Palatal implant extrusion: Palatal implants have an extrusion rate of 9.3%.[7] Most of these extruded implants require removal in the office under local anesthesia.
- Infection: Infection is a rare but reported complication of palatal implantation.[7]

Alternative Management Plan

This chapter should serve as a menu of procedures and therapies from which to choose. If a patient fails with a certain procedure in the short or long term, one could always consider oral appliance therapy. As noted previously, these procedures can often be performed in succession in the appropriate patient. For example, pillar implants may be used to stiffen the palate that has already undergone palatoplasty and/or uvulectomy. Lastly, it should be reiterated that snoring is currently considered medically benign. Thus observation alone is always an option.

Discussion

Evidence-Based Medicine Question

What are the expected outcomes associated with snoring procedures?

In general, it seems that a majority of patients undergoing any of these procedures see some meaningful, short-term decrease in snoring. Both injection snoreplasty and RFA tend to require multiple treatments in

order to achieve this benefit. Good, long-term data are relatively lacking; however, the long-term data available indicate that many patients experience a return of snoring symptoms. Additionally, patients with higher BMIs tend to have poorer outcomes.

1. Anterior palatoplasty:

- At about 2.5 years, all patients and sleep partners were noted to be satisfied with snoring results. VAS scores were significantly reduced from a mean of 8.4 preoperatively to 2.5 at 30 months.[5]
- Randomized, placebo controlled studies as well as longer-term studies are lacking.

2. RFA of the soft palate:

- Patients tend to note benefit in the short term.
  - A placebo-controlled trial showed significant reduction in snoring compared to placebo at approximately 2 months.
  - Also at about 2 months, most patients' (79% to 96%, depending on number of lesions) snoring is seen to decrease to levels no longer bothersome to their bed partner. Of note, most of these success stories required multiple treatments.
- Long-term results are variable.
  - A second placebo-controlled trial showed no significant difference in snoring outcomes at 1 year based on the subjective perception of patients' bed partners.[6]
  - Satisfaction rates seem to drop off in the long term. At 3 to 4 years postprocedure, only 25% of patients and bed partners were noted to be satisfied.
  - BMI seems to be the main factor influencing treatment results; BMI over 30 is associated with poorer outcomes.[10]

3. Palatal implants:

- Snoring is significantly reduced in the short term compared to placebo.
  - A majority of patients experience at least 50% reduction in snoring VAS scores.
  - At 90 days, 75% of patients and 90% of bed partners recommend this

procedure.

- Long-term results are variable; in one study, only 21.7% of patients recommend the procedure at 4 years.
- Responders tend to have lower BMIs and lower Mallampati scores.[8]
- In nonresponders with appropriately sized palates, the surgeon may consider an additional one to two implants, placed just laterally to the initial three.

4. Injection Snoreplasty:

- In the short term, 92% of patients report a significant decrease in snoring. Of note, about two-thirds of patients require more than one injection session, with about 15% requiring three or more to achieve these results.[9]
- Subjective success was noted to drop to 75% at a mean of 19 months; however, most patients (95%) stated that they would still recommend the procedure to others at that point.

Editorial Comment

Snoring most often results from palatal flutter and is a very common sleep-disordered breathing symptom that brings patients and bed partners into the otolaryngist's office. Since positive pressure therapy, custom mandibular repositioning appliances, and more involved surgical procedures are often not covered services in the absence of sleep apnea, minimally invasive procedures for the treatment of nonapneic snoring are potentially very applicable to the large population affected by nonapneic snoring. Palatal stiffening procedures may reduce snoring by reducing palatal flutter with low morbidity and risk. Combination therapy to manage all of the specific anatomic and pathophysiologic factors (e.g., positional therapy, lowering nasal resistance, weight loss) of each nonapneic snoring patient likely improves the outcome of the palatal procedures.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. Approximately _____% of males and _____% of females are habitual snorers.

   a. **40 and 20**

   b. 50 and 50

   c. 25 and 10

   d. 10 and 5

2. Procedures for snoring

   a. Are 100% effective

   b. **Should follow a PSG to first rule out more significant OSA**

   c. Are equal in effectiveness to OTC products

   d. Have shown no improvement in bed partner satisfaction

3. When considering palatal procedures for snoring

   a. Place pillar implants if palatal length less than 2 cm

   b. Injection snoreplasty works best if soft palate very thin

   c. **Anterior palatoplasty can increase the anterior-posterior dimension of the velopharynx**

   d. Pillar implants more effective if soft palate very long

Drug-Induced Sedated Endoscopy

Raj C. Dedhia, and David Kent

Introduction

Obstructive sleep apnea (OSA) is a state-dependent phenomenon in which the pharyngolarynx undergoes repetitive obstruction. For the otolaryngologist, the ability to phenotype the specific site(s), anatomic structures, and patterns involved in the upper airway obstruction appears crucial to successful outcomes.[1]

Upper airway evaluation in a sedated state was first published by Croft and Pringle in 1991.[2] Since that description, drug-induced sedated endoscopy (DISE) has demonstrated moderate-to-substantial inter-rater reliability and discriminant validity between snorers and non-snorers.[3-5] Patients undergoing DISE have been noted to have significantly more severe velopharyngeal and hypopharyngeal collapse than that observed during awake endoscopy with Müller maneuver.[6]

However, there are several important limitations, including a learning curve for the otolaryngologist and anesthesiologist to obtain the optimal plane of sedation, nonnatural sleep, variability in technique and staging systems, and the lack of quantitative measurements.

Key Operative Learning Points

1. Proper technique and depth of sedation are critical to approximate natural sleep.

2. DISE provides an opportunity for dynamic assessment of the airway during a sleep-disordered breathing state and the effect of mandibular repositioning or other interventions.

3. The role of DISE is an adjunctive diagnostic tool to improve surgical

decision making and outcomes, rather than a surgical roadmap in isolation.

Preoperative Period

History

1. History of present illness
    a. Presence of common sleep disorders, such as insomnia and restless legs syndrome. Failure to treat these disorders will result in suboptimal outcomes.
    b. Subjective benefit from previous weight loss, positional therapy, oral appliance, or positive airway pressure (PAP) implicates OSA as driving force behind symptomatology.
    c. In-depth review of most recent diagnostic sleep study with attention to positional or stage-related differences. DISE is considered to largely resemble non-REM rapid eye movement sleep.
2. Past medical history
    a. Prior surgical otolaryngology treatment
    b. Comorbidities associated with OSA: diabetes, hypertension, stroke, myocardial infarction, arrhythmia, depression, obesity
    c. Difficulty with entrance or emergence from anesthesia

Physical Examination

1. Anterior rhinoscopy
    a. Septal deviation, turbinate hypertrophy, and nasal polyps: These structures can create proximal obstruction, thereby increasing negative pressure in the distal pharynx.
2. Facial skeleton evaluation
    a. Significant maxillary or mandibular constriction may require skeletal correction.
3. Neck exam

a. Inferiorly positioned hyoid bone (greater than two fingerbreadths below mandibular plane) intimates an unfavorably elongated airway; treatment options must be tailored to this phenotype.

Imaging

- None—although DISE findings may be correlated with existing imaging results

Indications

Surgical evaluation for sleep apnea requires synthesis of patient's OSA symptoms, medical history, physical exam (including awake nasolaryngoscopy), sleep study results, patient preference, and patient expectations. If these elements are favorable for surgical treatment, the DISE can be performed as a planning tool either as a standalone procedure or immediately prior to surgical therapy in the operating room. Common indications include:

1. To plan a multilevel upper airway surgical plan in patients who have failed medical device therapy and present with concern for multilevel or multifactorial airway collapsibility

2. To evaluate the upper airway after prior failure of airway reconstructive surgery

3. To evaluate for anatomic candidacy for hypoglossal nerve stimulation therapy. At present, the Inspire hypoglossal nerve stimulator is the only surgical therapy that requires a priori DISE evaluation for candidacy determination. This requirement is related to indication guidelines from the US Food and Drug Administration.

4. At the time of staged or adjunctive nasal surgery, DISE to evaluate the rest of the upper airway anatomy should additional surgical considerations be needed in the future

5. In patients who achieve partial but incomplete results with oral appliance therapy, DISE with and without the oral appliance to evaluate for residual locations of collapse and additional medical or surgical treatment options to further augment the effectiveness of the oral

appliance

6. In patients with persistent apnea-hypopnea index elevation or other evidence of airway obstruction despite CPAP (continuous positive airway pressure) use, DISE with and without the CPAP in place to investigate the reasons for CPAP failure, such as epiglottic collapse or iatrogenic airway obstruction due to the interface impact on the jaw and neck position

7. In the pediatric population, to evaluate for persistent OSA after adenotonsillectomy and other first-line therapy. DISE is often preferred to in-office awake laryngoscopy for both patient tolerability and visualization of dynamic collapsibility.

Contraindications

- History of drug allergy to sedating agent
- Pregnancy
- Significant nasal obstruction precluding endoscopic examination

Preoperative Preparation

- No food or drink after midnight because the patient is receiving general anesthesia

Operative Period

Perioperative Medications

1. Fifteen minutes prior to the procedure, the patient is given 0.2 to 0.4 RCD mg intravenous glycopyrrolate (depending upon ideal body weight) to decrease oronasal secretions.

2. Topical oxymetazoline 0.05% and/or lidocaine 4% solution or 2% jelly are applied unilaterally to the more patent entry nostril.

3. No antibiotic prophylaxis is required.

Positioning

1. At the outset, supine position with one pillow under the head. Positioning changes over the course of the procedure (see "Surgical Technique" later).

2. Do not tuck the arms because this may lead to increased combativeness.

3. Place blow-by oxygen below chin for supplemental oxygen reservoir, if needed, without interfering with scope placement.

Anesthesia

1. Propofol
   a. Most commonly used agent with rapid sedation/emergence profile
   b. Continuous infusion started at 100 to 150 μg/kg/minutes and gradually titrated based on clinical parameters of sedation
   c. Boluses of 100 to 300 μg/kg optionally added as needed depending on surgeon judgment and patient sedation
2. Alternative agents include midazolam and dexmedetomidine.

Monitoring

1. Pulse oximetry

2. Blood pressure cuff

3. Five-lead EKG electrocardiogram monitoring

4. Bispectral index (BIS) monitoring is optional but may serve as a useful adjunct to determine proper depth of sedation. BIS range of 57 to 71 has been reported to correlate with the collapsibility and loss of genioglossus muscle activity seen in OSA.[7]

Instruments and Equipment to Have Available (Figs. 52.1 and 52.2)

1. Laryngoscope tower with audio and video recording capability
2. Flexible laryngoscope (3.5 mm or smaller)
3. Defog solution with sponge
4. Lubricating jelly applied on 4 × 4 gauze
5. Cotton-tipped applicators ×2 covered with 2% lidocaine jelly
6. Standard pillow

FIG. 52.1 Nasal medications, including oxymetazoline and lidocaine jelly with cotton-tipped applicators.

FIG. 52.2 Flexible laryngoscope with lubricating jelly and defog solution.

7. Foam doughnut

8. Body wedge

9. Anesthesia airway equipment (Ambu bag, laryngeal blades, endotracheal tubes)

Key Anatomic Landmarks

1. Velum
   a. Sagittal soft palate configuration (oblique vs. vertical)
   b. Position of and depth behind the maxilla
   c. Position of and depth behind the levator muscle sling or genu
   d. Soft palate length
   e. Degree of lateral velopharyngeal wall component
   f. Presence and degree of adenoid hypertrophy
   g. Pattern of collapse—concentric versus anterior-posterior
2. Oropharyngeal lateral walls
   a. Structure and position of the salpingopharyngeus, palatopharyngeus, palatoglossus, and palatine tonsils
   b. Degree of lateral oropharyngeal wall collapse
3. Tongue
   a. Upper tongue base versus lower/vallecular tongue base collapse
   b. Presence and degree of lingual tonsil hypertrophy
4. Larynx
   a. Epiglottis length, position, and pattern of collapse (anterior-posterior vs. lateral), if present
   b. Presence of other supraglottic collapse (aryepiglottic folds, arytenoids) or other laryngeal lesions

FIG. 52.3 DISE room setup with surgeon on patient *right*, screen for surgeon viewing on patient *left*, anesthesia at head of bed.

5. Jaw position and laxity

6. Nasal airway

Assessment

1. Multiple assessment tools have been proposed, but no single tool has been accepted as standard.

2. VOTE (velum, oropharyngeal lateral walls, tongue, epiglottis)[8]

   a. Most commonly used

3. NOHL (nose, oropharynx, hypopharynx, larynx)[9]

4. DISE index[10]

Prerequisite Skills

1. Flexible laryngoscopy

Operative Risks

1. Mucosal irritation and bleeding: These can be minimized by

atraumatic technique and recommended preprocedure Afrin application.

2. Oversedation requiring assisted ventilation and causing central apnea

Surgical Technique

- Setup (Fig. 52.3; see also Figs. 52.1 and 52.2)
- In the procedure room, a single cotton-tipped applicator covered in 2% lidocaine jelly is placed along the floor of the entry nasal passage, approximately halfway back in the nasal cavity. A second cotton-tipped applicator covered in 2% lidocaine jelly is placed between the inferior and middle turbinate, at the same depth. The patient is to remain upright until the cotton-tipped applicators are removed.
  - NOTE: This technique minimizes unwanted anesthesia of the pharynx and contralateral nasal cavity, both of which may cause artificial worsening of OSA and false positives.
- After anesthesia is ready to deliver intravenous medication, the cotton-tipped applicators are removed and the patient is made supine with one pillow to simulate home environment. The room lights are dimmed. If BIS monitoring is used (optional), it should be placed over the forehead at this time.
- The laryngoscope lens is treated with defog solution, and the distal 3 to 5 cm of the shaft (not including the lens) are submerged in lubricating jelly.

FIG. 52.4 Right lateral decubitus positioning.

- Prior to nasal insertion, an image of the patient's wristband should be recorded to ensure correct labeling of patient and DISE exam. The laryngoscope is then inserted transnasally to the level of the proximal soft palate. Intravenous propofol bolus is administered by anesthesia.
  - NOTE: Placement of the laryngoscope prior to administration of sedating agent allows for visualization of the pharyngeal motion leading up to the obstruction ("crash"), as opposed to placing the telescope after obstruction has occurred (arriving "after the crash"). In addition, stimulation from the scope passage can interrupt the steady descent of increasing somnolence.
- The correct depth of sedation is clinically determined as the patient becomes unresponsive to verbal commands and experiences signs of obstructive periodic breathing. At this time, the patient's gown should be lowered to waist level to observe inspiratory effort, as well as paradoxical breathing. Throughout the exam, the scope should alternate between visualization of the palate and tongue base. After the patient has reached an obstructive steady state, notation should be made regarding the degree (percentage obstruction) and configuration of collapse (anterior-posterior, circumferential, lateral) at the soft palate, lateral walls, tongue base, and larynx.

- Evaluate mandibular laxity by viewing the patient's profile.
- Standard maneuvers
  - Ask assistant to place thumbs in mouth (mandibular gingivobuccal sulcus on either side of midline) with fingers outside mouth (below mandible) and protrude mandible 50% to 75% of maximal range, leaving 5 to 10 mm anterior open bite. Maximal range (millimeter) should be obtained in the office examination.
    - Observe both palate and tongue base for minimum of two respiratory cycles during maneuver until dominant collapse pattern is determined.
    - NOTE: Open bite simulates the interincisal gap generated by a standard oral appliance.
  - With use of room staff, roll patient on right side and use body wedge to maintain position (Fig. 52.4).
    - Observe both palate and tongue base for minimum of two respiratory cycles during maneuver until dominant collapse pattern is determined.

FIG. 52.5 Elbow bronchoscopy/laryngoscopy adapter between PAP mask and tubing.

- The right side is preferred because the surgeon stands on the right side of patient.

- Exchange pillow for foam doughnut, placing the head in extension.
  - Observe both palate and tongue base for minimum of two respiratory cycles during maneuver, until dominant collapse pattern is determined.
  - This maneuver simulates the cervical pillow, which can be treatment for primary epiglottic obstruction.

- Optional maneuvers
  - If the patient uses an oral appliance, start sleep endoscopy with the oral appliance in place. Remove the appliance and compare airway collapse with and without oral appliance to determine efficacy.
    - Oral appliance may be difficult to seat without patient's aid; therefore it is recommend to start exam with oral appliance in place, and then remove it after patient is sedated.
  - If the patient uses PAP therapy with suboptimal objective or subjective results, ask the patient to bring the PAP machine. The use of a bronchoscopy elbow (Fig. 52.5) with full face mask allows for concurrent DISE with PAP therapy. This should allow for detection of residual obstruction with PAP therapy.
    - Similar to oral appliance, place mask with patient's cooperation while awake to ensure adequate seal. After the sedation steady state is achieved, the mask can be removed for baseline examination.

Common Errors in Technique

- Failure to achieve appropriate plane of anesthesia; oversedation can lead to excessive and even global upper airway collapse, overestimating the severity of patient's anatomic collapse
- Failure to prepare for difficult airway management scenarios
- Failure to perform maneuvers to simulate oral appliance or positional therapy

Postoperative Period

Postoperative Management

- Patients should be advised that they had a general anesthesia.
- They are not to drive or make major decisions following the procedure.
- As a result, the surgeon should *not* discuss future treatment plans with the patient on the day of the DISE.
- They may return to normal activity on post-procedure day 1.

Complications

- Minor bleeding from scope trauma
- Loss of airway
  - NOTE: This should be a *never* event. Airway management during the procedure is a joint effort between the otolaryngologist and anesthesia team. In the event of obstructive apneas resulting in significant desaturation, jaw thrust should be performed by the anesthesia provider, with endosopic visualization of the airway until reoxygenation is complete. In the event of prolonged central apnea, mask ventilation and, if required, endotracheal intubation should be performed.

Alternative Management Plan

- Forego DISE and rely on awake clinical examination to develop operative plan.
  - Again, only Inspire hypoglossal nerve stimulator requires a priori DISE evaluation for candidacy determination.

Discussion

Evidence-Based Medicine Question

Does DISE resemble natural sleep?

Two studies have examined stage of sleep during DISE. One study used midazolam and demonstrated the electroencephalogram tracings similar to N1 and N2 sleep; the other study used propofol and illustrated largely N2 and N3 sleep.

Editorial Comment

Successful implementation of second-line therapy for OSA is critically dependent upon accurate determination of the anatomic and physiologic phenotype of each patient. Proper phenotyping of the muscular and skeletal anatomy of the upper airway allows for integration of the individual anatomy into a personalized medical, surgical, or multimodality treatment plan. DISE is simply one common, widespread, low-risk method available to facilitate this treatment planning. With proper technique and clinical application, DISE provides the sleep surgery specialist with key information on the anatomic structures, locations, and patterns of collapse under conditions that more closely resemble sleep rather than wakefulness. Further studies are needed to standardize technique and descriptive staging systems as well as to demonstrate whether DISE changes OSA outcomes.

Review questions

1. If bispectral index (BIS) monitoring is used, what is the target level?

   a. 10 to 30

   b. 30 to 50

   c. **50** to **70**

   d. 70 to 90

2. Which medication(s) should be given preoperatively?

   a. Glycopyrrolate

b. Oxymetazoline and cetacaine spray

c. **Glycopyrrolate and oxymetazoline**

d. Glycopyrrolate, oxymetazoline, and Unasyn

3. To determine benefit of oral appliance, the mandible should be advanced what percentage of maximal range?

a. 20%

b. 40%

c. **60%**

d. 100%

Uvulopalatopharyngoplasty and Related Modifications (Traditional Uvulopalatopharyngoplasty, Uvulopalatal Flap, Anterior Palatoplasty)

David Kent, and Amy Schell

Introduction

Obstructive sleep apnea (OSA) is a dynamic collapse and obstruction of the upper airway occurring in sleep due to decreased upper airway neuromuscular activity. At least 13% of men and 6% of women aged 30 to 70 years in the United States have moderate-to-severe OSA (apnea-hypopnea index [AHI] ≥ 15/hour), and at least half of this population are likely to be intolerant of the first-line therapy, continuous positive airway pressure (CPAP).[1-3]

The traditional uvulopalatopharyngoplasty (UPPP) was developed by Fujita in 1981.[4] Despite numerous modifications, it remains the most commonly performed surgical intervention for snoring and OSA. Between 2000 and 2006 UPPP and its related modifications accounted for more than 80% of the surgeries performed for OSA in the United States.[5] UPPP has been demonstrated to significantly improve subjective OSA outcome measures and AHI in appropriately selected CPAP-intolerant patients.[6] Several UPPP modifications have been developed to target palatal anatomy variations and clinical scenarios, including the uvulopalatal flap (UPF) and anterior palatoplasty (AP).[7] More advanced palatal surgery modifications are discussed separately in Chapter 54.

Key Operative Learning Points

- Careful patient selection and anatomic phenotyping are key to successful functional outcomes with UPPP, UPF, and AP.
- The patients most likely to benefit from a UPPP as primary therapy are those with a type I or II Friedman clinical stage.
- The UPF should be reserved for the patient with a thin and relatively atrophic soft palate.
- AP may be performed under local or general anesthesia.
- Transient velopharyngeal insufficiency is common and generally resolves spontaneously.
- Consider drug-induced sleep endoscopy (DISE) to help to guide surgical decision making.
- Many OSA patients benefit from a combination of surgical and medical therapies; upper airway surgery can improve CPAP treatment results and adherence.

Preoperative Period

Patients with sleep-disordered breathing may present to the otolaryngologist with a wide variety of subjective and objective concerns, including: loud, disruptive snoring; daytime hypersomnolence; poor sleep quality; impaired quality of life; increased risk of motor vehicle accidents; and cardiovascular disease. As part of the initial evaluation, OSA patients undergo overnight diagnostic sleep testing either in the home via home sleep test (HST) or via in-lab polysomnography (PSG) to document OSA severity and to differentiate OSA from central sleep apnea, sleep-related hypoventilation, nonapneic snoring, or other sleep medicine pathology.

Patients diagnosed with moderate-to-severe OSA should undergo a trial of CPAP before surgical management in considered. A large body of evidence has shown that CPAP is highly effective in reducing OSA-associated morbidity and mortality. However, approximately 50% of patients are unable to adhere to long-term therapy. Each patient's experience with CPAP and the reasons for intolerance should be carefully reviewed for potential targeted intervention. Alternative positive pressure modalities may be helpful for patients having trouble

tolerating CPAP. For others with complaints of nasal obstruction, nasal airway surgery may decrease the amount of positive airway pressure required, improving acceptance of CPAP.

Nonsurgical interventions for OSA include weight loss, behavioral modification, mandibular repositioning devices (MRDs) and other oral appliances, or positional therapy aids.[8] Positional therapy aids assist patients with maintaining lateral positioning during sleep and are most effective for patients with a clinically significant reduction in AHI in the lateral position. An MRD can be an effective alternative to CPAP in select patients and is an acceptable initial alternative to trial in patients with mild OSA. However, approximately half of patients will have persistent subjective symptoms or residual OSA during repeat testing. Patients should also be counseled that MRDs may eventually cause undesired occlusal changes.

The heterogeneous clinical presentations of snoring and OSA are further complicated by the large variety of pharyngeal collapse patterns. Comprehensive awake physical examination remains the most used tool in the diagnostic workup. Patients with significant skeletal abnormalities may be best served by maxillomandibular interventions. The patients most likely to benefit from a UPPP are those with a type I Friedman clinical stage (3 to 4+ tonsils, modified Mallampati score I or II) and a body mass index (BMI) less than 40.[9] Flexible nasopharyngoscopy should be used to visualize the base of the tongue and epiglottis. Because multilevel collapse is common and many patients do not have a clear site and pattern of pharyngeal obstruction during awake examination, DISE may provide a useful diagnostic tool to better characterize that anatomic location and pattern of obstruction and to better predict appropriate surgical therapy (see Chapter 52). CPAP-intolerant patients with multiple sites of upper airway obstruction may require combination medical and surgical therapy, multiple surgical procedures, or craniofacial modification.

UPPP is the most aggressive and excisional of the procedures described herein, followed by UPF and then AP. Although UPPP may benefit patients with more severe OSA, current evidence supports reserving UPF and AP for patients with mild-to-moderate OSA or nonapneic palatal snoring. UPF is most likely to be successful when used in patients with a thin, relatively atrophic soft palate with a significant

vertical length. Folding the posterior, vertical component anteriorly alleviates airway obstruction. However, this maneuver can create significant anterior soft palate bulk that is bothersome to the patient with a more robust soft palate. AP advances the entire soft palate structure anteriorly and is likely most effective in the patient with a shorter vertical palatal length. It can be performed under local anesthesia in appropriate patients.

All patients undergoing UPPP, UPF, or AP should be counseled that transient hypernasal speech or nasal regurgitation due to velopharyngeal insufficiency is not uncommon in the immediate postoperative period and almost always resolves spontaneously. Patients with significant OSA should also be counseled that postoperative sleep testing is recommended to assess for residual OSA, regardless of residual snoring symptoms. Those with significant residual OSA may find that surgery has improved their results and adherence with CPAP or MRD therapy.

History

1. History of present illness
    a. Nighttime symptoms
        1) Snoring (intensity, fluctuation with changes in weight/body position)
        2) Witnessed apneas
        3) Sleep maintenance insomnia or nocturia
    b. Daytime symptoms
        1) Sleepiness or fatigue
        2) Morning headaches
        3) Neurocognitive symptoms (e.g., memory loss, concentration difficulty, mood disturbance
    c. Nasal obstruction (daytime, nighttime, positional)
    d. Previous evaluation and diagnosis
        1) Prior diagnostic PSG or HST studies
        2) Prior CPAP titration studies

e. Comorbid sleep disorders

1) Other sleep-related breathing disorders (e.g., central sleep apnea, sleep-related hypoventilation due to pulmonary disease)

2) Movement disorders (e.g., restless leg syndrome, periodic limb movement disorder)

3) Circadian rhythm disorders

4) Insomnias

5) Parasomnias

f. Prior treatment

1) CPAP

2) MRD

3) Positional therapy

4) Weight loss

2. Past medical history

a. Hypertension, cardiovascular disease, stroke, functional status

b. Endocrine disorders (e.g., diabetes, hypothyroidism)

c. Prior head and neck surgery (for OSA or other indications)

d. Prior head and neck radiation exposure

e. History of cleft palate or velopharyngeal insufficiency

3. Family history of OSA

4. Medications

a. Anticoagulants

b. Alcohol

c. Hypnotics

d. Narcotics

e. Allergies to antibiotics

5. Smoking history

6. Mental and social status

a. Sleep-related quality of life

b. Impact on bed partner

c. Employment status (high-risk employment requiring optimal alertness)

Physical Examination

1. Body habitus, including BMI
2. Anterior rhinoscopy
   a. Septal deviation
   b. Turbinate hypertrophy
   c. Other sources of nasal airway obstruction (e.g., external/internal nasal valve compromise, nasal polyposis)
3. Facial skeleton evaluation
   a. Mandibular hypoplasia
   b. Maxillary deficiency
4. Neck evaluation
   a. Thyromental angle and hyoid position
   b. Neck circumference
5. Oral cavity and oropharyngeal evaluation
   a. Dentition
   b. Occlusion
   c. Palate width, thickness, and vertical length
   d. Modified Mallampati score
   e. Tonsil size, evidence of prior tonsillectomy or other upper airway surgery
   f. Lateral oropharyngeal wall (palatopharyngeus) component
6. Flexible nasopharyngoscopy (awake supine or DISE)
   a. Structural nasal airway obstruction

b. Soft palate sagittal configuration (oblique vs. vertical) and length

c. Tonsil and lateral oropharyngeal wall component

d. Degree and pattern of collapse of the base of the tongue including lingual tonsillar hypertrophy

e. Epiglottic collapse or other laryngeal pathology

f. Impact of mandibular repositioning on retropalatal space

Imaging and Testing

1. Have prior PSG data available for review.

2. Consider DISE if the site(s) of obstruction are questionable.

Indications

1. OSA without significant central sleep apnea in the setting of CPAP intolerance

2. Upper airway resistance syndrome (significant sleep-disordered breathing symptoms and respiratory-related arousals on PSG in the absence of elevated AHI)

3. Selected cases of nonapneic snoring

Contraindications

1. Medically unstable

2. History of velopharyngeal insufficiency

3. History of cleft palate

4. History of pharyngeal malignancy or radiation therapy

Preoperative Preparation

1. Discontinue anticoagulant drugs if possible.

2. Other routine preparation for general anesthesia

Operative Period

Anesthesia

- Nasotracheal intubation is not required.
- An oral RAE or armored endotracheal tube may help to reduce compression of the endotracheal tube by a McIvor mouth gag but is not required.
- The surgeon should always stand by during induction of anesthesia because OSA patients are frequently difficult to intubate.

Positioning

- Rotate the table either 90 or 180 degrees to allow the surgeon adequate working space at the head of the bed.
- The patient is placed in the supine position with a shoulder roll for neck extension.
- AP under local anesthesia may be completed with the patient sitting upright in the sniffing position.

Perioperative Antibiotic Prophylaxis

- Clean contaminated surgery
- Antibiotics are administered during induction of anesthesia and continued for 24 hours.
- Choices
  - Penicillin and β-lactamase (e.g., ampicillin/sulbactam)
  - Clindamycin
  - Amoxicillin-clavulanate
  - Cephalosporin and metronidazole

Monitoring

- Routine anesthesia monitoring
- Patient should remain paralyzed during surgery to facilitate mandibular relaxation and optimal oropharyngeal exposure

Instruments and Equipment to Have Available

- Monopolar and bipolar or suction electrocautery with protected tips
- Standard tonsillectomy set

Key Anatomic Landmarks

- Palate
  - Junction of the hard palate and soft palate
  - Genu of the soft palate (levator muscle sling)
  - Velum
  - Uvula
- Lateral pharyngeal wall
  - Palatine tonsils
  - Superior constrictor muscle
  - Palatoglossus and palatopharyngeus muscles

Prerequisite Skills

- Tonsillectomy

Surgical Technique

- UPPP
  - Remove the tonsils bilaterally, being careful not to violate the superior constrictor muscle and working to preserve the palatoglossus (anterior tonsillar pillar) and palatopharyngeus

(posterior tonsillar pillar) muscles, as well as their overlying mucosa.

- Adenoidectomy is not recommended to be simultaneously performed with traditional UPPP, due to increased risk for pharyngeal stenosis.
- Local injection along the intended lines of dissection with 1% lidocaine with 1:100,000 epinephrine reduces intraoperative bleeding and immediate postoperative pain.
- Begin dissection at the anterior tonsillar pillar and proceed superiorly in the sagittal plane to the intended coronal incision, approximately 8 to 10 mm anterior to the posterior edge of the soft palate.
  - Cold dissection and hemostasis using conservative bipolar electrocautery may reduce thermal injury and subsequent postoperative pain.
  - The coronal dissection line should be posterior to the natural genu of the soft palate to decrease the risk of velopharyngeal insufficiency.
- A 90-degree angle between the coronal and sagittal incisions is favorable because a rounded transition may result in a purse-string contracture of the resulting scar (Fig. 53.1).
- Complete the incisions through the palate, resecting the posterior section of the palate and the uvula.
- Suture the anterior and posterior tonsillar pillars bilaterally to close the tonsillar fossa.
  - Vicryl or Monocryl sutures are favored for their durability due to the significant muscle forces generated during swallowing.
- Approximate and suture the coronal incision mucosa in a similar fashion (Fig. 53.2).

- UPF
  - Remove the tonsils bilaterally, being careful not to violate the superior constrictor muscle and working to preserve the palatoglossus (anterior tonsillar pillar) and palatopharyngeus (posterior tonsillar pillar) muscles, as well as their overlying mucosa.

- Gently fold the distal tip of the muscular uvula anteriorly to identify the anterior-most extent of oropharyngeal mucosa dissection; note the natural S-shaped curve of the posterior palatal edge as it courses across the oropharyngeal mucosa.
  - Applying excessive tension to the folded palate during incision planning increases the risk of postoperative wound dehiscence.
- Generous injection in the intended areas of dissection with 1% lidocaine with 1:100,000 epinephrine reduces intraoperative bleeding and immediate postoperative pain.

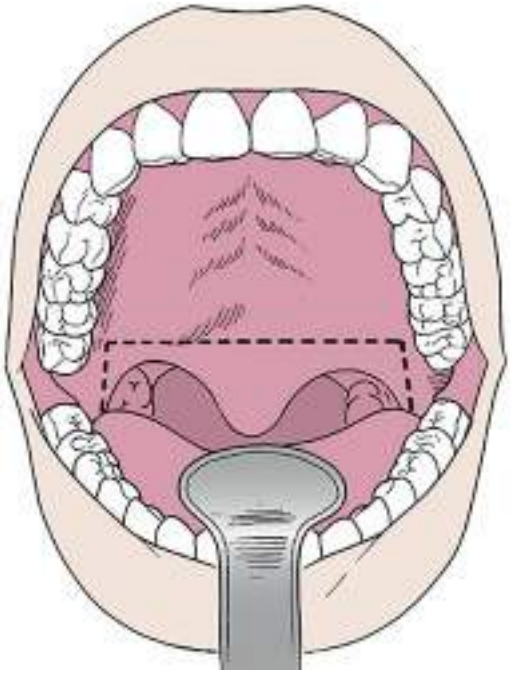

FIG. 53.1 Proposed incision line for traditional uvulopalatopharyngoplasty posterior to the soft palate genu.

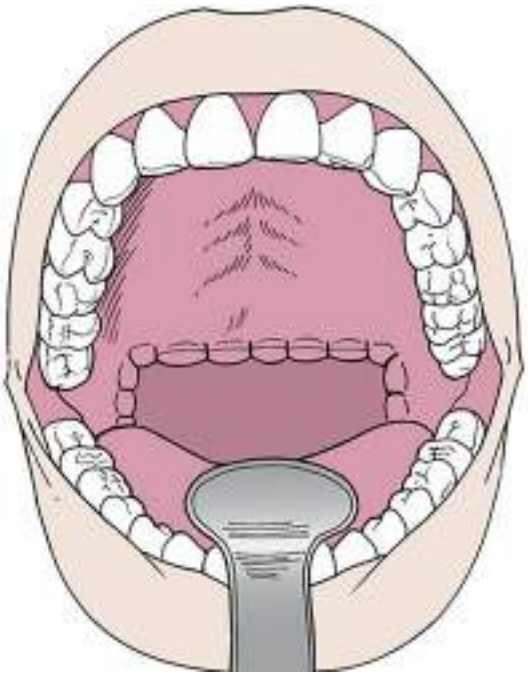

FIG. 53.2 Maintain a right angle between the coronal and sagittal closure to optimize lateral oropharyngeal dimension during wound healing.

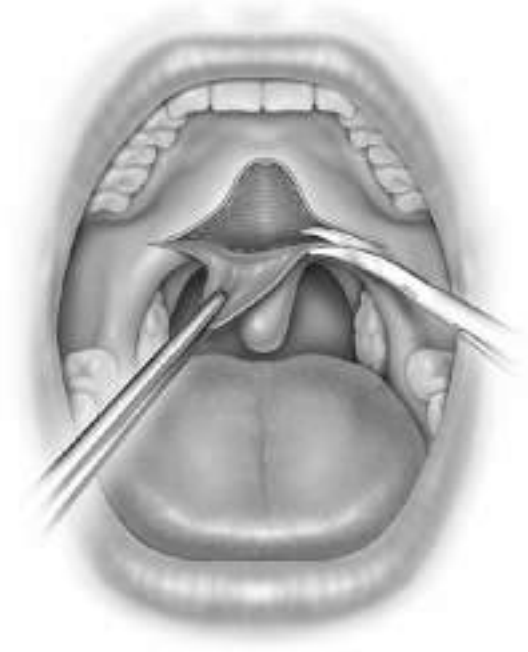

FIG. 53.3 Elevation of the uvulopalatal flap from the underlying palatal muscle. From Friedman M [ed]: *Sleep Apnea and Snoring: Surgical and Non-Surgical Therapy,* 1st ed. Philadelphia, PA: Elsevier;

2009, p 208 [Fig. 53.2].

- Allow several minutes for epinephrine to achieve maximal effect.

- Incise the oropharyngeal mucosa along the planned lines of incision from the anterior-most point of dissection to the posterior edge of the soft palate bilaterally.
  - Cold dissection and hemostasis using conservative bipolar electrocautery help to minimize postoperative pain.

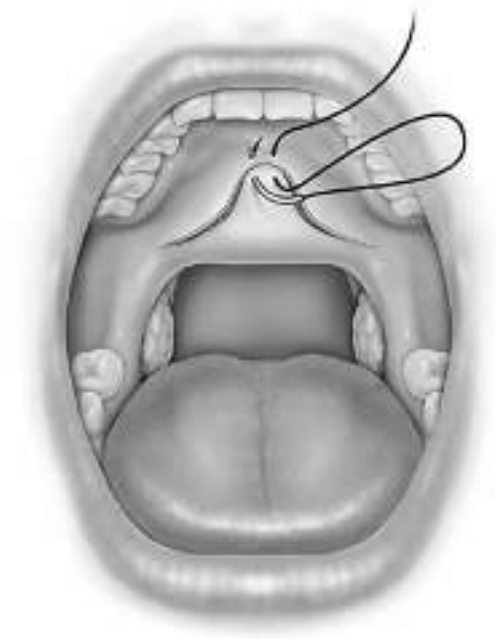

FIG. 53.4 Suturing of the uvulopalatal flap after folding the dorsal mucosa and flap anteriorly. From Friedman M [ed]: *Sleep Apnea and Snoring: Surgical and Non-Surgical Therapy,* 1st ed. Philadelphia, PA: Elsevier, 2009; p 209 [Fig. 53.3].

- Beginning at the anterior-most point of dissection, create a stellate-shaped mucosal defect by resecting the oropharyngeal mucosa from the underlying palatal musculature posteriorly until the posterior edge of the soft palate and the distal tip of the muscular uvula are exposed (Fig. 53.3).
  - Include redundant uvular mucosa distal to the musculus uvulae in the resection.

- Fold the distal tip of the uvula anteriorly and suture the nasopharyngeal mucosa of the uvular tip to the anterior-most point of dissection.
  - Vicryl or Monocryl sutures are favored for their durability due to the significant muscle forces generated during swallowing.
- Approximate and suture the remaining lines of dissection (Figs. 53.4 and 53.5).

- AP
  - Remove the tonsils bilaterally, being careful not to violate the superior constrictor muscle and working to preserve the palatoglossus (anterior tonsillar pillar) and palatopharyngeus (posterior tonsillar pillar) muscles, as well as their overlying mucosa.
    - Consider local anesthesia only if the patient has had a prior tonsillectomy or if the tonsils are very small (1+).
  - Generous injection of the intended dissection areas with 1% lidocaine with 1:100,000 epinephrine reduces procedural bleeding and pain.
    - Allow several minutes for epinephrine to achieve maximal effect.
  - A uvulectomy or partial uvulectomy may be performed, depending on the individual patient's anatomy.
    - Cold dissection and hemostasis using conservative bipolar electrocautery help to minimize postoperative pain.
  - If significant mucosal webbing between the posterior tonsillar pillars and the posterior pharyngeal wall is present, bilateral parauvular incisions in the sagittal plane may reduce tethering of the soft palate after advancement.

FIG. 53.5 Postoperative appearance of the uvulopalatal flap.

- Excise an approximately 1 × 4 cm^2 rectangle of mucosa from the soft palate immediately posterior to the insertion into the hard palate.
- After obtaining hemostasis, approximate and suture the anterior and posterior wound edges.
  - Vicryl or Monocryl sutures are favored for their durability due to the significant muscle forces generated during swallowing.

Common Errors in Technique

- UPPP
  - Rounding off the intersection of the coronal and sagittal palatal incisions may result in a purse-string contracture of the palatal scar and further aggravation of OSA.
  - Resection of soft palate tissue anterior to the natural palatal genu increases the risk of postoperative velopharyngeal insufficiency.
- UPF
  - Application in patients with robust palatal musculature may result in irritating palatal bulk postoperatively.
  - Excessive tension during wound closure increases the risk of wound

dehiscence.

- AP
  - Failure to incise significant posterior tonsillar pillar webbing may reduce the effectiveness of palatal advancement.

Postoperative Period

- Antibiotics for 24 hours
- Patients with moderate-to-severe OSA undergoing upper airway surgery are often monitored overnight for airway observation and pulse oximetry.
- Patients using CPAP or MRD at the time of surgery maybe able to wear the medical device in the postoperative period to reduce perioperative respiratory risk.
- Diet
  - A soft diet for 10 to 14 days after surgery is recommended.
  - Monitor for adequate nutritional and fluid intake in the immediate postoperative period before hospital discharge.
- Monitor for adequate pain control using oral narcotic and acetaminophen medications before hospital discharge.
- Monitor viability of wound closure.

Complications

- Edema and airway obstruction
  - Monitor patients with moderate-to-severe OSA undergoing upper airway surgery in the immediate postoperative period.
- Narcotic respiratory suppression
  - Titrate narcotic therapy during inpatient observation to the minimal dose required for adequate pain control.
- Dehydration and poor nutritional intake

    - Monitor for adequate oral intake during inpatient observation and adequately control pain.
- UPF wound dehiscence
    - Débride UPF dehiscence to avoid further damage and airway obstruction.
- Velopharyngeal insufficiency/nasopharyngeal regurgitation
    - Typically self-limited but may benefit from speech or swallowing therapy in rare instances
- Nasopharyngeal stenosis
    - Rare but potentially debilitating complication of traditional UPPP. Best approach is *prevention* by avoiding concomitant adenoidectomy and by maximal mucosal preservation of the posterior pillars

Discussion

Evidence-Based Medicine Question

Is UPPP effective (AHI <20 and decreased 50% from preoperatively) in isolation in patients with a Friedman clinical stage III examination?

A 2002 study of 134 patients undergoing UPPP found that Friedman clinical stage I patients had a surgical success rate of 80.6%, whereas stage II patients had a surgical success rate of 37.9% and stage III patients had a success rate of only 8.1%.[8]

Editorial Comment

UPPP has served as the cornerstone of surgical therapy for patients who fail medical treatment for OSA since the 1980s. UPPP and related modifications have substantial data on improving OSA symptoms and quality of life measures, as well as reducing the severity of the disease and associated health risks. A complete sleep medicine evaluation, thorough examination of the upper airway with proper patient selection and phenotyping, and meticulous surgical technique are all keys to successful implementation of UPPP. UPPP technique continues to evolve

with increased focus on reconstruction (rather than excision) and modifications that can be tailored to the anatomy of each individual patient to further improve results and reduce morbidity.

Review Questions

1. What is a component of the traditional UPPP?

   a. Adenoidectomy

   b. Excision of the posterior tonsillar pillars bilaterally

   c. Avoiding suture closure of the anterior and posterior tonsillar pillars

   d. **Join the coronal and sagittal incisions at a 90-degree angle**

2. UPF is most appropriate for what anatomic findings?

   a. Thick, robust soft palate

   b. Modified Mallampati type IV

   c. **A thin soft palate with little muscle bulk**

   d. Short vertical soft palate length

3. Which patient is the best candidate for anterior palatoplasty?

   a. **A 74-year-old male with AHI-7, modified Mallampati class II, loud snoring, associated daytime sleepiness, failure of medical therapy, and BMI of 26**

   b. A 34-year-old female with AHI-29, CPAP intolerance, modified Mallampati class III, and BMI of 37

   c. A 62-year-old male with AHI-14, failure of medical device therapy, a low and anteriorly displaced hyoid, modified Mallampati class IV, and BMI of 23

   d. A 19-year-old female with AHI-21, central apnea index of 15, daytime sleepiness, idiopathic pulmonary hypertension, and BMI of 25

Advanced Palatal Surgery

Expansion Sphincter Pharyngoplasty & Transpalatal Advancement Pharyngoplasty

Raj C. Dedhia, and Ryan Soose

Abstract

Obstructive sleep apnea (OSA) is a state-dependent phenomenon in which the pharyngolarynx undergoes repetitive collapse. Retropalatal obstruction is often the primary site of sleep-disordered breathing. Traditional uvulopalatopharyngoplasty (UPPP) as described by Fujita has important potential limitations including non-physiologic modification, residual proximal palatal obstruction, and risk of nasopharyngeal stenosis and velopharyngeal insufficiency. The two techniques discussed in this chapter, expansion sphincter pharyngoplasty and transpalatal advancement, represent advanced palatal surgery modifications that employ more reconstructive (rather than excisional) methods to improve effectiveness and reduce morbidity over traditional UPPP. Expansion sphincter pharyngoplasty (ESP) is the reverse of sphincter pharyngoplasty, which is used to address velopharyngeal incompetence. In ESP, the palatopharyngeus (posterior pillar) is transected inferiorly and the muscle pedicle is rotated anteriorly, superior, and laterally to enlarge the lateral velopharyngeal dimension. While it bears similarity to UPPP in its effect on the distal palate, it avoids potential untoward consequences of UPPP such as nasopharyngeal stenosis and globus sensation (at least in part by maximal mucosal and uvular preservation). Transpalatal

advancement (TPA) is designed to address proximal palatal obstruction, especially for those patients with a vertically oriented soft palate and maxillary deficiency. TPA removes a segment of hard palate and advances the soft palate anteriorly to increase the distance between the posterior nasal spine and posterior pharyngeal wall.

Keywords

expansion pharyngoplasty; obstructive sleep apnea (OSA); palatal surgery; transpalatal advancement pharyngoplasty; uvulopalatopharyngoplasty

Introduction

Obstructive sleep apnea (OSA) is a state-dependent phenomenon in which the pharyngolarynx undergoes repetitive collapse. Retropalatal obstruction is often the primary site of sleep-disordered breathing. Traditional uvulopalatopharyngoplasty (UPPP) as described by Fujita has important potential limitations, including nonphysiologic modification, residual proximal palatal obstruction, and risk of nasopharyngeal stenosis and velopharyngeal insufficiency. The two techniques discussed in this chapter, expansion sphincter pharyngoplasty (ESP) and transpalatal advancement (TPA), represent advanced palatal surgery modifications that use more reconstructive (rather than excisional) methods to improve effectiveness and reduce morbidity over traditional UPPP.[1]

ESP is the reverse of sphincter pharyngoplasty, which is used to address velopharyngeal incompetence. In ESP, the palatopharyngeus (posterior pillar) is transected inferiorly and the muscle pedicle is rotated anteriorly, superior, and laterally to enlarge the lateral velopharyngeal dimension. Although it bears similarity to UPPP in its effect on the distal palate, it avoids potential untoward consequences of UPPP, such as nasopharyngeal stenosis and globus sensation (at least in part by maximal mucosal and uvular preservation).

TPA is designed to address proximal palatal obstruction, especially for those patients with a vertically oriented soft palate and maxillary deficiency (Fig. 54.1). TPA removes a segment of hard palate and

advances the soft palate anteriorly to increase the distance between the posterior nasal spine and posterior pharyngeal wall.

Key Operative Learning Points

- Anatomic phenotyping with drug-induced sedation endoscopy (DISE) or other imaging or endoscopic techniques is essential for proper patient and procedure selection.

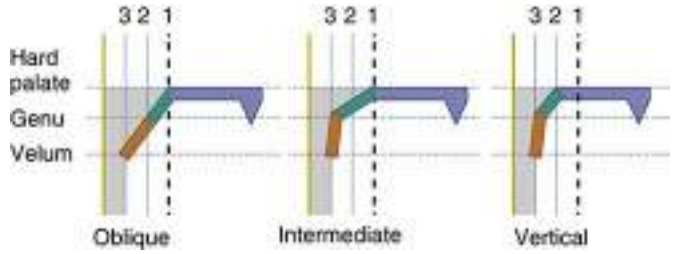

FIG. 54.1 Sagittal configuration of the soft palate.

Key components include the posterior aspect of the hard palate, the insertion point of the levator veli palatini ("genu"), and velum. The size, shape, and position of these anatomic structures are integrated into palatal surgery decision making. Reproduced with permission from Woodson BT, Sitton M, Jacobowitz O: Expansion sphincter pharyngoplasty and palatal advancement pharyngoplasty: airway evaluation and surgical techniques. *Oper Tech Otolaryngol* 23:3-10, 2012.

- ESP is ideally suited for a more obliquely or horizontally oriented soft palate with a large lateral oropharyngeal wall component and a circumferential pattern of collapse at the velum.
- TPA is ideally suited for a more vertically oriented soft palate with maxillary retrusion and anterior-posterior pattern of soft palate collapse at the genu and velum.
- Maximal mucosal preservation is key to preserving the largest potential velopharyngeal airway, as well as to maintaining the physiologic function of the palate and reducing morbidity.
- To minimize flap dehiscence in ESP, ensure that the suspension suture

passed through the muscle belly contains fascia and that the anchor suture passed near the hamulus contains aponeurosis of the tensor tendon and/or buccopharyngeal raphe.

- To minimize risk of oronasal fistula in TPA, include hearty palatal aponeurosis in the suture around the bony keel segment.

Preoperative Period

A comprehensive sleep medicine history is the critical first step before considering surgical therapy for any OSA patient. Approximately one-third of OSA patients have been reported to have another primary sleep disorder or sleep-modulating medical comorbidities, such as psychophysiologic insomnia, chronic pain, shift work sleep disorder, restless legs syndrome, or narcolepsy. Medications that negatively affect control of breathing (e.g., opiates or benzodiazepines), or alter sleep architecture or continuity directly (e.g., antidepressants), must also be taken in account in evaluating a patient's candidacy.

Because surgery is most commonly a second-line or alternative treatment strategy, it is also important to thoroughly evaluate and exhaust first-line medical therapy options. For patients who are unable to tolerate or achieve benefit with positive airway pressure (PAP) therapy, a detailed analysis of the PAP data download software and troubleshooting of specific PAP side effects remain important strategies prior to surgery. Many of the common mask-related, pressure-related, and psychosocial side effects of PAP can be overcome with therapy or equipment adjustments, behavioral modifications, positional therapy, or other conservative interventions. Furthermore, in patients with symptomatic nasal obstruction or chronic sinonasal disease, medical or surgical therapy of the nose can provide a pathway to improved adherence and results with PAP therapy (see Chapter 95; Chapter 97).

For patients who have exhausted PAP, oral appliance, positional therapy, and/or weight loss and require an effective option for disease reduction and symptomatic improvement, successful surgical therapy requires effective phenotyping of the patient's anatomy and sleep-disordered breathing pathophysiology. A standardized anatomic and physiologic staging system does not exist; however, physical examination, upper airway endoscopy, and imaging techniques are

available to describe the upper airway anatomy and tailor a surgical treatment plan appropriately.

History

1. History of present illness
    a. Sleep-related symptoms and impact on quality of life, including snoring, witnessed apnea, gasping, choking, nocturnal awakenings, nocturia, morning headaches, daytime sleepiness, and cognitive dysfunction.
    b. Timing, duration, and onset of symptoms. Severe OSA that has already been present and untreated for many years may have implications on cardiovascular comorbidities. OSA symptom onset that coincides with specific events, such as a nasal injury, jaw surgery, weight gain, cerebrovascular event, or change in sleep position due to musculoskeletal problem, may have therapeutic implications.
    c. Presence of other sleep disorders, such as insomnia and restless legs syndrome, that may confound the assessment of OSA outcome measures. Successful management of the patient will often require treatment of both the OSA and other sleep pathology. A comprehensive sleep medicine history is essential.
    d. Prior OSA treatment history, both medical and surgical, including detailed information on side effects, treatment response, and adherence with PAP and other medical devices. Excellent PAP adherence in the setting of persistent daytime sleepiness, for example, is suggestive of other non-OSA etiology of sleepiness, and surgery may not be indicated.
2. Sleep laboratory testing
    a. Type of study: home sleep apnea test (HST) versus in-lab polysomnography (PSG)
    b. Sleep efficiency: Poor sleep efficiency may raise concern for unreliable sleep study results or the possibility of comorbid insomnia.
    c. Sleep architecture: Abnormal sleep architecture may be caused by

OSA, as well as by medications (e.g., antidepressants, steroids) or other sleep pathology.

d. Sleep continuity: An elevated arousal index or abnormal sleep continuity can also be caused by OSA or by chronic pain, medications, or other sleep or medical pathology.

e. Respiratory analysis: snoring, apnea-hypopnea index (AHI), respiratory disturbance index (RDI), and oxygen saturations should be assessed to determine the severity of OSA. The presence of central sleep apnea, Cheyne-Stokes respiration, or other sleep-related hypoventilation or hypoxemia conditions (e.g., due to cardiopulmonary disease) should be ruled out because surgery may be contraindicated in many such conditions.

f. Signs of other sleep pathology: PSG should evaluate for periodic limb movement disorder (PLMD), nocturnal seizure activity, rapid-eye movement (REM)-behavior disorder (RBD), or other nonrespiratory sleep disorders.

3. Past medical history

a. Comorbidities associated with OSA (hypertension, diabetes, myocardial infarction, atrial fibrillation, cerebrovascular event, depression, gastroesophageal reflux disease, erectile dysfunction)

b. Chronic back or neck pain, fibromyalgia, or other pain syndromes that may negatively impact sleep

c. Cardiopulmonary disease (e.g., chronic obstructive pulmonary disease, valvular heart disease, or congestive heart failure) that may complicate control of breathing at night and introduce additional respiratory pathology beyond OSA

d. History of dysphagia

e. History of neuromuscular disease

4. Past surgical history

a. Prior sinonasal surgery

b. Prior pharyngeal or skeletal OSA surgery

c. Prior bariatric surgery

5. Medications

a. Anticoagulants

b. Opiate pain medication, benzodiazepines, or other medications that can alter nocturnal control of breathing

c. Selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), lithium, or other neuropsychiatric medication that can independently alter sleep architecture and continuity

d. Stimulant therapy (e.g., modafinil or methamphetamines), which may confound the assessment of daytime sleepiness

6. Family history

a. Strong family history of OSA may provide insight in the anatomic/structural vulnerability.

7. Social history

a. Occupation

1) OSA in truck drivers, airline pilots, railroad engineers, and other occupations involving public safety risk has additional implications on treatment and report of outcomes.

2) Shift workers may have residual sleep-related symptoms due to their circadian rhythm disturbance even after otherwise successful OSA treatment.

b. Alcohol: Evening alcohol use has been correlated with increased obstructive respiratory events.

c. Tobacco: Smoking has been shown to independently increase the risk of moderate-to-severe OSA, as well as increase sinonasal and pulmonary disease.

d. Total sleep duration: Behaviorally induced insufficient sleep is one of the most common causes of daytime sleepiness and may confound the assessment of OSA treatment outcomes. Sleep deprivation has also been shown to exacerbate OSA.

Physical Examination

1. Anterior rhinoscopy

a. Acquired nasal deformity, septal deviation, turbinate hypertrophy, rhinitis, nasal polyps, and nasal valve pathology may increase upper airway resistance and directly contribute to sleep-disordered breathing.

b. Increased nasal resistance may also increase negative intraluminal pressure in the pharynx and increase the fraction of maladaptive mouth breathing, further contributing to OSA pathophysiology.

c. Nasal surgery to lower nasal resistance should be considered either in conjunction with or prior to pharyngeal surgery in most cases.

2. Facial skeleton

a. Significant maxillary or mandibular hypoplasia may require orthodontic or orthognathic surgical correction prior to consideration of pharyngeal surgery.

b. Occlusion

1) Angle classification

2) Degree of overjet and overbite

3. Oral cavity

a. Tongue ridging or scalloping suggests relative macroglossia for the available mandibular size.

b. Quality and quantity of dentition have implications on the availability of adjunctive custom mandibular repositioning device (oral appliance) in the treatment plan.

c. Height and width of the hard palate. A narrow high-arched soft palate may increase the difficulty of soft tissue work on the soft palate and may negatively affect treatment outcomes.

d. The presence of large palatal tori may reduce operative exposure and make palatal surgery more technically challenging.

4. Oropharynx[2]

a. Sagittal configuration of the soft palate (see Fig. 54.1)

1) ESP is ideally suited for a more obliquely oriented soft palate with an open maxilla and open genu.

2) TPA is ideally suited for a more vertically oriented soft palate

with anteroposterior collapse pattern and maxillary retrusion.

b. Soft palate length

c. Modified Mallampati (MM) or Friedman Tongue Position (FTP). Low (stage I or II) MM or FTP scores have been associated with more favorable outcomes with isolated palate surgery.

d. Tonsil size. Larger (3+ or 4+) tonsil sizes have been correlated with improved surgical outcomes.

e. Lateral oropharyngeal wall component. The size and position of the posterior tonsillar pillars (palatopharyngeus muscles) have treatment implications. ESP specifically targets and repositions the lateral oropharyngeal wall collapse.

f. Uvula size and configuration

5. Neck

a. Neck circumference

b. Hyoid bone position: A low or inferiorly positioned hyoid bone suggests a longer pharyngeal airway and greater risk of hypopharyngeal collapse that will likely require additional treatment beyond palatal or oropharyngeal surgery alone.

6. General health

a. Blood pressure

b. Cardiovascular

c. Respiratory

d. Mental

7. Drug-induced sleep endoscopy (DISE)[2]

a. The length, width, and depth of the soft palate space are documented. Specifically, endoscopy assesses the position of the hard palate, the levator muscle sling (genu), the velum, and the lateral velopharyngeal walls.

b. ESP is more conducive to the complete concentric pattern of collapse with an oblique soft palate and obstruction more distally at the velum due to large lateral velopharyngeal wall components (Fig. 54.2).

c. TPA is more conducive to the anteroposterior pattern of collapse with maxillary constriction, more proximal obstruction at the genu, and a long vertical segment of soft palate.

Imaging

1. Chest radiography

   a. Preoperative screening

   b. Evaluate for cardiopulmonary disease

   c. Rule out immobility of the hemidiaphragm

2. Facial skeletal imaging may be indicated in select cases preoperatively particularly in cases of prior surgery of the mandible, suspected craniofacial abnormalities, or signs of maxillomandibular deficiency. Imaging studies may include:

   a. Lateral cephalometric radiograph

   b. Panorex

   c. Computed tomography (CT) three-dimensional imaging

3. Sinonasal imaging may be indicated in patients with suspected chronic sinonasal disease when simultaneous or staged nasal surgery is being considered with the palatal surgery.

4. Modified barium swallow study may be indicated prior to ESP or TPA in patients with baseline dysphagia or velopharyngeal insufficiency symptoms, particularly in those with swallowing problems after prior pharyngeal surgery.

Indications

1. OSA patients who are nonaccepting or intolerant or have inadequate adherence with PAP, oral appliance, weight loss, or other first-line medical device options with:

   a. Moderate-to-severe OSA (AHI >15), or

   b. Mild OSA (AHI 5 to 15) with medical comorbidities or excessive daytime sleepiness or other sleep-related symptoms impairing

quality of life

2. Salvage therapy for OSA patients who have failed traditional UPPP or other prior upper airway surgery and have modifiable residual anatomic abnormalities

3. Anatomically, ESP is specifically indicated for patients with a more obliquely oriented soft palate with an open maxilla and genu but distal concentric palatal obstruction at the velum due to large lateral oropharyngeal wall component.

4. Anatomically, TPA is indicated for patients with a more vertically oriented soft palate with maxillary retrusion and an anteroposterior pattern of retropalatal obstruction at the genu and velum.

Relative Contraindications

1. Patient factors

   a. High perioperative risk

   b. Anticoagulation

   c. Poor nutritional status

   d. Pre-existing dysphagia or xerostomia

   e. Occupation dependent upon pharyngeal function (e.g., professional musician or vocalist)

FIG. 54.2 Endoscopic view of the velopharyngeal space during sedated endoscopy.

The palate on the left exhibits an anteroposterior pattern of collapse more common in vertical or intermediate soft palate configurations. TPA is more conducive to addressing this configuration, particularly when maxillary deficiency is present. However, ESP is more appropriate for the complete concentric pattern of collapse seen on the right image because the ESP procedure better addresses the large lateral pharyngeal wall component. Key—*White arrow:* soft palate; *white asterisk*: lateral velopharyngeal walls; *white line*: pattern of soft palate collapse.

2. Anatomic factors

   a. Cleft palate or prior cleft palate repair

   b. Poorly vascularized tissue due to radiation or scar tissue

   c. Large palatal tori

Preoperative Preparation

1. Anesthesiology consultation if there is a concern for difficult airway or intubation

2. Stop anticoagulation temporarily.

3. Request patient bring continuous positive airway pressure (CPAP) or oral appliance (if still available and in use) to the day of surgery in the event airway support is needed in the hospital setting

Operative Period

Anesthesia

1. General anesthesia with oral intubation

2. Videolaryngoscope (i.e., Glidescope) and fiberoptic intubation

equipment should be available if needed.

Positioning

- Rose position

Perioperative Antibiotic Prophylaxis

- Intravenous antibiotic dose preoperatively and continued for 24 hours postoperatively
- Antibiotic choice, such as ampicillin-sulbactam or clindamycin, should cover oropharyngeal pathogens, including anaerobes.

Monitoring

- Standard anesthesia and cardiopulmonary monitoring

Instruments and Equipment to Have Available

- ESP
  - Tonsillectomy set
  - Monopolar needle-tip cautery
  - We prefer Coblation (Smith and Nephew PLC, London, United Kingdom) instrumentation for the tonsillectomy portion and additional work related to the uvula and hemostasis during the pharyngoplasty.
  - Toothed forceps
  - Right angle clamp
  - Metzenbaum scissors
  - Haney needle driver
  - 2-0 polysorb suture or similar for muscle suspension
  - 4-0 chromic suture for mucosal closure

- TPA
  - Previous ESP instrumentation plus:
  - TPS drill with 4-mm pineapple burr
  - Woodson periosteal elevator
  - 0 Vicryl suture on UR-6 needle

Key Anatomic Landmarks

- ESP
  - Palatopharyngeus muscle in each posterior tonsillar pillar. The insertion point of the muscle into the soft palate serves as the fulcrum for the pedicled muscle flap.
  - Constrictor muscle in the lateral aspect of the tonsillar fossa (preserve constrictor to avoid unnecessary bleeding and reduce morbidity)
  - Pterygoid hamulus and buccopharyngeal raphe provide the target area to which the muscle flap is anchored
- TPA
  - For incision placement: greater palatine foramina, junction of hard and soft palate, maxillary tuberosity
  - Tendinolysis requires transection of the tensor tendon and fascial bands of the anterior belly of the levator palatine muscle.
  - The bony keel of the posterior nasal spine provides ligamentous attachments to the soft palate and should be preserved during the bony osteotomy.

Prerequisite Skills

- ESP: Tonsillectomy
- TPA: Skeletal surgery/drilling techniques

Operative Risks

- Bleeding

Surgical Technique

- ESP (Fig. 54.3)[3,4]

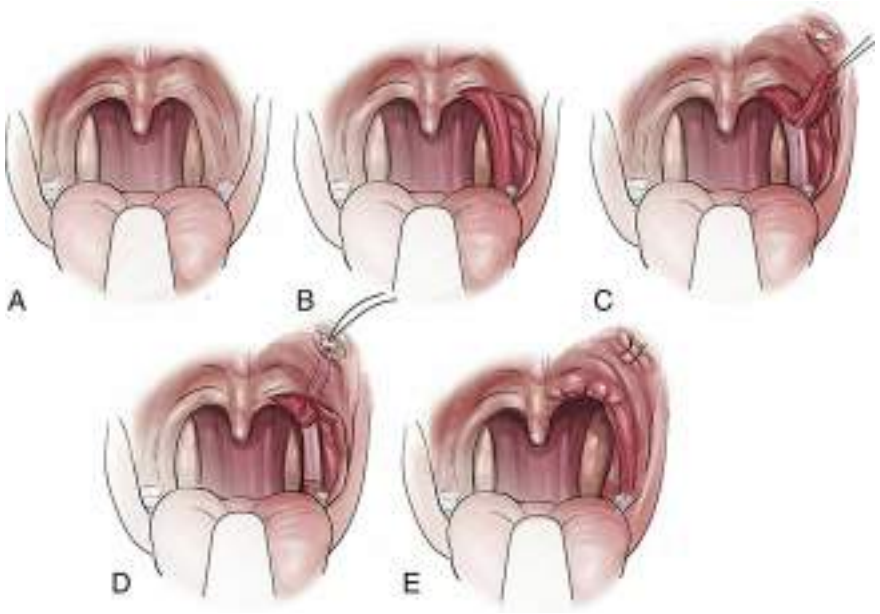

FIG. 54.3 Expansion sphincter pharyngoplasty technique.

If tonsils are present, tonsillectomy is performed with maximal mucosal preservation followed by identification and dissection of the palatopharyngeus muscle, **A**, **B**. The palatopharyngeus muscle is rotated toward the hamulus as a pedicled muscle flap and pulled through a submucosal tunnel in the lateral soft palate, **C**, **D**. The muscle flap is anchored to the fibrous tissue adjacent to the soft palate, and additional palatoplasty along the velum may be tailored to the specific anatomy as needed, **E**. Reproduced with permission from Woodson BT, Sitton M, Jacobowitz O: Expansion sphincter pharyngoplasty and palatal advancement pharyngoplasty: airway evaluation and surgical techniques. *Oper Tech Otolaryngol* 23:3-10, 2012.

- Mirror examination of the nasopharynx is performed first to obtain a baseline retropalatal airway assessment to be used for comparison

after completion of the pharyngoplasty.

- If an elongated or edematous uvula is present, we prefer to perform uvular resection or shortening first, before edema distorts the anatomy of the uvula. Most commonly the distal polypoid or edematous half of the uvula is transected sharply while preserving the uvular muscle and glandular function at the base.
- If palatine tonsils are present, bilateral tonsillectomy is performed. Care must be taken to preserve the mucosa overlying the posterior pillar.
- If palatine tonsils were previously removed, Colorado-tipped electrocautery on low setting should be used to incise the mucosa overlying the vertically oriented fibers of the palatopharyngeus muscle. At the lateral aspect of this muscle, the horizontally oriented fibers of the superior constrictor should be identified.
- A portion of the palatopharyngeus muscle is dissected from the surrounding mucosa medially and the constrictor muscle laterally with Metzenbaum scissors, being careful to keep the mucosa intact. A cuff of muscle may be left along the mucosal side and on the constrictor side to facilitate preserving these structures and to facilitate closure. A Mixter clamp or right angle forceps can be used to isolate the palatopharyngeus.
- The muscle is transected inferiorly with electrocautery adjacent to the base of the tongue with electrocautery and elevated as a pedicled muscle flap to the insertion point into the soft palate (fulcrum). Two 2-0 polysorb anchor sutures are placed in each muscle flap in a tendon stitch fashion.
- A separate stab incision is made in the lateral soft palate mucosa and submucosa just lateral to the pterygoid hamulus. The right angle clamp is used to dissect a tunnel (superficial to the palate musculature) from this stab incision into the superior pole of the tonsillar fossa.
- The palatopharyngeus pedicled muscle flap is then rotated anteriorly, superiorly, and laterally. The exact vector of the muscle flap may vary depending on each patient's palatal anatomy and width. Manual traction on the muscle flap should result in visible enlargement of the retropalatal space.

- The muscle flap and the attached sutures are brought through the tunnel in the superior pole and out through the stab incision. The 2-0 polysorb sutures are then anchored to the fibrous tissue of the lateral soft palate including the tensor aponeurosis and periosteum of the pterygoid hamulus.
- Mirror examination of the nasopharynx should demonstrate significant improvement in the retropalatal space and lateral oropharyngeal dimension.
- Additional 2-0 polysorb sutures are used to reapproximate the anterior and posterior tonsillar pillars on each side.
- 4-0 chromic mucosal sutures are used to close mucosal edges along the velum and uvula, as well as to close the lateral soft palate incisions and bury the 2-0 polysorb anchor sutures.

Transpalatal Advancement Pharyngoplasty (Figs. 54.4 and 54.5)[5]

- Maximal mouth opening and neck extension will optimize exposure.
- Bilateral greater palatine foramina should be infiltrated with 1% lidocaine with 1:100,000 epinephrine.
- NOTE: the greater palatine neurovascular bundle arises from the junction of alveolar, palatine, and maxillary bones.
- Fig. 54.4 highlights important landmarks for the incision. The trifurcation should be placed in the midline at the transition from the thinner, attached mucosa to thicker, unattached mucosa. The lateral limbs should be aimed toward the pterygoid hamulus. At all limb margins, several millimeters should be maintained from the alveolus to facilitate closure.
- The incision is made with Colorado-tipped electrocautery on low setting.
- The submucosal flaps should be elevated laterally and posteriorly using a Cottle elevator or equivalent. The posterior edge of the hard palate defines the posterior limit of flap elevation.

- For retraction of lateral flaps, dual Cottle elevators can now be placed in the greater palatine foramina.
- Hemostasis is achieved with bipolar cautery to minimize collateral damage.
- Using a pencil, a bony rectangle 10 mm in height should be marked out. The lateral extent varies but a wider window is preferred.
- The posterior nasal spine should be preserved (1 to 2 mm) to maintain the ligamentous attachments to the soft palate.
- A 4-mm pineapple burr (ovoid shape to minimize collateral damage) is used to thin the bony rectangle. As the bone becomes thin, a mastoid curette can be used to expose the nasal mucosa.

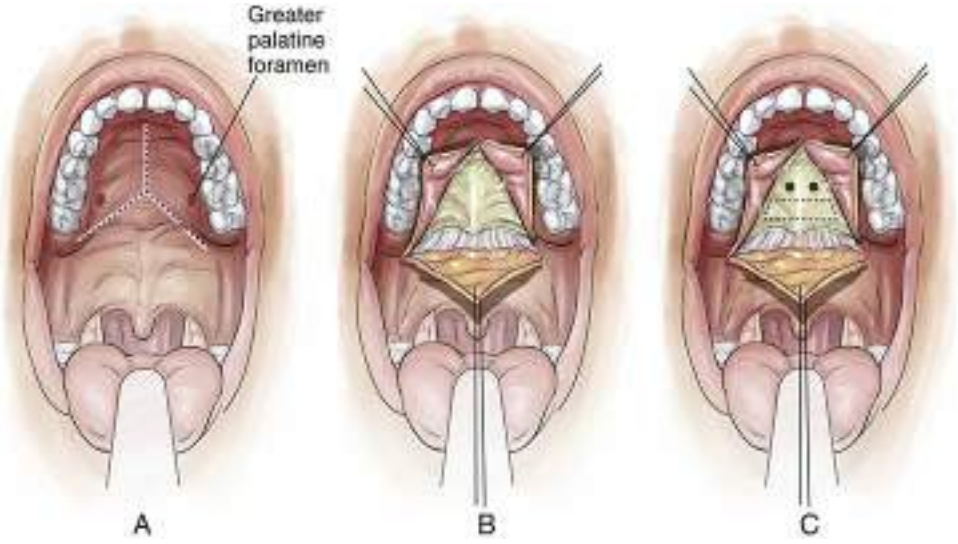

FIG. 54.4 Transpalatal advancement pharyngoplasty technique.

After a propeller incision over the posterior aspect of the hard palate, flaps are elevated to fully expose the hard-soft palate junction, **A**, **B**. An osteotomy is marked for removal of approximately 8 to 10 mm of bone while preserving the posterior nasal spine ("keel") and its ligamentous attachments to the soft palate, **C**. Reproduced with permission from Woodson BT, Sitton M, Jacobowitz O: Expansion sphincter pharyngoplasty and palatal advancement pharyngoplasty: airway evaluation and surgical techniques. *Oper Tech Otolaryngol* 23:3-10, 2012.

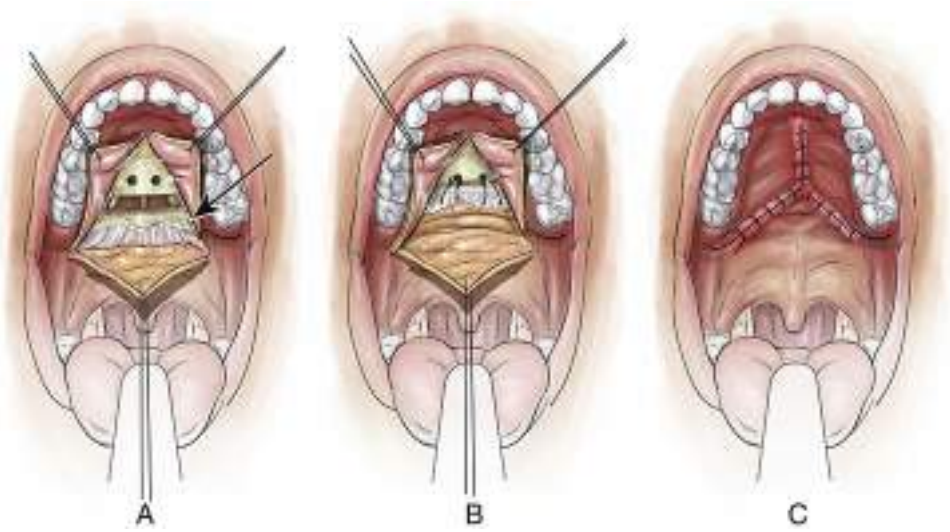

FIG. 54.5 Transpalatal advancement pharyngoplasty technique.

After the osteotomy is complete, the soft palate is mobilized by releasing the tensor aponeurosis laterally, **A**, *(arrow)*. Soft palate advancement sutures are placed around the bony keel and through separate drill holes in the hard palate, and the mucosal incisions are subsequently closed without tension, **B**, **C**. Reproduced with permission from Woodson BT, Sitton M, Jacobowitz O: Expansion sphincter pharyngoplasty and palatal advancement pharyngoplasty: airway evaluation and surgical techniques. *Oper Tech Otolaryngol* 23:3-10, 2012.

- Heavy scissors should be used to separate nasal septum (superiorly) and maxillary alveolus (laterally).
- Two drill holes (each approximately 5 mm from the midline) using 1 mm TPS drill bit are created 5 mm proximal to osteotomized segment.
- If the nasal mucosa is violated using electrocautery, be careful not to inadvertently injure the adjacent inferior turbinates.
- As the nasopharynx is visualized, the palatine aponeurosis is identified as a condensed white band medial to the hamulus.
- After the aponeurosis is adequately incised with electrocautery, the eustachian tube orifices should be visualized.
- To validate adequate mobilization, anterior traction placed on the distal palatal segment should result in anterior displacement of the uvula.

- Vicryl sutures (0) on a UR-6 needle are passed (blunt end first) through the drill holes into the nasopharynx. Two sutures are placed in each drill hole. From each of the drill holes, a suture is placed medially around the center of the soft palate and another laterally to capture the palatal aponeurosis.
- After all four sutures are placed, the assistant approximates the posterior nasal spine to the new free edge of the hard palate with a blunt instrument while the surgeon ties the knot.
- Excess fibroadipose tissue is removed and mucosal flaps are closed with monofilament sutures.

Common Errors in Technique

- ESP
  - Tearing of the palatopharyngeus muscle flap
  - Perforation of the lateral oropharyngeal wall mucosa ("rent" or "buttonhole") during flap elevation
- TPA
  - Inadequate release of palatine tensor aponeurosis for distal palate mobility
  - Drill trauma to the nasal turbinate and subsequent epistaxis

Postoperative Period

Postoperative Management

- Discharge according to same-day surgery criteria regarding adequate oral intake, pain and nausea control, and cardiopulmonary monitoring.
- For patients with very severe OSA, significant obesity, medical comorbidities, high opioid pain medication requirement, or those not meeting acceptable outpatient discharge criteria, overnight hospital observation may be required for respiratory monitoring.
- Diet: soft, smooth, and slimy for approximately 2 weeks

- Activity: Avoid strenuous activity, frequent talking, heavy lifting, or bending over for approximately 2 weeks.
- Moisturization: Maintain adequate hydration throughout day and run humidifier at night.
- Medications
  - Opioid pain medication
  - Over-the-counter acetaminophen and/or nonsteroidal anti-inflammatory medication
  - Antibiotics for 24 hours
  - Steroid course in the first week
  - Sucralfate suspension swish and swallow for comfort and to promote remucosalization

Complications

- ESP
  - Bleeding
  - Velopharyngeal insufficiency
  - Dysphagia
- TPA
  - Bleeding
  - Velopharyngeal insufficiency
  - Dysphagia
  - Oronasal fistula should be initially treated with an oral splint. This hastens healing by reducing bacterial contamination, as well as facilitates speech and diet. If the fistula persists, suture closure in office or operative room can be undertaken.

Alternative Management Plan

At any stage of evaluation and management, patients should always be

offered to continue or revisit PAP or other medical device therapy. In patients with persistent or residual OSA after advanced palatal surgery, adherence and success rates with PAP and oral appliance may be higher after surgical therapy to lower upper airway resistance.

Discussion

Evidence-Based Medicine Question

Is expansion sphincter pharyngoplasty as effective as traditional uvulopalatopharyngoplasty in reducing the apnea-hypopnea index?

One randomized trial by Pang and Woodson showed that ESP was more effective than traditional UPPP as defined by 50% reduction in AHI and AHI less than 15. The ESP group had 78% success rate, whereas the UPPP group had 45% success rate (P <.05).[3]

Editorial Comment

Palatal surgery plays a key role in the management of patients with OSA who are intolerant or unable to achieve benefit with medical device therapy. However, traditional UPPP has several important limitations due to the excisional nature of the procedure and subsequent fibrosis. Research has demonstrated that postoperative improvement in airflow and OSA outcome measures is directly related to the increase in upper airway volume and cross-sectional area. ESP and TPA pharyngoplasty are examples of advanced modifications of palatal surgery that better reconstruct and enlarge the upper airway, which may reduce side effects and morbidity compared with traditional excisional techniques.

Ryan Soose

Review Questions

1. Which of the following palatal configurations is best suited for TPA?

   a. Oblique

   b. Intermediate

c. **Vertical**

d. Horizontal

2. The greater palatine foramen is located at the intersection of:

a. Palatine, maxillary, and sphenoid bones

b. **Palatine, maxillary, and alveolar bones**

c. Maxillary, alveolar, and sphenoid bones

d. Alveolar, sphenoid, and palatine bones

3. Initial management of oronasal fistula after TPA includes:

a. Primary closure

b. Secondary closure

c. Local flap

d. **Dental splint**

Volumetric Tongue-Base Reduction (Lingual Tonsillectomy, Coblation Midline Glossectomy, Trans Oral Robotic Surgery)

Don Keamy Jr. , and Umamaheswar Duvvuri

Introduction

First-line surgical treatment of obstructive sleep apnea (OSA) in both pediatric and adult patients is adenotonsillectomy and has often been uvulopalatopharyngoplasty in adults. When initial medical or surgical treatment of OSA fails to successfully treat the condition, adjunct surgical treatment may be warranted. Lingual tonsillectomy and tongue-base reduction are two of these surgical techniques that can lead to improved outcomes in patients with OSA.[1,2]

In the pediatric population, adenotonsillectomy seems to be very successful initially. Months to years later, some of these initial successes present with recurrent symptoms. In these cases, lingual tonsillar hypertrophy may be the cause. In obese patients, the risk of lingual hypertrophy of the tonsil appears to be higher after adenotonsillectomy.

Lingual tonsillectomy alone can be very effective in relieving upper airway obstruction when the lingual tonsils are noted to be large and obstructive during drug-induced sleep endoscopy (DISE) or other methods of upper airway assessment. When lingual tonsils are small or absent, but there is still significant tongue-base collapse leading to upper airway obstruction, tongue-base reduction surgery may be beneficial (Fig. 55.1).

Various methods of video-assisted lingual tonsillectomy have been described. One such method is via suspension laryngoscopy with the use of the coblation device.[3] This has proven to be a reliable technique that

can be performed without needing any assistants for retraction.

Both procedures aim to improve the retroglossal airway during sleep, which may improve OSA symptoms. Even if OSA is not resolved, these procedures can potentially improve compliance with continuous positive airway pressure (CPAP), leading to reduced pressure settings on CPAP devices.

Key Operative Learning Points: Endoscopic Lingual Tonsillectomy

- Preoperative airway assessment with DISE is advocated for proper patient selection. Some centers employ CINE MRI when sleep endoscopy is not available.
- Lingual tonsillectomy is best considered in patients who have previously had adenotonsillectomy.
- While nasal intubation may aid in surgical ease, it is not necessary. The procedure can be performed with oral intubation to facilitate concurrent nasal surgery.
- The vallecula should be unobstructed and completely free of lingual tonsil tissue at the completion of the surgery.
- The lateral lingual tissue may be more superficially removed to reduce the risk of significant peri- or postoperative bleeding.
- This procedure can be performed in both pediatric and adult patients by using the appropriate pediatric and adult-sized laryngoscopes.

Preoperative Period

A comprehensive medical history remains the cornerstone of the preoperative evaluation. Once it has been determined that a patient is intolerant or unable to achieve adequate benefit with standard medical treatments, surgical options should be considered. Physical examination, upper airway endoscopy, and imaging techniques should be used to describe the anatomy of the upper airway and tailor a comprehensive surgical treatment plan. The key to success with these techniques is

patient selection, and significant time should be spent with the patient preoperatively to be certain that chances for success are optimized.

Patients considered for second-line surgical treatment should be evaluated for other medical conditions that could lead to sleep disorders. In pediatric patients, CPAP is often not tolerated and, when used long term, it may lead to craniofacial abnormalities. In this population, lingual tonsillectomy may be considered without a trial of CPAP. In adults, surgery would be considered for patients who fail or are intolerant of CPAP or other medical and dental treatments.

History

1. History of present illness
    a. Symptoms and impact on quality of life including snoring, apnea, gasping, choking, oropharyngeal pain, dysphagia, and cognitive dysfunction
    b. Timing, duration, and onset of symptoms. The severity and duration of symptoms should be carefully assessed. It is important to make the determination that removing hypertrophied lingual tonsils will alleviate the symptoms.
    c. Prior history of treatments, both medical and surgical, including detailed information on side effects and treatment response, should be gathered.
2. Past medical history
    a. Comorbidities associated with upper airway obstruction should be sought (hypertension, diabetes, myocardial infarction, atrial fibrillation, cerebrovascular event, depression, gastroesophageal reflux disease, erectile dysfunction).
    b. Chronic neck pain, trismus, and other conditions that may negatively impact exposure of the base of the tongue
    c. History of dysphagia
    d. History of neuromuscular disease
3. Past surgical history
    a. Prior surgery or injury to the tissues of the neck may be

contraindications to tongue-base reduction surgery and need to be evaluated on an individual basis.

b. Prior maxillofacial surgery that may lead to difficulty with exposure and/or injury to the teeth

4. Medications

a. Anticoagulants

b. Opiate pain medication, benzodiazepines, or other medications that can alter nocturnal control of breathing

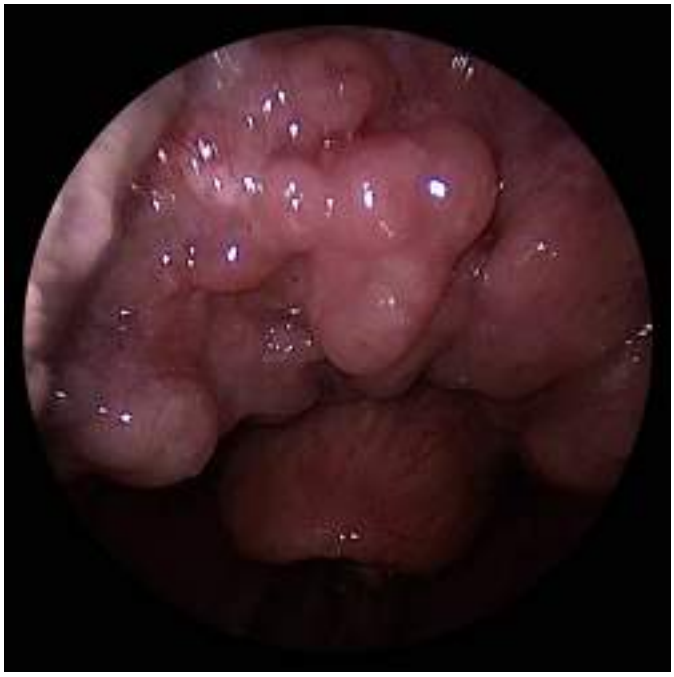

FIG. 55.1 Endoscopic view demonstrating hypertrophic lingual tonsil tissue.

5. Family history

a. A strong family history of OSA may provide insight into the anatomic/structural vulnerability.

6. Social history

a. Alcohol: Excessive alcohol use in adults can lead to postoperative withdrawal and complications.

b. Tobacco: Smoking has been shown to independently increase the

risk of pulmonary disease and hence anesthesia-associated complications. Also, in older patients with an extensive smoking and drinking history, the risk of malignancy in the oropharynx should also be considered.

Physical Examination

1. Evaluation of the facial skeleton
   a. Significant maxillary or mandibular hypoplasia may be associated with increased difficulty in exposure.
   b. Occlusion:
      1) Angle's classification
      2) Degree of overjet and overbite
2. Oral cavity
   a. Tongue ridging or scalloping suggests relative macroglossia for the available mandibular size.
   b. Quality and quantity of dentition have implications on the potential for injury to the teeth during the surgery.
   c. Height and width of the hard palate. A narrow high-arched soft palate may increase the difficulty of soft tissue work on the soft palate and may negatively affect treatment outcomes.
   d. The presence of large palatal tori may reduce operative exposure and make palatal surgery more technically challenging.
3. Oropharynx
   a. Tonsil size
   b. Crowded nature of the oropharynx
   c. Modified Mallampati (MM) or Friedman tongue position (FTP)
   d. Size and structure of the lateral oropharyngeal wall

FIG. 55.2 Postoperative view of the tongue base after coblation lingual tonsillectomy.

4. Examination of the neck
   a. Neck circumference
   b. Hyoid bone position: A low or inferiorly positioned hyoid bone suggests a longer pharyngeal airway.
5. Cranial nerve examination with specific attention to the functional status of the hypoglossal nerve and glossopharyngeal nerves
6. General health
   a. Blood pressure
   b. Cardiovascular
   c. Respiratory
   d. Mental
7. Flexible fiberoptic laryngoscopy
   a. Awake
   b. DISE

Imaging

1. Chest radiograph
   a. Preoperative screening
   b. Evaluate for cardiopulmonary disease
   c. Rule out immobility of the hemidiaphragm

2. Computed tomographic imaging: may be indicated preoperatively to assess the extent of lingual tonsil hypertrophy and oropharyngeal crowding

3. Modified barium swallow study may be indicated prior to surgery for patients with baseline dysphagia, particularly in those with swallowing problems after prior pharyngeal surgery (Fig. 55.2).

Indications

1. Patients with enlarged lingual tonsils with symptoms of either hypertrophy of the lingual tonsil leading dysphagia/odynophagia or OSA

2. DISE is currently recommended to evaluate the anatomic location and pattern of pharyngeal collapse prior to proceeding with tongue-base reduction surgery. Particular attention is paid to the pattern of palatal collapse and the degree of multilevel coupling between the tongue protrusion and enlargement of the retropalatal space.

Contraindications

1. Patient factors
   a. High perioperative risk due to comorbidities
   b. Patient taking anticoagulants
   c. Poor nutritional status

2. Anatomic factors
   a. Craniofacial abnormalities prevent access to the lingual tonsils or tongue base.

Preoperative Preparation

1. Anesthesiology consultation if there is a concern for difficult airway or intubation

2. Hold anticoagulation if possible

3. Request that the patient bring CPAP or an oral appliance (if still available and in use) to the day of surgery in the event that airway support is needed in the hospital setting.

Operative Period

There are several techniques that can be used to perform tongue-base reduction surgery. The most commonly used are (1) coblator-based reduction performed through a laryngoscopy approach or (2) transoral robotic resection of the base of the tongue using either the Intuitive da Vinci or Medrobotics Flex system. We describe these methods in the subsequent sections.

Anesthesia

1. General anesthesia with nasal or oral intubation

2. Videolaryngoscope (i.e., GlideScope) and fiberoptic intubation equipment should be available if needed

3. Bronchoscopic equipment should be available for difficult intubations.

4. Perioperative dexamethasone administration should be requested.

Positioning

- Rose position unless patient has trisomy-21
- Neutral neck position for trisomy-21 patients

Perioperative Antibiotic Prophylaxis

- Not indicated

Monitoring

- Standard anesthesia and cardiopulmonary monitoring

Instruments and Equipment to Have Available (Lingual Tonsillectomy)

- Lindholm suspension set
- Coblation device with Procise Xact 70 wand
- Thirty-centimeter rigid endoscope with video tower
- Rigid laryngeal suction

Key Anatomic Landmarks

- Identify the circumvallate papillae.
- Palpate the hyoid bone.
- Visualize the epiglottis and the valleculae.

Surgical Technique

Lingual Tonsillectomy Using the Coblator

- The patient may be intubated nasally or orally. If no concurrent nasal or nasopharyngeal surgery is planned, a nasal intubation provides better exposure and increases the ease of surgery.
- The Lindholm suspension laryngoscope is inserted orally and suspended with a view of the lingual tonsils and epiglottis.
- A long 0-degree endoscope is inserted to further inspect the surgical field.
- The Procise Xact 70 coblation wand connected with setting of 7 coblate and 3 coagulate
- The wand and endoscope are both inserted through the Lindholm

laryngoscope, and ablation of the lingual tonsils is performed.

- Care is taken not to injure the epiglottis. Lingual tonsil tissue should be pushed away from the epiglottis with the coblation wand prior to engaging the coblate peddle.
- Bleeding is controlled via the coagulation mode of the coblater.
- Coblation of the central lingual tonsils continues until the musculature of the tongue is reached and the vallecula is unobstructed.
- Lateral lingual tonsil tissue may also be ablated, but the risk of significant bleeding will be reduced if the lateral tissue is ablated more superficially.
- The Lindholm laryngoscope may need to be repositioned several times and further coblation performed to ensure adequate removal of lingual tonsillar tissue.
- We check for hemostasis and use gelatin foam with thrombin for hemostasis.
- Instrumentation is removed after adequate removal of lingual tonsillar tissue is obtained.

Lingual Tonsillectomy Using the da Vinci Robotic System

- The patient may be intubated nasally or orally. If no concurrent nasal or nasopharyngeal surgery is planned, a nasal intubation provides better exposure and increases the ease of surgery.
- A Dingman mouth gag using a flat blade is inserted orally and suspended with a view of the lingual tonsils and epiglottis.
- The surgical robotic system is placed into the mouth to further inspect the surgical field.
- The robotic instruments, a 5-mm Maryland and a 5-mm spatula cautery, are placed into the oral cavity.
- The dissection begins at the circumvallate papilla with a horizontal incision. The lingual tonsil tissue is bisected in the midline. The dissection then continues down to the level of the tongue musculature.

Using cautery, the fasciculation of the muscles delineates the plane of dissection. The dissection is continued posteriorly to the level of the vallecula, and lymphoid tissue is removed from the vallecula as well.

- Care is taken not to injure the epiglottis. Lingual tonsil tissue should be pushed away from the epiglottis with the robotic instruments before the tissue planes are transected.
- Bleeding is controlled using the coagulation mode of the coblater.
- Instrumentation is removed after adequate removal of lingual tonsillar tissue is obtained.

Lingual Tonsillectomy Using the Medrobotics System

- The patient may be nasally or orally intubated. If no concurrent nasal or nasopharyngeal surgery is planned, a nasal intubation provides better exposure and increases the ease of surgery.
- A Dingman mouth gag using a flat blade is inserted orally and suspended with a view of the lingual tonsils and epiglottis.
- The Medrobotics Flex system is brought into the field.
- The Flex drive is placed in the mouth, and the surgical field is visualized.
- The instrument support system is placed and affixed to the surgical bed.
- The Maryland and cautery instruments are positioned into the patient's mouth.
- The Flex drive is manipulated and driven into the oral cavity to obtain appropriate visualization of the surgical field.
- Care is taken not to injure the epiglottis. Lingual tonsil tissue should be pushed away from the epiglottis prior to tissue dissection.
- Bleeding is controlled with coagulation using the cautery device or using a bipolar device operated by the bedside assistant.
- The dissection begins at the circumvallate papilla with a horizontal incision. The lingual tonsil tissue is bisected in the midline. The

dissection then continues down to the level of the tongue musculature. Using cautery shows the fasciculation of the muscles, which delineates the plane of dissection. The dissection is continued down to the level of the vallecula, when tissue is removed.

- Lateral lingual tonsil tissue may also be ablated, but the risk of significant bleeding is reduced if the lateral tissue is more superficially ablated.
- Instrumentation is removed after adequate removal of lingual tonsillar tissue.

Common Errors in Technique

- Injury to the epiglottis, especially the tip, with the coblation wand
- Incomplete removal of the central lingual tonsil tissue

Postoperative Period

- Overnight postoperative observation in a monitored setting is appropriate given the potential for edema of the epiglottis and tongue postoperatively as well as possible bleeding.
- Postoperative steroids may help to reduce swelling.
- Diet: soft and smooth (mechanical soft) for approximately 2 weeks
- Activity: Avoid strenuous activity, frequent talking, heavy lifting, or bending over for approximately 2 weeks.
- Moisturization: Maintain adequate hydration throughout the day, and use the humidifier on a bedside table at night.
- Medications:
  - Opioid pain medication should be used with caution in pediatric patients.
  - Over-the-counter acetaminophen and/or nonsteroidal anti-inflammatory medication

Complications

- Bleeding can be encountered intraoperatively or postoperatively.
  - Intraoperative bleeding can be avoided through careful management of hemostasis, which is usually accomplished using a bipolar cautery. Postoperative bleeding occurs in 8% of patients. This can be ameliorated by performing vessel ligation, although this is usually performed in patients undergoing surgery for malignant processes.
- Airway edema and obstruction—airway edema occurs in a small subset of patients
  - This can, in certain cases, lead to obstructive symptoms and potentially result in airway compromise. This problem often occurs because of tongue swelling caused by traction injury. Such complications can be reduced or avoided if operative times are reduced and traction injury is avoided.
- Dysphagia—short term and long term
  - Short-term dysphagia is an expected side effect of tongue-base surgery. Long-term dysphagia is considered an undesired side effect/complication of this surgery.
  - Long-term dysphagia is often attributed to oropharyngeal stenosis, which occurs due to circumferential swelling. This can be avoided by not removing the palatine tonsils and lingual tonsils simultaneously.

Alternative Management Plan

At any stage of evaluation and management, patients should always be offered to continue or revisit CPAP or other medical device therapy. In patients with persistent or residual OSA after advanced palatal surgery, adherence and success rates with CPAP and oral appliance may be higher after surgical therapy to lower upper airway resistance.

Discussion

Evidence-Based Medicine Question

Is lingual tonsillar hypertrophy common in obese patients?

One study by Guimaraes et al.[2] showed that 62% of obese children have measurable lingual tonsils on imaging.

Editorial Comment

For the treatment of obstructive sleep-disordered breathing, in both pediatric and adult patients, the retrolingual airway is of utmost importance. Traditionally, this portion of the upper airway has been difficult to assess and examine, and it has been challenging to expose and treat. Advanced diagnostic tools including sedated endoscopy and imaging have improved the clinician's ability to evaluate for tongue-base pathology. Furthermore, advances in microlaryngoscopy and endoscopy techniques, robotic surgery systems, and plasma wand technology have substantially improved the surgical exposure and the ability to safely and effectively treat retrolingual airway obstruction.

Ryan Soose

- Access the review questions online at http://www.expertconsult.com

Review Questions

1. Lingual tonsillectomy is most appropriate

   a. As a primary treatment for obstructive sleep apnea (OSA)

   b. Only in pediatric or adult patients who have failed continuous positive airway pressure

   c. **In pediatric patients who have previously had adenotonsillectomy and demonstrate obstructive lingual tonsils on DISE**

   d. Whenever large lingual tonsils are found on fiberoptic laryngoscopy in patients with OSA

2. The most appropriate intubation technique for lingual tonsillectomy is

   a. Always nasotracheal intubation

   b. Always endotracheal intubation

c. Decided by the anesthesiologist

d. **Either oral or nasotracheal depending on other planned nasal or nasopharyngeal procedures**

3. The most feared complication of lingual tonsillectomy is

a. Dysgeusia

b. **Hemorrhage**

c. Dysphagia

d. Dysarthria

4. How long does dysphagia usually persist after lingual tonsillectomy?

a. 1 day

b. 1 month

c. **2 weeks**

d. 2 months

Hypoglossal Nerve Stimulation Therapy

Ryan Soose, and David Kent

Introduction

The prevalence of obstructive sleep apnea (OSA), its complex pathophysiology, and the suboptimal adherence rates with positive pressure therapy require alternative treatment strategies in many OSA patients. Hypoglossal nerve stimulation (HNS) represents a novel and unique therapeutic approach that combines a surgical implant procedure with a titratable medical device to provide multilevel upper airway improvement via neuromodulation of the hypoglossal nerve.[1] A recent multicenter prospective trial of HNS reported significant reduction in polysomnographic measures of disease severity and significant improvement in patient-reported quality of life measures that were maintained at 3 years follow-up, with overall low morbidity and good patient acceptance and adherence.[2-4] HNS therapy has established itself as a key component of the OSA treatment armamentarium, although further work is needed to advance the technology, determine the most appropriate patient phenotypes, refine the implant procedure, and optimize stimulation parameters and titration protocols.[5]

Traditional surgical procedures for sleep apnea exclusively target the anatomic structural vulnerability of the upper airway. There is increasing evidence that the neuromuscular control of breathing during sleep also plays a key role in the pathophysiology of sleep-disordered breathing for many OSA patients. A simplified version of the upper airway neuromuscular feedback loop has been described with afferents from the pharynx, through the superior laryngeal nerve, to the nucleus solitarius and efferents from the hypoglossal nerve motor nucleus to the genioglossus muscle. The genioglossus muscle is the primary upper

airway dilator muscle and, in normal healthy subjects, responds to negative intraluminal pressure with a corresponding increase in genioglossus electromyographic (EMG) activity. This negative pressure reflex appears to be dysfunctional in many patients with OSA. Augmenting the efferent limb of the neuromuscular feedback loop by stimulating the hypoglossal nerve, or the genioglossus muscle directly, may provide a therapeutic mechanism for some OSA patients.

Two key factors play an important role in the potential success of the HNS therapy: (1) the ability of the therapy to provide *multilevel* upper airway improvement and (2) the ability to adjust and titrate the therapy. Imaging, fluoroscopy, and drug-induced sedated endoscopy (DISE) evaluation of HNS therapy responders demonstrated that HNS resulted in enlargement of the retropalatal space as well as the retrolingual portion of the airway.[6] Anterior displacement of the hyoid bone also occurred in the majority of participants. This multilevel improvement may be due to a number of factors but is primarily thought to occur from the mechanical coupling of the tongue and palate via the palatoglossal and palatopharyngeus muscles. During therapy titration, prior studies have shown a graded increase in airflow and airway measurements with increasing stimulation amplitudes. Unlike traditional sleep apnea surgery, HNS therapy can be titrated in the clinical or sleep laboratory setting to optimize both effectiveness and comfort across a longitudinal care model.

The role of anatomic phenotyping of the upper airway has been increasingly recognized as essential to successful patient selection and improved outcomes. For example, feasibility study data on the currently available HNS system suggest that outcomes are better in patients without a complete circumferential pattern of collapse at the soft palate during DISE. HNS differs from traditional OSA airway surgery in that the procedure does not alter the anatomy of the upper airway and is technically reversible. Unlike volumetric reduction of the base of the tongue or other surgeries of the pharynx, the HNS surgical procedure is completely external to the pharynx, thus substantially reducing postoperative discomfort and recovery time, and minimizing or even eliminating the traditional risks of hemorrhage, dysphagia, change in taste, or other untoward pharyngeal side effects of anatomy-altering procedures.

Key Operative Learning Points

- Successful HNS therapy requires proper patient selection, anatomic phenotyping, meticulous procedure execution, and precise titration of stimulation parameters postoperatively.
- Intraoperative hypoglossal nerve monitoring is used to identify and selectively capture the distal tongue protrusor branches supplying the genioglossus muscle and to exclude lateral branches innervating the tongue retractor muscles.

Preoperative Period

As discussed in Advanced Palatal Surgery, Chapter 54, a comprehensive sleep medicine history remains the cornerstone of preoperative evaluation. Once a patient is determined to be intolerant of or unable to achieve adequate benefits with standard medical treatments, surgical options may be considered. The optimal anatomic and physiologic phenotypes for HNS remain unclear and controversial. Physical examination, upper airway endoscopy, and imaging techniques are available to describe the upper airway anatomy and tailor a comprehensive and multilevel surgical treatment plan appropriately. The current US Food and Drug Administration (FDA)-approved HNS system has been studied in and approved for the treatment of *moderate-severe* OSA as second-line therapy after failure of positive pressure therapy. Several preoperative considerations are specific to HNS therapy and are also highlighted in the following list (**).

History

1. History of present illness
   a. Sleep-related symptoms and impact on quality of life, including snoring, witnessed apnea, gasping, choking, nocturnal awakenings, nocturia, morning headaches, daytime sleepiness, and cognitive dysfunction
   b. Timing, duration, and onset of symptoms. Previously untreated severe OSA may be further complicated by associated

cardiovascular comorbidities. Specific events may coincide with OSA onset such as an injury to the nose, surgery of the mandible, weight gain, cerebrovascular events, and change in sleep position due to musculoskeletal problems. All may have therapeutic implications.

c. The presence of other sleep disorders such as insomnia and restless legs syndrome may confound the assessment of OSA outcome measures. Successful management of the patient will often require treatment of both the OSA and the additional comorbid sleep pathology. A comprehensive sleep medicine history is essential.

d. Prior OSA treatment history, both medical and surgical, including detailed information on side effects, treatment response, and adherence with PAP and other medical devices. Excellent positive airway pressure (PAP) adherence in the setting of persistent daytime sleepiness, for example, is suggestive of a non-OSA etiology of sleepiness, and surgery may not be indicated.

2. Sleep laboratory testing

a. Type of study: Home sleep apnea test (HST) versus in-lab polysomnography (PSG)

b. Sleep efficiency: Poor sleep efficiency may raise concern for unreliable sleep study results or the possibility of comorbid insomnia.

c. Sleep architecture: Abnormal sleep architecture may be caused by OSA as well as by medications (e.g., antidepressants, steroids) or other sleep pathology.

d. Sleep continuity: An elevated arousal index or abnormal sleep continuity can also be caused by OSA or by chronic pain, medications, or other sleep or medical pathology.

e. Respiratory analysis: Snoring, apnea-hypopnea index (AHI), respiratory disturbance index (RDI), and oxygen saturation should be assessed to determine the severity of OSA. The presence of central sleep apnea, Cheyne–Stokes respiration, or other sleep-related hypoventilation/hypoxemia conditions (e.g., due to cardiopulmonary disease) should be ruled out, as surgery may be contraindicated in such conditions.

f. Signs of other sleep pathology: PSG should evaluate for periodic limb movement disorder (PLMD), nocturnal seizure activity, REM-behavior disorder (RBD), or other nonrespiratory sleep disorders.

3. Past medical history

a. **Medical conditions requiring the regular use of magnetic resonance imaging (MRI) such as multiple sclerosis or central nervous system neoplasm. MRI is contraindicated in patients with the current HNS implantable device.

b. **History of allergy to metal or other synthetic materials

c. Comorbidities associated with OSA (hypertension, diabetes, myocardial infarction, atrial fibrillation, cerebrovascular event, depression, gastroesophageal reflux disease, erectile dysfunction)

d. Chronic back or neck pain, fibromyalgia, or other pain syndromes that may negatively impact sleep

e. Cardiopulmonary disease (e.g., chronic obstructive pulmonary disease, valvular heart disease, or congestive heart failure) that may complicate control of breathing at night and introduce additional respiratory pathology beyond OSA

f. History of dysphagia

g. History of neuromuscular disease

4. Past surgical history

a. **Prior surgery or injury to the tissues of the neck or upper chest (e.g., radiation of the head and neck, breast cancer surgery, pectoralis muscle flap, neck dissection) may be relative contraindications to HNS implant surgery and need to be evaluated on an individual basis.

b. Prior sinonasal surgery

c. Prior pharyngeal or skeletal OSA surgery

d. Prior bariatric surgery

5. Medications

a. Anticoagulants.

b. Opiate pain medication, benzodiazepines, or other medications that

can alter nocturnal control of breathing.

c. Selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), lithium, or other neuropsychiatric medication that can independently alter sleep architecture and continuity.

d. Stimulant therapy (e.g., modafinil or methamphetamines) that may confound the assessment of daytime sleepiness.

6. Family history

a. A strong family history of OSA may provide insight into the anatomic/structural vulnerability.

7. Social history

a. Occupation

i. **Occupations that include repeated mechanical trauma to the neck and chest (e.g., contact sports, martial arts) or the use of heavy firearms (e.g., hunting, law enforcement, military) may be relative contraindications to implantable HNS therapy due to possible damage to the device or patient discomfort. The pulse generator placement may be adjusted, however, to avoid contact with the stock of a rifle or shotgun.

ii. OSA in truck drivers, airline pilots, railroad engineers, and other occupations involving public safety risk has additional implications on treatment and reporting of outcomes.

iii. Shift workers may have residual sleep-related symptoms due to their circadian rhythm disturbance, even after otherwise successful OSA treatment.

b. Alcohol: Evening alcohol use has been correlated with increased obstructive respiratory events.

c. Tobacco: Smoking has been shown to independently increase the risk of moderate to severe OSA as well as increase sinonasal and pulmonary disease.

d. Total sleep duration: Behaviorally induced insufficient sleep is one of the most common causes of daytime sleepiness and may confound the assessment of OSA treatment outcomes. Sleep deprivation has also been shown to exacerbate OSA.

Physical Examination

1. Anterior rhinoscopy
    a. Acquired nasal deformity, septal deviation, turbinate hypertrophy, rhinitis, nasal polyps, and other nasal valve pathology may increase upper airway resistance and directly contribute to sleep-disordered breathing.
    b. Increased nasal resistance may also increase negative intraluminal pressure in the pharynx and increase the fraction of maladaptive mouth breathing, further contributing to OSA pathophysiology.
    c. Nasal surgery designed to lower nasal resistance should be considered either in conjunction with or prior to pharyngeal surgery in most cases.
2. Facial skeleton
    a. Significant maxillary or mandibular hypoplasia may require orthodontic or orthognathic surgical correction prior to consideration of pharyngeal or HNS surgery.
    b. Occlusion:
        i. Angle's classification
        ii. Degree of overjet and overbite
3. Oral cavity
    a. Tongue ridging or scalloping suggests relative macroglossia in relation to the size of the mandible.
    b. Quality and quantity of dentition has implications on the availability of adjunctive custom mandibular repositioning devices (oral appliance) in the treatment plan.
    c. Height and width of the hard palate. A narrow high-arched soft palate may increase the difficulty of soft tissue work on the soft palate and may negatively affect treatment outcomes.
    d. The presence of large palatal tori may reduce operative exposure and make palatal surgery more technically challenging.
4. Oropharynx

a. Sagittal configuration of the soft palate

b. Length of the soft palate

c. Modified Mallampati (MM) or Friedman Tongue Position (FTP)

d. Size of the tonsils

e. Size and structure of the lateral oropharyngeal wall

f. Size and configuration of the uvula

5. Neck

a. Circumference of the neck

b. Position of the hyoid bone: A low or inferiorly positioned hyoid bone suggests a longer pharyngeal airway.

6. Chest

a. To evaluate for chest wall deformity, scars, or other signs of prior surgery or trauma

7. Cranial nerves

a. Examination with specific attention to the functional status of the hypoglossal nerves and the facial nerve

8. General health

a. Blood pressure

b. Cardiovascular

c. Respiratory

d. Mental

9. Flexible fiberoptic laryngoscopy

a. Awake

b. DISE

Imaging

1. Chest radiograph

a. Preoperative screening

b. Evaluate for cardiopulmonary disease.

c. Rule out immobility of the hemidiaphragm.

2. Imaging of the facial skeleton may be indicated in select cases preoperatively, particularly in cases of prior mandibular surgery, suspected craniofacial abnormalities, or signs of maxillomandibular deficiency. Imaging studies may include:

a. Lateral cephalometric radiograph

b. Orthopantomogram

c. Computed tomography (CT) three-dimensional imaging

3. Sinonasal imaging may be indicated in patients with suspected chronic sinonasal disease when simultaneous or staged nasal surgery is being considered with HNS surgery.

4. Modified barium swallow study may be indicated prior to expansion sphincter pharyngoplasty (ESP) or transpalatal advancement pharyngoplasty (TPA) in patients with baseline dysphagia or velopharyngeal insufficiency symptoms, particularly in those with swallowing problems after prior pharyngeal surgery.

Indications

1. Moderate to severe OSA patients who are not significantly obese and who are intolerant or have inadequate adherence with PAP therapy or other first-line medical device options

2. Drug-induced sedated endoscopy (DISE) is currently recommended to evaluate the anatomic location and pattern of pharyngeal collapse prior to proceeding with HNS therapy. Particular attention is paid to the pattern of palatal collapse and the degree of multilevel coupling between the protrusion of the tongue and enlargement of the retropalatal space. Early feasibility studies have demonstrated poorer results with a complete concentric pattern of palatal collapse but higher success rates with an anterior-posterior pattern of palatal collapse (Fig. 56.1).[6]

3. Patients who are willing to undergo implantation of a neurostimulation device should not have anticipated MRI requirements and should also have the ability and dexterity to operate a basic remote

control.

Relative Contraindications

1. Patient factors
   a. High perioperative risk
   b. Anticoagulation
   c. Poor nutritional status
   d. Allergy to metal
   e. Occupation associated with repetitive trauma to the neck or chest

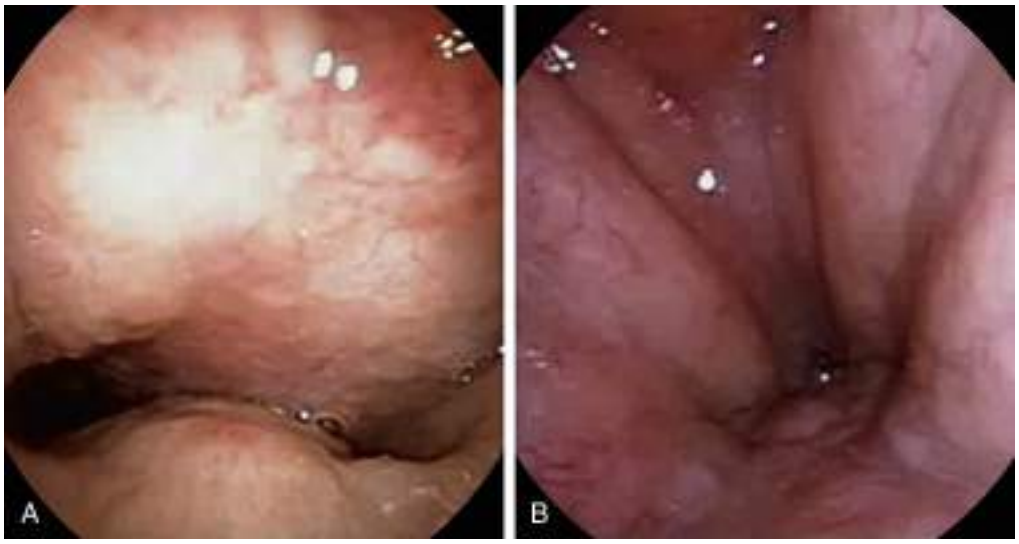

FIG. 56.1 Anterior-posterior versus circumferential velopharyngeal collapse during DISE.

A primarily anterior-posterior pattern of velopharyngeal collapse **(A)** is favorable for hypoglossal nerve stimulation (HNS) therapy, while a circumferential pattern of collapse **(B)** is less likely to have a significant response to HNS therapy.

2. Anatomic factors
   a. Complete concentric pattern of palatal collapse on DISE
   b. Body mass index (BMI) greater than 32 kg/m^2

Preoperative Preparation

- Anesthesiology consultation if there is a concern regarding a difficult airway or intubation
- Hold or bridge anticoagulation.
- Have patient bring continuous positive airway pressure (CPAP) or oral appliance (if still available and in use) the day of surgery in case airway support is needed in the hospital.

Operative Period

Only one HNS implantable device is FDA approved and commercially available in the United States at the time of publication. Although other systems may be available in the future, the operative portion of this chapter will focus on the procedure and technology components of the currently available system (Inspire Medical Systems, Minneapolis, Minnesota). The system consists of three implantable components: a pulse generator in a subcutaneous chest pocket, a stimulation cuff electrode on the distal portion of the hypoglossal nerve, and a pleural respiratory sensor in the intercostal space (Fig. 56.2).

Anesthesia

- General anesthesia with oral intubation
- Videolaryngoscope (i.e., GlideScope) and fiberoptic intubation equipment should be available if needed for a difficult intubation.
- Avoid long-acting muscle relaxant agents due to intraoperative nerve monitoring.

Positioning

- Supine position, head turned to the left, with exposure of the right side of the face, neck, and chest
- Shoulder roll for neck extension and right trunk roll for maximal

exposure of the right side of the chest

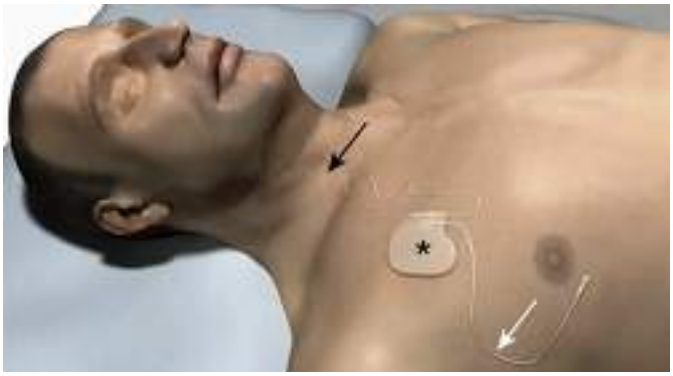

FIG. 56.2 Implantable upper airway stimulation hypoglossal nerve stimulation system.

The hypoglossal nerve stimulation system consists of three implanted components: (1) an implantable pulse generator in a subcutaneous pocket in the upper chest *(asterisk),* (2) a stimulation lead with a cuff electrode placed on the medial branch of the hypoglossal nerve in the submandibular space *(black arrow),* and (3) a sensing lead to detect ventilatory effort placed in the intercostal space facing the pleura *(white arrow)*.

Perioperative Antibiotic Prophylaxis

- Standard intravenous antibiotics dose preoperatively

Monitoring

- Standard anesthesia and cardiopulmonary monitoring
- Intraoperative nerve monitoring with fine-wire electrodes in the genioglossus muscle and hyoglossus muscle

Instruments and Equipment to Have Available

- Intraoperative nerve monitoring system with bipolar stimulation probe
- Standard head and neck instrument set. Instrumentation and nerve dissection share similarities with parotidectomy.
- Monopolar and bipolar cautery
- Angled Debakey forceps and right angle clamp for placement of the cuff electrode on the nerve
- The three implantable HNS components: Stimulation cuff electrode, pulse generator, and pleural respiratory sensor
- Sterile telemetry unit and physician programmer for intraoperative device testing and programming

Key Anatomic Landmarks

- Cuff electrode placement
  - Junction of the digastric tendon and the antero inferior border of the submandibular gland
  - Free edge of the mylohyoid muscle
  - Breakpoint between the lateral hypoglossal nerve branches to the retractor muscles and the medial branches to the tongue protrusor muscles
  - Distal edge of the hyoglossus muscle
- Pulse generator placement
  - Pectoralis fascia
- Respiratory sensor placement
  - Fifth or sixth intercostal space
  - External intercostal muscle
  - Superior border of the lower rib (to avoid injury to the neurovascular bundle)

Prerequisite Skills

- Neck dissection
- Excision of the submandibular gland

Operative Risks

- Bleeding
- Nerve injury (cranial nerve XII or marginal branch of cranial nerve VII)
- Pneumothorax
- Poor cuff placement and suboptimal tongue movement
- Inadequate respiratory sensor waveform
- Device malfunction

Surgical Technique

- Surgical incision planning
  - The incision in the neck for the cuff electrode is similar to a standard submandibular gland incision but placed slightly more anteriorly to access the distal branches of the hypoglossal nerve. The incision is approximately 3 cm in length, between the mandibular body and hyoid, parallel to or within a natural skin crease (Fig. 56.3). The right side is most commonly used for implantation, unless there is a contraindication requiring use of the left side.
  - The chest incision for the pulse generator is placed ipsilateral to the planned neck incision, approximately 4 cm below the clavicle and medial to the deltopectoral groove to avoid restriction of arm movement (Fig. 56.4).
  - The respiratory sensing lead incision is placed ipsilateral to the planned chest incision, overlying the fifth or sixth rib space at approximately the intersection of the anterior axillary line and the nipple line.
- Preparation and draping
  - Fine-wire electrodes are placed in the genioglossus muscle and hyoglossus muscle on the planned side and connected to the nerve

monitoring system.

- Standard sterile preparation including iodine impregnated drape (Ioban)
- View of the tongue is maintained through a clear sterile drape to allow for intraoperative assessment of tongue movement.

- Cuff electrode placement
  - An incision is made in the right upper neck and carried through the platysma, exposing the junction of the digastric tendon and the antero inferior border of the submandibular gland.

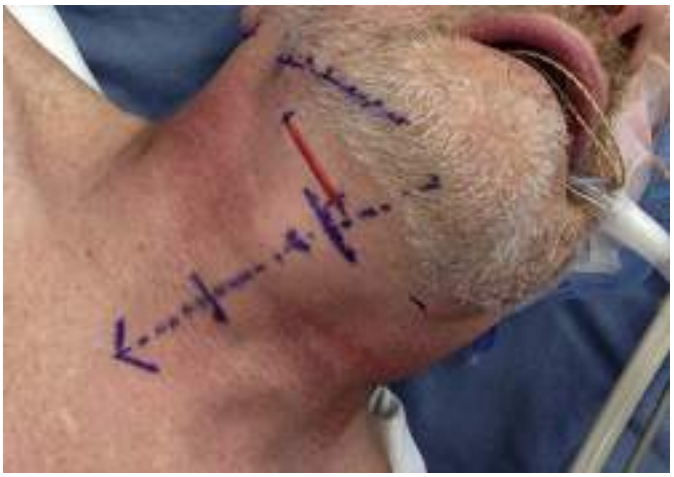

FIG. 56.3 Cuff electrode incision planning.

The incision in the neck for the cuff electrode *(red line)* is placed in the submandibular triangle. It is placed more anteriorly and superiorly than a standard submandibular gland incision to ease access of the distal branches of the hypoglossal nerve. It is ideally placed in a natural skin crease for cosmesis.

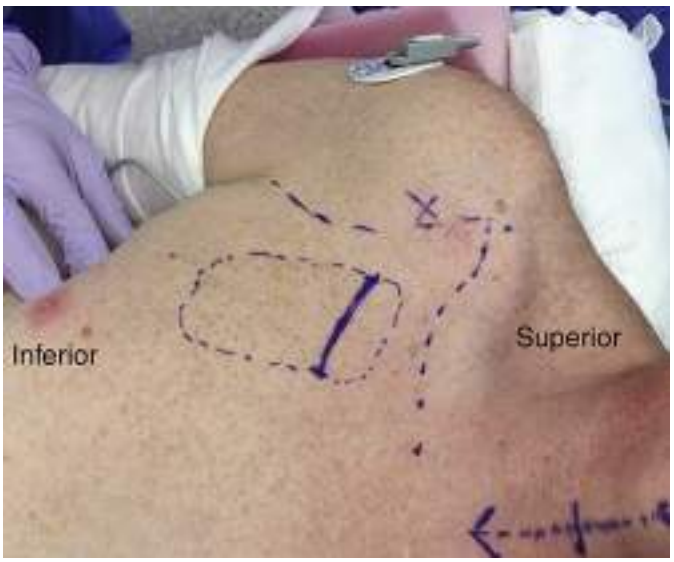

FIG. 56.4 Pulse generator incision planning.

The chest incision for the pulse generator is placed on the ipsilateral side as the planned neck incision, approximately 4 cm below the clavicle and medial to the deltopectoral groove to avoid restriction of arm movement.

- The gland is retracted postero superiorly and the free edge of the mylohyoid retracted antero superiorly to expose the floor of the submandibular triangle where the hypoglossal nerve is identified.
- The ranine vein is clamped, divided, and ligated.
- Anatomic landmarks and intraoperative nerve monitoring are used to selectively capture the distal tongue protrusor branches supplying the genioglossus muscle activity and to exclude branches innervating the tongue retractor muscles (Fig. 56.5).
- The stimulation cuff electrode is placed around the distal protrusor branches and secured to the digastric tendon. If accessible, the C1 branch coursing along the inferior aspect of the hypoglossal nerve and innervating the geniohyoid muscle may also be included in the cuff.

- Pulse generator placement
  - A second incision is made in the right upper chest approximately 4 cm below the clavicle. The incision should be roughly centered over the right pectoralis muscle. Placing the pulse generator more laterally near the deltopectoral groove may cause it to interfere with

shoulder movement.

- A subcutaneous pocket overlying the pectoralis fascia is created for placement of the pulse generator.

- Respiratory sensor placement
  - A third incision is made in the right lateral chest at approximately the intersection of the anterior axillary line and the nipple line for placement of the pleural respiratory sensor.
  - Dissection is carried to the chest wall, staying inferior to the pectoralis muscle and anterior to the serratus muscle, until the external intercostal muscle of the exposed rib space is identified.

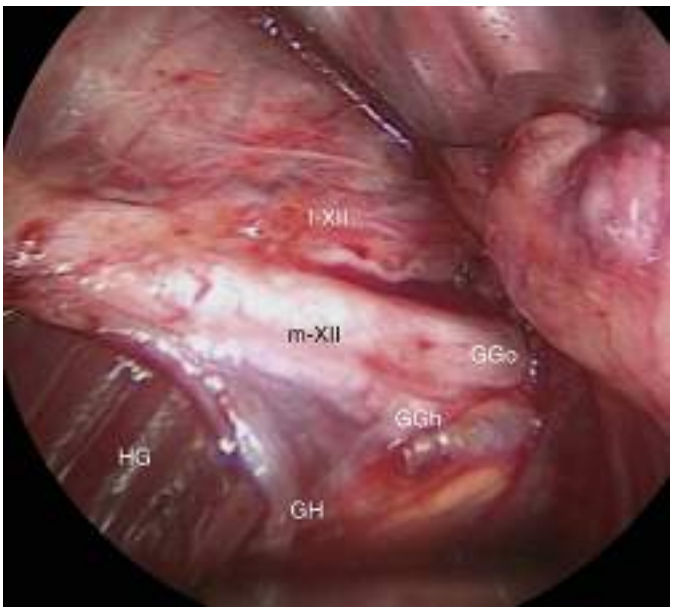

FIG. 56.5 Intraoperative neuroanatomy of the hypoglossal nerve.

The tongue protrusor branches (m-XII, GGo, GGh, and GH) are selectively included in the cuff electrode, while the retractor branches (l-XII) are excluded, to maximize tongue protrusion during stimulation. *GGh,* Medial branch to the horizontal fibers of the genioglossus muscle; *GGo,* medial branch to the oblique fibers of the genioglossus muscle; *GH,* medial branch to the geniohyoid muscle; *HG,* hyoglossus muscle; *l-XII,* lateral hypoglossal nerve branches to the styloglossus and hyoglossus muscles; *m-XII,* medial hypoglossal nerve branches to the genioglossus and geniohyoid muscles.

- The sensor is inserted, facing the pleura, into a tunnel between the external and internal intercostal muscles in approximately the fifth or sixth intercostal space and secured to the chest wall.

- Completion
  - The sensing lead and stimulation lead are each tunneled into the subcutaneous pocket in the right upper chest and connected to the implantable pulse generator. The generator is then secured to the pectoralis fascia.
  - The sterile telemetry unit is brought into the field for device interrogation and programming. Electrical stimulation of the appropriate distal protrusor branches and an adequate respiratory sensing lead waveform are confirmed, followed by visual confirmation of adequate tongue protrusion. The three wounds are then irrigated and closed in a multilayer fashion with absorbable suture.
  - Steri-strips and pressure dressings are applied. Drains are not used.

Common Errors in Technique

- Placing the incision in the neck too far posteriorly, similar to a standard submandibular gland approach, may create a long tunnel and difficult access to the distal branches of the hypoglossal nerve.
- Incorrect placement of the cuff electrode. A common pitfall involves inclusion of a distal lateral retractor branch in the cuff. Intraoperative nerve monitoring and/or observation of tongue movement should identify suboptimal placement of the cuff. Repositioning of the cuff should be directed accordingly.
- Violating the external jugular vein during the tunneling process. Staying anterior to the external jugular vein may avoid troublesome intraoperative bleeding.

Postoperative Period

Postoperative Management

- Radiographs of the neck and chest are obtained in the recovery room prior to discharge to document baseline position of the components.
- Disposition: Unlike traditional anatomy-altering sleep surgery procedures, the majority of HNS patients can be safely discharged the same day given the lack of airway surgery, the minimal or lack of opioid pain medication use, and absence of significant obesity per the screening criteria.
- Diet: Regular
- Activity: Avoid strenuous activity or heavy lifting, particularly repetitive activity of the right arm, for the first 2 to 3 weeks.
- Medication: Over-the-counter acetaminophen and/or non-steroidal anti-inflammatory medication
- Follow-up:
  - Postoperative check-up and wound examination 1 to 2 weeks after surgery
  - Device activation and programming in the outpatient office approximately 1 month after surgery
  - Postoperative sleep study to evaluate therapy effectiveness and to optimize stimulation settings approximately 2 months after surgery (1 month after activation and therapy initiation)
  - Standard long-term outpatient follow-up to monitor therapy adherence, to assess symptomatic improvement and subjective outcomes, and to check device

Complications

- Procedure-related
  - Bleeding
  - Infection, including possible need for device explants
  - Hematoma or seroma
  - Injury to the hypoglossal nerve and associated change in speech or swallowing

    - Injury to the marginal branch of the facial nerve and associated lower lip weakness
    - Pneumothorax
- Therapy-related
    - Abrasion of the tongue
    - Discomfort or sleep disturbance (insomnia) due to stimulation
    - Unfavorable tongue protrusion and inadequate therapy response

Alternative Management Plan

At any stage of OSA evaluation and management, patients should always be offered to continue or revisit PAP or other medical device therapy. Upper airway reconstructive surgery options may also be considered as an alternative to HNS therapy. Finally, combination therapy with more than one medical and/or surgical treatment may be required in some patients, particularly those with more severe disease.

Discussion

Evidence-Based Medicine Question

What is the long-term safety and effectiveness of HNS therapy in patients who meet recommended clinical and anatomic screening characteristics?

Editorial Comment

The multicenter prospective Stimulation Therapy for Apnea Reduction (STAR) Trial demonstrated that approximately two-thirds of participants met responder status for objective measures of OSA and even more reported significant improvements in snoring, daytime alertness, and sleep-related quality of life. Furthermore, the results were maintained at 2- and 3-year follow-up periods. Subjective adherence rates were high while serious device- and procedure-related adverse events were very low, including no cases of permanent nerve injury.[3,4]

Review Questions

1. Which of the following muscles is the primary upper airway dilator?

   a. Hyoglossus

   b. **Genioglossus**

   c. Styloglossus

   d. Geniohyoid

   e. Stylohyoid

2. Electrical stimulation of nerve branches to which of the following muscles will result in retraction of the tongue?

   a. Genioglossus

   b. Hyoglossus

   c. Styloglossus

   d. **Both B and C**

   e. A, B, and C

3. Based on the current available literature, which of the following clinical characteristics are contraindications to HNS therapy?

   a. **BMI of 42 kg/m^2**

   b. AHI of 62

   c. Anterior-posterior pattern of palatal collapse on DISE

   d. Patient age of 82

   e. Presence of a cardiac pacemaker

Hyoid Suspension

Andrea Lewis, and Allison Ordemann

Abstract

For patients with moderate to severe obstructive sleep apnea who fail continuous positive airway pressure, a variety of surgical procedures are available. To determine the surgical intervention most suitable, the airway is fully evaluated for level, pattern, and degree of airway collapse. In a prospective study of 108 patients, Kezirian et al. found hypopharyngeal collapse in 83% to 84% of subjects undergoing sleep endoscopy. Treating the tongue base and epiglottis can be difficult with a number of available procedures being invasive, thus requiring significant recovery time and potential for complications. Hyoid suspension is a relatively noninvasive technique with a low complication rate often utilized to address anteroposterior collapse at the base of tongue and epiglottic levels. It can be performed as an isolated procedure or in combination with those addressing velopharyngeal, oropharyngeal, or nasal obstruction. This chapter describes the hyoid to mandible suspension procedure in detail and includes preoperative, perioperative, and postoperative recommendations as well as potential complications.

Introduction

It is estimated that adequate adherence to continuous positive airway pressure (CPAP) may vary from 28% to 80%.[1] For patients with moderate-to-severe obstructive sleep apnea (OSA) who fail CPAP, a variety of surgical procedures are available. To determine the surgical intervention most suitable, the airway is fully evaluated for level, pattern,

and degree of airway collapse. In a prospective study of 108 patients, Kezirian et al. found hypopharyngeal collapse in 83% to 84% of subjects undergoing sleep endoscopy.[2] Treating the base of the tongue and epiglottis can be difficult, with a number of available procedures being invasive, thus requiring significant recovery time and the potential for complications.

Hyoid suspension (HS) is a relatively noninvasive technique with a low complication rate, often used to address anteroposterior (AP) collapse at the base of the tongue and epiglottic levels (Fig. 57.1). It can be performed as an isolated procedure or in combination with those addressing velopharyngeal, oropharyngeal, or nasal obstruction.

Key Operative Learning Points

1. Operative procedures for OSA should minimize morbidity and preserve function. Leave the stylohyoid muscles attached to the hyoid bone. This is the key mechanism that advances the base of the tongue when the hyoid is suspended to the mandible.

2. When suspending the hyoid, make sure the patient's head is in normal pillow supine position. Adequate suspension should be obtained without overtightening to avoid suture breakage or complications.

3. The patient should be reevaluated with polysomnography (PSG) and long-term follow-up after HS is necessary, to evaluate for return of symptoms or signs of progression of OSA.

Preoperative Period

History

1. History of present illness

   a. Sleep architecture: Assess hours of sleep per night, number of nighttime awakenings, and use of sleep medications.

   b. Sleep-related symptoms: Evaluate for the presence of snoring, witnessed apneas, restless sleep, sleep maintenance or onset insomnia, perspiration during sleep, nocturnal enuresis, nighttime

seizures, narcolepsy, and restless leg symptoms.

c. Daytime-related symptoms: Evaluate for the presence of excessive daytime sleepiness, morning headaches, and awakening feeling tired.

d. Changes in weight should be quantified over a defined period of time.

e. PSG: Has a PSG been obtained? If so, what are the results? When was the study done? Has there been any weight or health changes since the study? PSG should always be obtained prior to any surgical procedures.

f. CPAP use: Has this been trialed yet? If so, is the patient able to tolerate it? If the patient is not able to tolerate it, why? Has any other medical therapy been tried?

2. Past medical history

a. Medical comorbidities

1) Hypertension (controlled?), cardiac arrhythmias (atrial fibrillation?), congestive heart failure, obesity hypoventilation syndrome, pulmonary hypertension, chronic obstructive pulmonary disease, neuromuscular/neurodegenerative disorder, additional sleep disorders

b. Surgical history

1) Tonsillectomy, adenoidectomy, septoplasty, turbinate reduction, rhinoplasty, bariatric surgery

c. Family history

1) Anesthesia-related complications

d. Medications

1) Antiplatelet drugs

2) Herbal products

3) Alcohol

e. Social history

1) Smoking status

2) Caffeine intake per day

3. Epworth sleepiness scale

A subjective patient self-assessment tool to determine sleepiness level with various activities. Comparison of preoperative and postoperative scores may assist in the evaluation of subjective outcome measures.

Physical Examination

1. Vital signs

Resting pulse oximetry and body mass index (BMI) should be recorded.

2. Nose

Evaluate for deviated septum, inferior turbinate hypertrophy, and nasal valve collapse.

3. Oral cavity and oropharynx

Note size and presence or absence of tonsils, ability to visualize the uvula, soft palate, and hard palate for determination of Friedman tongue position. This can be instrumental in guiding surgical management.

4. Neck

Measure the circumference of the neck. Note whether there is a large amount of subcutaneous adipose tissue or musculature, especially over the hyoid, because this may limit surgical success. Palpate laryngeal landmarks (i.e., hyoid bone and thyroid cartilage).

5. Flexible supine nasopharyngoscopy

Flexible supine endoscopy is the most important preoperative portion of the examination. This can be done awake in the office and/or under sedation in the operating suite. We prefer drug-induced sedation endoscopy in the operating suite because it best mimics the sleep state. If performed in the office, addition of the Müller maneuver (inhalation with nasal and oral passages closed) can help to simulate an obstructive event. During endoscopy, the level (velopharyngeal, oropharyngeal, or hypopharyngeal), degree, and pattern of upper airway collapse is noted to determine the most suitable surgical intervention. Perform a jaw thrust

maneuver to evaluate whether collapse improves. Note VOTE (velum, oropharynx, tongue base, epiglottis) classification.

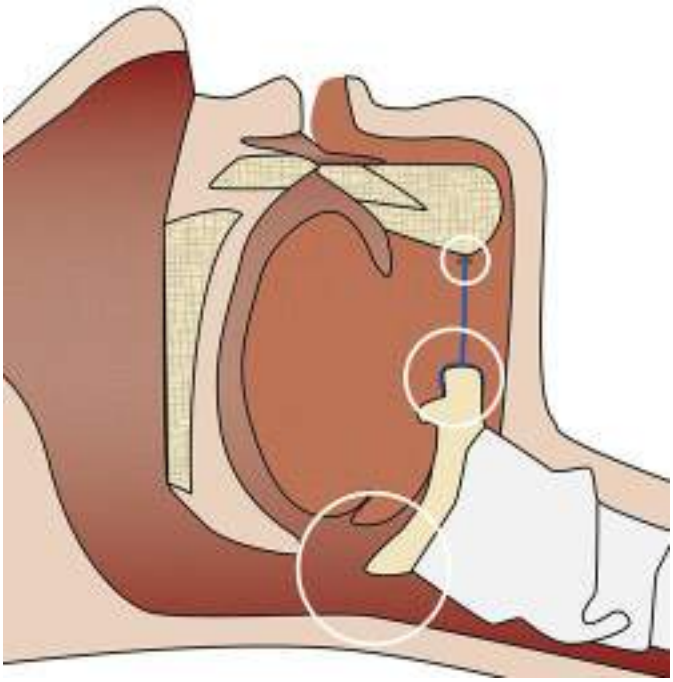

FIG. 57.1 Hyoid to mandible suspension showing favorable expansion of the hypopharyngeal space.

Procedures

Polysomnography

Preoperative sleep testing with home portable monitoring or in-lab PSG is necessary for diagnosis of OSA. Medical necessity for treatment is often considered an apnea-hypopnea index (AHI) of greater than 15 or an AHI greater than 5 with sleep-related symptoms or comorbidities. Prior to surgical intervention, all patients should demonstrate inability to successfully use CPAP or other medical therapy options.

Imaging

No required imaging procedures, although lateral cephalometric radiograph may be considered for preoperative planning and

documentation of hyoid position.

Indications

1. Patients with moderate-to-severe OSA (AHI of 15 or greater), who have failed adequate trial of CPAP or other medical therapy, with specific hypopharyngeal collapse at the base of tongue or epiglottis, as demonstrated on supine awake and/or sedated flexible endoscopy (Fig. 57.2)

2. Often used as a multilevel treatment of OSA in conjunction with other sleep surgical interventions aimed at addressing nasal, velopharyngeal, and/or oropharyngeal collapse

Contraindications

1. Medical comorbidities presenting increased risk for undergoing general anesthesia or upper airway procedures

2. Prior Sistrunk procedure

Preoperative Preparation

1. Preoperative anesthesia visit should be performed on all patients due to their history of OSA. Bloodwork, chest radiograph, electrocardiogram, and additional preoperative testing are dictated by the patient age, comorbidities and symptoms, and factors as with any procedure using general anesthesia.

FIG. 57.2 Collapse of the base of the tongue and epiglottis.

2. Discontinue antiplatelet drugs.

Operative Period

Anesthesia

General

Dependent on technique and surgeon preference, the type of anesthesia will vary. We prefer general anesthesia for patient comfort.

Awake sedation

Awake sedation may also be used as an alternative. One advantage is to allow for better postoperative evaluation of hypopharyngeal airway collapse with drug-induced supine sleep endoscopy. This should be used with caution in patients with severe OSA or those suspected to be difficult to intubate.

Local

Local anesthetic has been described as a viable technique for patients undergoing isolated HS to the thyroid cartilage.

Positioning

Supine

The head of the bed should be rotated 90 to 180 degrees away from the anesthesiologist. This will vary depending on surgeon preference and room setup. This is done to allow room for one or two assistants who are placed directly opposite the surgeon and/or at the patient's head.

Perioperative Antibiotic Prophylaxis

First-generation cephalosporin

Cefazolin is often used in the our institution because this provides adequate gram-negative and gram-positive coverage. The typical dose is 2 g given intravenously prior to incision.

Clindamycin

Clindamycin is used if the patient is allergic to penicillin. The typical dose is 600 mg given intravenously prior to incision.

Monitoring

Routine general anesthesia monitoring

Instruments and Equipment to Have Available

1. Standard soft tissue neck instrument set

This should include knife handle, Senn retractors, Army-Navy retractors, Molt elevator #9, hemostat or other blunt dissecting instruments, Lahey or Allis clamp, toothed forceps, and needle driver.

2. Monopolar electrocautery: for division of subcutaneous tissues and

musculature

3. Bipolar electrocautery: for control of bleeding around nerves. Can be used instead of monopolar electrocautery in the event of a pacemaker or defibrillator device.

4. For hyoid to mandible suspension, specific equipment will be needed. Two systems are currently available on the market.

a. Encore (Siesta Medical, Los Gatos, CA) system

1) A drill is necessary with this system.

b. AIRvance (Medtronic, Dublin, Ireland) system

Key Anatomic Landmarks

1. Hyoid Bone: A horseshoe-shaped bone in the anterior midline of the neck situated between the base of the mandible and the thyroid cartilage that aids in tongue movement and elevation of the larynx anteriorly and superiorly in swallowing for airway protection. An inferiorly positioned hyoid is strongly associated with hypopharyngeal collapse.

2. Thyroid cartilage: A shield-shaped cartilage that protects the vocal cords and whose movement produces a change in vocal pitch. Its easily palpable superior thyroid notch marks midline, and it is attached to the hyoid via the thyrohyoid membrane.

3. Stylohyoid muscle: A slender muscle attaching at the junction of the lesser and greater cornu of the hyoid bone originating from the styloid process. It acts to elevate the hyoid bone during swallowing. This should be preserved to ensure proper advancement of the base of the tongue.

4. The inferior border of the mandible.

Prerequisite Skills

1. Familiarity with midline neck and floor of mouth anatomy to be able to correctly identify the hyoid bone and associated musculature

2. Efficiency in drug-induced sleep endoscopy and ability to discern the level, pattern, and severity of airway collapse

Operative Risks

1. Injury to the hypoglossal nerve

If dissection around the hyoid is carried out too far laterally or superiorly, the hypoglossal nerve may be damaged. This can be avoided by staying in the midline, identifying the hyoid bone with blunt dissection, and carefully skeletonizing only the central portion of the hyoid bone.

2. Injury to the internal branch of the superior laryngeal nerve

Limiting the dissection near the lesser cornu will minimize the risk of injury to the superior laryngeal nerve.

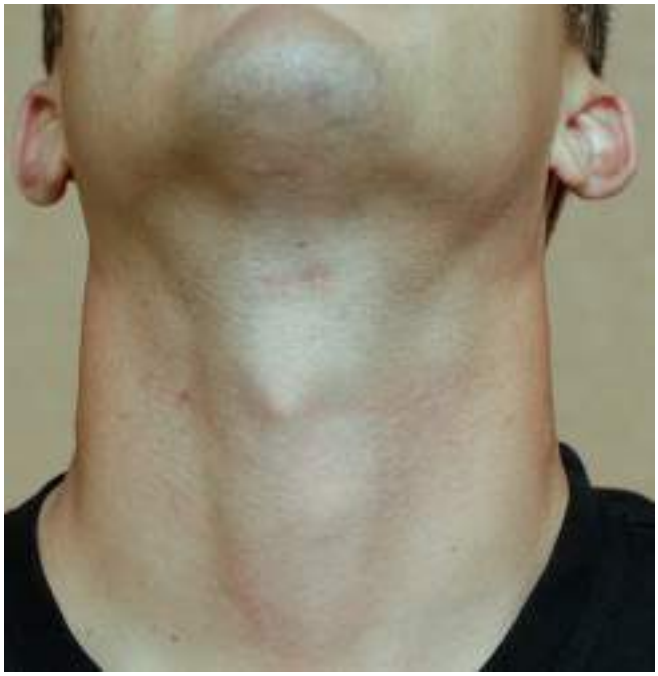

FIG. 57.3 Healed incisions.

3. Dental injury

Placement of bone screws in the mandible is performed along the posterior lingual surface of the mandible at the level of the canines. If the screw is placed too far superiorly, injury to the tooth roots can occur. Screws are typically placed 1 cm superior from the inferior border of the mandible.

4. Bleeding

Bleeding is managed in standard fashion with bipolar electrocautery and suture ligation.

Surgical Technique

Hyoid to Mandible Suspension

- Surgical incisions marked

  We use two incisions on the anterior neck (Fig. 57.3). The first is a 2-cm horizontal incision near the hyoid in a neck crease. The second is a 2-cm or smaller horizontal incision in the submental area posterior to the mentum.

  Some surgeons prefer one larger incision placed in the submental region above the hyoid. The author We prefer two incisions for better visualization throughout the surgery and flexibility to camouflage the incisions.

- Local anesthetic injection

  Lidocaine (1%) with epinephrine (1:100,000). A small amount is injected subcutaneously at planned incision sites. Avoid excessive amounts that may obscure laryngeal landmarks.

- Standard surgical preparation and draping

  Betadine solution, or chlorhexidine if the patient is allergic to iodine. The entire midline neck, including submental area, should be prepped. Four sterile towels should be placed, leaving the midline neck and chin visible.

- Skin incisions and dissection

  The skin is incised with a no. 15 blade at previously described incisions. Monopolar cautery is used to extend skin incisions through the subcutaneous adipose tissue and platysma layers. Next, the hyoid bone is identified through the inferior incision and inferior border of the mandible through the submental incision. Care is taken to stay right on the hyoid bone and limit dissection so that the muscles can remain attached.

- Skeletonization of the lingual surface of the inferior mandible approximately 1.0 cm lateral to the midline on either side

  Using monopolar cautery and a Molt elevator #9 through the submental incision, a small area of bone should be cleared of muscular and soft tissue attachments as described in preparation for insertion of bone screws. Avoid skeletonizing large areas.

- Insertion of bone screws into the mandible

  There are various products on the market currently to accomplish this. Depending on the system used, these steps will vary slightly. We have used both the handheld self-drilling AIRvance system and the Encore system, which requires predrilled 1.5-mm holes. In either system the bone screws are placed along the inferior lingual surface of the mandible in a region previously skeletonized. Screws should not be placed more than 1 cm superior from the inferior edge to avoid damage to the tooth roots. In the AIRvance system, two sutures are embedded within the bone screw and used in the next step.

- Placement of looping sutures around the hyoid bone

  A Lahey or Allis clamp should be placed around the hyoid bone to facilitate this step.

  In the Encore system the provided suture passer is passed from inferior to superior around the hyoid. The working suture is then loaded into the suture passer and brought around the hyoid bone as the passer is removed. The loops of the two suspension sutures are then placed through the loop of the working suture, which is then pulled so that the suspension sutures are around the hyoid bone. Girth hitches are created by pulling the tails of the suspension sutures through the loops and tightening (Fig. 57.4A and B).

  In the AIRvance system the looped sutures are embedded within the bone screws. A 1-inch McGowan needle is used to pass the sutures around the hyoid. On one side the suture is passed in an inferior to superior manner, whereas the contralateral side should be passed superior to inferior to allow opposing suture ends (Fig. 57.5A). Each suture should be passed twice around the hyoid. An additional suture can be used as a working suture and tightened to the suspension sutures to prevent having to pass each suture around the hyoid more than once.

- Tightening of sutures

  At this point, we prefer to use a flexible endoscope, which should be passed by an assistant for visualization of the hypopharynx to ensure that tightening the sutures to the airway will improve the airway space and does not retroflex the base of the tongue. Sutures should be tightened until adequate improvement in the anteroposterior dimension of the hypopharyngeal airway is achieved. Usually this requires approximately 1.5 cm of anterior superior pull with the patient's head in the neutral position.

  In the Encore system the tightened sutures are locked in place using a binary screw with a bone screw and a set screw. Subsequently the sutures are passed through the holes in the screw system. The set screws are then used to hold the sutures in place in position (see Fig. 57.4C). In the AIRvance system the tightened sutures are tied in a standard fashion with multiple surgeon's knots (see Fig. 57.5B).

- Hemostasis is obtained.

  In the event of any bleeding, which is rare, bipolar electrocautery should be used prior to wound closure.

- Irrigation of the wound with antibiotic solution

- Closure of the incision

  Closure can be performed to surgeon preference. We prefer to reapproximate the platysma and subcutaneous tissues with 4-0 Vicryl in an interrupted, buried fashion. The skin is closed with Dermabond. A drain is typically not used, although this has been described in the literature in an effort to prevent a seroma.

- Dressing

  A pressure dressing, such as the Jobst fascioplasty elastic dressing, is placed.

Common Errors in Technique

1. Overskeletonizing the hyoid bone: Release of the stylohyoid muscle will decrease the effectiveness of the surgery and may lead to aspiration postoperatively.

2. Difficulty placing bone screws: Check to ensure that the muscle attachments are completely removed from the mandible at the desired placement site to ensure proper seating of bone screws.

3. Incorrectly looping sutures: When using the AIRvance system, the surgeon must ensure that the contralateral sutures are looped in opposing directions around the hyoid to have the correct vector pull.

4. Suture tightening: The sutures must be tightened enough that the patient receives maximal benefit from an airway standpoint. However, tightening them too much may lead to aspiration or suture breakage, which may require further surgery.

5. Failure to create subplatysmal dissection tract between skin incisions: This may lead to unsightly suture lines under the skin.

Postoperative Period

Postoperative Management

1. Overnight observation: Patient is kept overnight in a monitored bed with pulse oximetry.

2. CPAP use restarted at current or decreased settings, if tolerated

3. Pain medication: Narcotic pain medication should be limited to avoid suppression of respiratory drive, but typically patients are discharged with liquid hydrocodone.

4. Postoperative steroids: Intravenous dexamethasone is given while in the hospital. Oral steroid course is often provided at discharge.

5. Postoperative antibiotics: 1 week of amoxicillin-clavulanate or comparable oral antibiotic

Complications

1. Dysphagia

Temporary difficulty and discomfort with swallowing is expected. Patients should be counseled preoperatively about this expectation. This

may last up to 4 weeks but usually resolves within the first 1 to 2 weeks.

2. Aspiration

The internal branch of the superior laryngeal nerve supplies sensation to the supraglottic airway, and injury may lead to aspiration. Patients have also had aspiration develop after aggressive suspension, leading us to believe that the hyoid should not be too aggressively suspended. This is treated with partial release. Aspiration is usually transient.

3. Seroma and Hematoma

A seroma should be drained with a large-gauge needle, and a compressive dressing should be placed. If a hematoma is occurring rapidly, the incision should be opened and the patient should be taken back to the operating suite to obtain hemostasis. Some surgeons leave in a drain for 1 to 2 days.

4. Cellulitis or breakdown of skin incision

Treat conservatively with broad-spectrum antibiotics and local wound care.

5. Breakage of suspension material

If this occurs, further surgical management will be needed. Alternative surgical interventions can be considered.

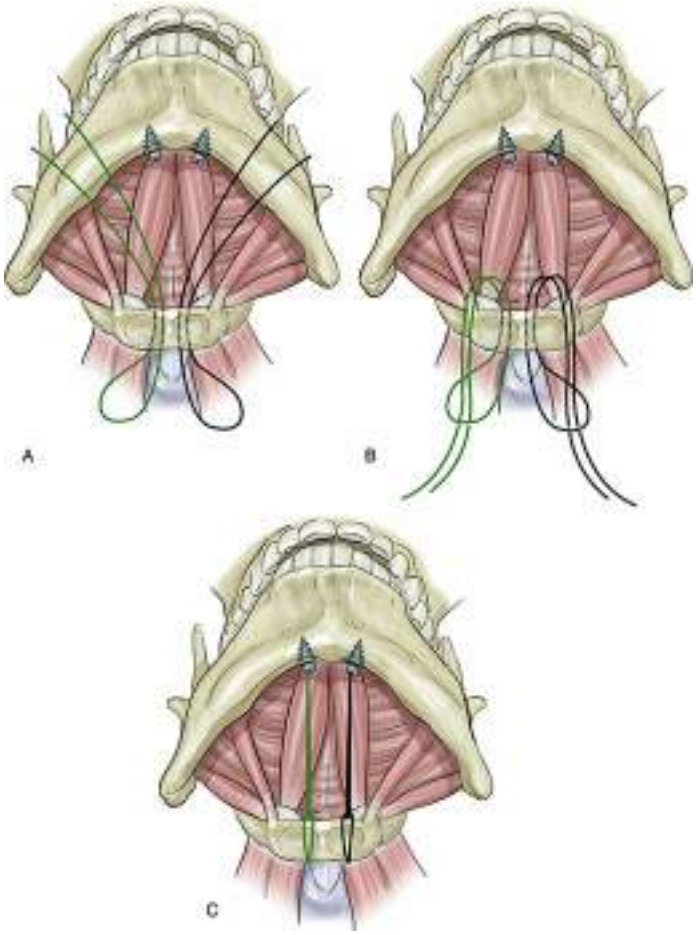

FIG. 57.4 Hyoid to mandible suspension technique using the Encore system. **A**, The loops of the suspension sutures are placed around the hyoid bone using the working suture. **B**, Girth hitches are created by pulling the tails of the suspension sutures through the loops and tightening. **C**, The sutures are passed through the holes in the screw system. The set screws are used to hold the sutures in place.

Alternative Management Plan

1. Other surgical interventions to address hypopharyngeal collapse: There are a variety of alternative surgical therapies to address base of tongue and hypopharyngeal collapse. These include tongue base reduction techniques (midline glossectomy, lingual tonsillectomy, radiofrequency ablation of the tongue), genioglossus advancement, maxillomandibular advancement, and hyoepiglottoplasty. These

procedures are not suitable for every patient and should be carefully selected on an individualized basis.

2. Weight Loss: Many OSA patients are overweight. Weight loss can lead to improvement in AHI in a large percentage of these patients and should always be encouraged.

3. Continued CPAP use: If the patient is not a suitable operative candidate or does not wish to undergo invasive techniques, alternative CPAP masks should be trialed to improve compliance. Different masks include nasal pillows, nasal prongs, and nasal and oral masks.

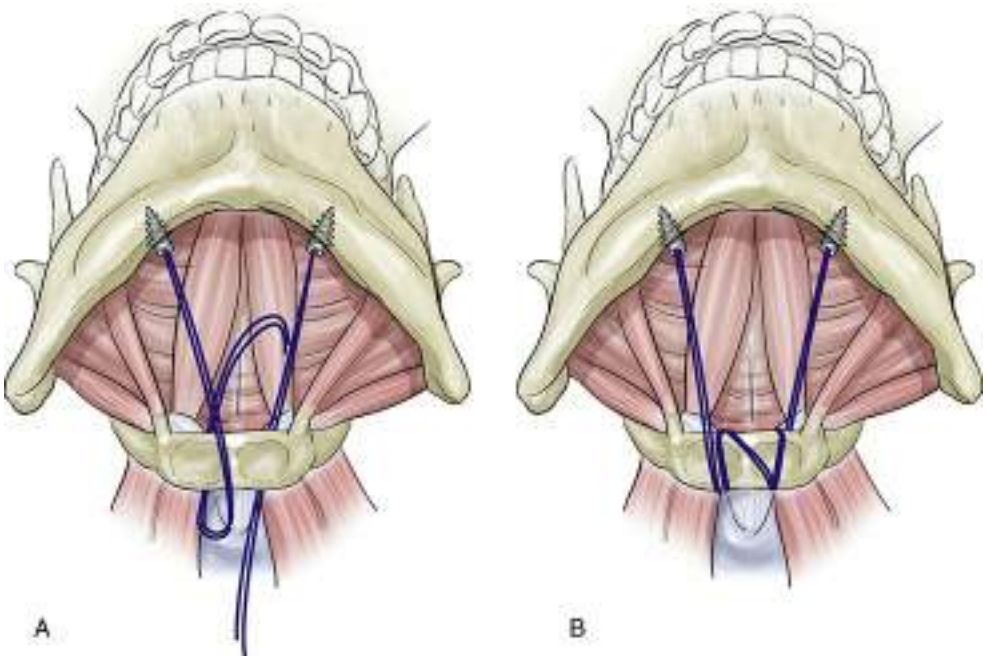

FIG. 57.5 Hyoid to mandible suspension technique using the AIRvance system. **A**, Suspension suture is passed inferior to superior on one side and superior to inferior on the contralateral side. Each suture is passed twice. **B**, The tightened sutures are tied to each other with multiple surgeon's knots.

Discussion

Evidence-Based Medicine Question

What is the efficacy of hyoid to mandible suspension when used as part of a multilevel airway surgical approach? Is the efficacy better or worse than hyoid to thyroid suspension when used as part of a multilevel airway surgical approach? How does BMI affect surgical success?

HS can be performed as hyoid to mandible, as described previously, or hyoid to thyroid. Original description of the procedure was that of using a fascia lata sling suspending the hyoid from the mandible. This was modified to the hyoid to thyroid suspension to reduce the morbidity of the surgery.[2] With advances in technology, hyoid to mandible suspension has become much less invasive, requiring minimal dissection and short operative length.

There is little in the literature directly comparing the two variations of the procedure. Indeed, most of the literature on HS outcomes has been done on the hyoid to thyroid suspension modification. However, Gillespie et al. reported a surgical success rate (defined as a >50% reduction in AHI and AHI <20 postoperatively) in 70% of their patients undergoing hyoid to mandible suspension as part of a multilevel upper airway surgery.[3] An evidence-based medicine review on hypopharyngeal surgery in OSA by Kezirian and Goldberg showed that surgical success rates (defined the same way) ranged from 17% to 78% in patients undergoing hyoid to thyroid suspension as part of a multilevel upper airway surgery.[4] Bowden et al. performed the previously described study with the lowest success rate (17%). She compared her results to that of Neruntarat et al. (2003) and found her population to have a statistically significant larger BMI (average BMI of 34.1 vs. 29.4, respectively) and lower nadir oxygen saturation on preoperative sleep study (72.7% vs. 82.1%, respectively).[5]

Therefore the literature supports the relative success of hyoid to mandible suspension in comparison with that of hyoid to thyroid suspension, although this is debatable given the paucity of data. Some feel that this is due to the anterosuperior vector of pull on the hyoid with hyoid to mandible suspension, which allows for greater hypopharyngeal displacement than that of the anteroinferior vector of hyoid to thyroid suspension. Others still feel the hyoid to thyroid technique to be less invasive and feel that it adequately stabilizes the base of the tongue and epiglottis, preventing collapse during sleep. Some surgeons also feel that hyoid to thyroid may be more successful in male patients versus female

patients, given the difference in anatomy.

Do additional procedures improve outcomes of HS or can it be used as a stand-alone procedure?

A MEDLINE review by Randerath et al. showed effectiveness of isolated HS for OSA to be 49.5% when averaging the success rates from three studies, assigning this a grade C recommendation level. Stronger recommendation level (grade B) was given to performing HS as part of a multilevel airway surgery (MLS), citing two level 2b studies finding a significant increase in effectiveness in those undergoing HS in MLS when compared with those not undergoing HS in MLS.[6]

Editorial Comment

The hyoid bone has key ligamentous and muscular attachments to the tongue and to the walls of the hypopharynx. HS provides a reconstructive method to enlarge and stabilize the hypopharyngeal portion of the upper airway with relatively low morbidity and risk. HS may further improve outcomes when combined with palatal surgery as part of a multilevel treatment plan. As with other surgical procedures for OSA, proper phenotyping of the upper airway and patient selection are critical to success. More research is needed to better understand the mechanism of action, most effective surgical technique, and selection of the most appropriate surgical candidates.

Access the review questions and additional sources list online at http://www.expertconsult.com

Review Questions

1. The most common complication following hyoid suspension:

   a. **Dysphagia**

   b. Seroma

   c. Tongue edema

   d. Aspiration

2. Muscle that inserts into the body of the hyoid at its junction with the

greater cornu and should be left intact in hyoid suspension to prevent destabilization of the airway

a. Omohyoid

b. Digastric

c. Genioglossus

d. **Stylohyoid**

3. Limiting dissection of the hyoid to near the lesser cornu will:

a. Prevent injury to the lingual nerve

b. Lessen tongue edema

c. **Decrease the risk of postoperative aspiration**

d. Prevent injury to the external branch of the superior laryngeal nerve

Genioglossus Advancement

Richard Bauer III , and David W. Parker II

Introduction

The pathogenesis of obstructive sleep apnea (OSA) is complex and involves many anatomic and physiologic factors. The Fujita system for classifying the level of airway obstruction is often employed as a diagnostic tool. Level 1 indicates obstruction at the retropalatal/oropharyngeal level area. Level 2 indicates obstruction at the retropalatal/oropharyngeal and retroglossal/hypopharyngeal levels. Level 3 indicates obstruction at the retroglossal/hypopharyngeal area only. One of the major contributors to airway collapse in OSA is loss of muscular activity or tone to the pharyngeal dilators during sleep. The genioglossus muscle is one of the major pharyngeal dilators and the primary muscle allowing tongue protrusion. The muscle is attached to the genial tubercles located on the lingual aspect of the anterior mandible. Thus, its influence on obstruction at the retroglossal/hypopharyngeal level in OSA cannot be understated. For this reason, the genioglossus advancement (GA) procedure, with all of its variations and modifications, was developed.

The original GA procedure was described in a case report detailing a "high" sliding advancement genioplasty osteotomy, which was secured in place via wire osteosynthesis.[1] A limitation of this procedure is failure to capture the entire genial tubercle complex, resulting in suboptimal airway improvement. Riley et al.[6] then modified this procedure to incorporate the entire genioglossus muscle insertion at the genial tubercles using a mortised sliding advancement genioplasty, but the procedure led to higher risks of pathologic fracture of the mandible.[1] Subsequent modifications to reduce fracture risk included a rectangular bicortical osteotomy of the anterior mandible around the region of the genial tubercles, with subsequent advancement and 90-degree rotation of

the attachments, followed by rigid fixation.[1] Lewis and colleagues later described a trephine osteotomy and rigid fixation system for advancing the genial tubercle/genioglossus muscles using the Stryker Leibinger genioglossus bone advancement technique (GBAT) system (Stryker Leibinger, Kalamazoo, Michigan).[1] There have been subsequent modifications and variations to this same theme during the past two decades. With many of these procedures, a simultaneous infrahyoid myotomy and hyoid suspension were often performed (see Chapter 37).

Key Operative Learning Points

1. Patient selection is important to optimize GA surgical results. Patients with mild-moderate OSA and collapse in the retroglossal/hypopharyngeal region may be most likely to respond.

2. GA can be combined with other surgical treatments such as uvulopalatopharyngoplasty (UPPP), bilateral sagittal split advancement osteotomies of the mandible, and bimaxillary advancement osteotomies.

3. Advanced imaging using cone beam computed tomography (CBCT) technology combined with computer-assisted virtual surgical planning and custom three-dimensional (3D) printed marking and positioning guides can minimize operating time and improve the precision of with which the genial tubercles are captured and advanced.

Preoperative Period

History

1. OSA history
   a. OSA diagnosis and severity
   b. Sleep-related symptoms
   c. Medical comorbidities (e.g., hypertension, heart disease)
   d. Prior OSA medical therapy (e.g., continuous positive airway pressure [CPAP], bilevel positive airway pressure [BIPAP], oral appliance)

e. Prior OSA surgical therapy (e.g., UPPP)

f. Comorbid sleep medicine disorders (e.g., insomnia)

2. Past medical history

3. Past surgical history

4. Family history

5. Social history, particularly alcohol and tobacco use

6. Medications, especially anticoagulants or herbal products

Physical Examination

1. *General*—A general examination of the patient is important to assess his or her overall health and development. It is also important to consider his or her body habitus or body mass index (BMI), as patients with high weights or BMI are less likely to benefit from a GA alone.

2. *Head and Neck*—It is important to carefully examine the patient's head and neck to look for any signs of skeletal hypoplasia that could be contributing to the patient's obstructive symptoms. Those individuals that could benefit most from GA often present with mandibular hypoplasia and/or microgenia. Mentalis strain and the competence of the lips are also important; often, skeletal Class II patients have lip incompetence and exhibit mentalis strain when trying to close their lips. Neck circumference and hyoid position are two other factors to consider, as larger, thicker necks are associated with higher risk of OSA, and a low-set hyoid may indicate the same.

3. *Nasal airway*—It is important to thoroughly examine the nasal cavity for any evidence of obstruction that could be resolved via nasal surgery alone or with a combination of nasal surgery and surgery, affecting another level of obstruction.

4. *Oral cavity and oropharynx*—This is a very important examination because it gives valuable information regarding the size of the tongue and its contributions to the patient's obstructive symptoms, the volume of soft tissue comprising the soft palate that may be amenable to UPPP, and the size of the tonsils, which may contribute to the symptoms. It is important to note that the presence or absence of periodontal disease

could increase the risk of fracture if a GA is performed. The amount and health of the keratinized tissue located buccal to the mandibular incisors are important during the postoperative course, as the incision, closure, and any subsequent scarring are located adjacent to this area, and contractures may result in unaesthetic gingival recession around the mandibular incisors.

Imaging

1. *Panoramic Radiograph*—To visualize the periodontal tissues, dentition, height of the anterior mandible, mental foramina, inferior alveolar nerve canal, and temporomandibular joints

2. *Lateral Cephalometric Radiograph*—Evaluate the presence and severity of maxillary, mandibular, and genial hypoplasia, all of which can contribute to various levels of obstruction in the airway during sleep.

3. *CBCT Scan or Maxillofacial CT Scan*—Maxillofacial CT scans, and more recently CBCT scans, have been incorporated into the planning stages of various sleep surgeries, including GA. This is a proven technology that has been used for years and has been shown to have a high degree of accuracy.[2] CBCT scans are advantageous in that they provide useful data regarding the volumetric aspects of the airway. The technology also facilitates the ability to make precise measurements to aid in planning osteotomies, avoiding critical structures such as the mental foramina, and to locate crucial aspects of the patient's anatomy, such as the genial tubercles in this case. In addition, surgical models of the patient's anatomy can be printed and studied along with the fabrication of surgical stents and guides to assist with various osteotomies to be certain that critical structures are included or avoided and that the specific surgical goal that was planned is accomplished. Postoperatively, the patient can be scanned again, and volumetric data can be generated about the increase in airway size and capacity.

Indications

Mild-moderate OSA with failure or inadequate adherence with medical therapy:

1. Retrolingual or hypopharyngeal location of collapse

2. Fujita type 2 or 3

3. Microgenia or mandibular hypoplasia. GA for these patients may have both airway and aesthetic benefits.

Contraindications

1. Significant medical comorbidities prohibiting operative intervention

2. Severe obesity likely to decrease GA effectiveness and increase perioperative risk

3. Airway obstruction localized to Fujita Level 1

4. Severe OSA

5. Severe periodontal disease

6. Patients concerned about transient or permanent V3 paresthesia

Preoperative Preparation

1. Discontinue any antiplatelet and anticoagulant medications if possible.

2. Oxymetazoline nasal spray prior to the induction of nasal endotracheal anesthesia.

3. Consider perioperative course of high-dose steroids to minimize postsurgical edema of the floor of the mouth, tongue, and airway.

Operative Period

Anesthesia

1. General anesthesia with local anesthesia

   a. The patient should be intubated for airway protection; ideally, the patient should have nasal intubation. In the event of a mandible fracture as a complication, the teeth would need to be wired together to set the occlusion before applying any rigid fixation plates.

b. Local anesthesia with epinephrine is helpful for postoperative pain management (mental blocks) but is mainly for infiltration into the anterior mandibular buccal vestibule and floor of the mouth to minimize bleeding and facilitate visualization intraoperatively.

Positioning

1. Supine position with shoulder roll for partial neck extension

Perioperative Antibiotic Prophylaxis

1. Ampicillin/Sulbactam (Unasyn)
2. Clindamycin (Cleocin) for patients who are allergic to penicillin

Monitoring

1. Routine anesthesia monitoring

Instruments and Equipment to Have Available

1. #9 periosteal elevator
2. Frazier tip suction
3. Dingman bone clamp
4. Obwegeser retractors
5. Fine-tipped hemostats
6. Twenty-four-gauge wire; or maxillomandibular fixation screws and 26-gauge wire
7. Wire drivers
8. Wire cutters
9. Scalpel with #15 blade
10. Electrocautery with Colorado microdissection tip

11. Symphyseal retractor

12. Sagittal safe oscillating saw blade

13. Long reciprocating saw blade

14. Maxillofacial plating set with bicortical screws, fixation plates, and/or pre-bent genioplasty advancement plates

15. Compressive facial support dressing

16. Computer-assisted marking and positioning guides (if surgery virtually planned and designed)

Key Anatomic Landmarks

1. Mandibular buccal vestibule—For most solitary GA procedures, a standard intraoral approach is used via the anterior buccal vestibule, which has the advantage of a hidden, intraoral scar. The mandibular buccal vestibule is located between the mandibular incisors and the lower lip. It contains nonkeratinized stratified squamous mucosa.

2. Mentalis muscle—Located beneath the anterior buccal vestibular tissue of the mandible, it is the only elevator of the lower lip and chin. If this muscle is not repositioned properly during the closure, the chin will "droop," leading to a "witch's chin"–type deformity along with the sagging appearing of the lower lip, exposing more lower incisor. The mentalis originates from the mental prominence of the mandible and inserts into the soft tissues of the chin prominence. The most superior fibers are the shortest and pass almost horizontally into the chin, while the most inferior fibers are the longest and pass obliquely or vertically to the skin at the lower aspect of the chin. The origin of the mentalis muscle determines the depth of the labial vestibule. The mentalis muscle is innervated by the marginal mandibular branch of the seventh cranial nerve (facial nerve).[3]

3. Mental neurovascular bundle—The major neurovascular structure that must be avoided during a GA procedure. The artery and vein that accompany the nerve are insignificant from a surgical standpoint. However, the mental nerve is a terminal branch of the mandibular division (V3) of the fifth cranial nerve (trigeminal nerve), and its function is to innervate the skin and mucosa of the lower lip, the facial gingiva of

the mandibular incisors, and the skin of the chin. The mental nerve exits the mental foramen located near the apex of the first or second mandibular premolar teeth and usually then splits into three smaller branches that fan out into the region of innervation. The branching pattern can be variable, and some branches can be superficial within the oral mucosa.[3]

4. Genioglossus muscles/genial tubercles—The genioglossus muscles are one set of extrinsic muscles of the tongue. As such, they originate from the genial tubercles located on the lingual aspect of the mandible and then fan out vertically and horizontally within the body of the tongue. They are the main protrusors of the tongue. The muscles are innervated by the 12th cranial nerve (hypoglossal nerve). They receive their major blood supply from the lingual arteries bilaterally.[3] Silverstein et al., in their classic cadaveric study from 2000, detailed many relevant measurements regarding the nature of the genial tubercles and surrounding anatomy.[4] They showed that the average thickness of the mandible at the genial tubercle was approximately 13 mm at the midline inferior border 14.5 mm.[4] In addition, the average distance from the genial tubercles to the inferior border at midline was 14.5 mm, and the average distance from the apex of the mandibular incisor teeth to the genial tubercle was 11.8 mm.[4] The width of the genioglossus muscle attachments themselves was approximately 14 mm.[4]

5. Digastric muscles—The anterior digastrics are attached to the inferior border of the anterior mandible and the hyoid posteriorly. When advancing the inferior border segment during a GA, these muscles are placed under tension along with the genioglossus, which helps to pull the hyoid anteriorly and superiorly and helps to further open the airway.

Prerequisite Skills

1. Basic mandibular osteotomy skills

2. Familiarity with anatomy of the mandible and the floor of the mouth

3. Experience with internal rigid fixation

Operative Risks

1. Hemorrhage from the floor of mouth from the genioglossus muscles, the mylohyoid muscles, or the lingual or sublingual arteries. This often occurs when patients have remained on antiplatelet or anticoagulant medications or when the reciprocating saw tip is placed too deep into the floor of mouth.

2. Fracture of the mandible—If the inferior border osteotomy is placed too superior, leaving minimal to no mandibular basal bone and only mandibular alveolar bone to provide continuity

3. Damage to the mental nerves—Damage to the nerves can occur during the dissection of the mandible or during the osteotomy.

4. Avulsion of the genioglossus muscles from the genial tubercles—If the osteotomized segment containing the genial tubercles is placed under significant tension, the muscles can avulse from the tubercles.

5. Perforation of the lower lip or labiomental groove—This complication can occur if the surgeon is not careful during the intraoral dissection that is done to access the mandible.

6. Damage to the mandibular dentition—Damage to the teeth can occur during the osteotomy if the osteotomy is made too superior. The apices of the teeth can be cut off the roots, endangering the vitality of the teeth.

Surgical Technique

1. The patient is positioned, padded, prepped, and draped.

2. The anterior mandibular buccal vestibule is injected with 1% lidocaine with 1:100,000 epinephrine, with additional local anesthetic being injected into the anterior floor of the mouth to assist with hemostasis.

3. A moist throat pack is placed in the posterior oropharynx.

4. The jaws can then be wired shut with 26-gauge wire and temporary bone screws to provide stability to the mandible while performing the osteotomy.

   a. You may elect to use surgical marking and positioning guides, which are wired temporarily between the teeth once the dissection is complete. These guides were also screwed into the mandibular bone (Fig. 58.1). The guides, which had been printed with 3D printing

technology, were based off of the data from the patient's preoperative CBCT scan and virtual surgical planning session. Their purpose was to allow us to include the genial tubercles with the osteotomized segment with a high degree of accuracy and then to advance the segment the intended, maximal amount (Figs. 58.2 and 58.3).

5. Two Obwegeser retractors or Army-Navy retractors are placed in each lateral mandibular vestibule to allow for visualization while the lower lip is retracted.

6. A needle tip Bovie cautery (settings 20/20) is then used to make an incision approximately 8 to 10 mm below the mucogingival junction on cut mode through the superficial mucosa from canine to canine. If the incision is made too high next to the attached gingiva, closure will be exceedingly difficult, and the surgeon risks dehiscence of the wound. If closure is done too inferior, the surgeon risks incising and scarring the lower lip musculature. Care is taken to locate and protect the three mental nerve branches using blunt dissection with a fine-tipped hemostat. The needle tip Bovie is then used on coag mode to incise through the mentalis muscle aiming toward the bone with one finger on the underside of the lower lip to give tactile sensation of how close the surgeon is coming to the external lower lip while not perforating it.

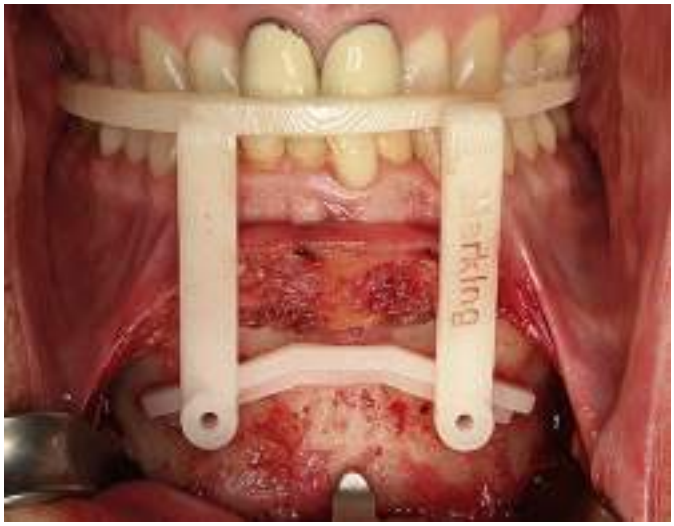

FIG. 58.1 Genioglossus marking guide.

FIG. 58.2 Genial tubercle and attachments included with the free distal segment.

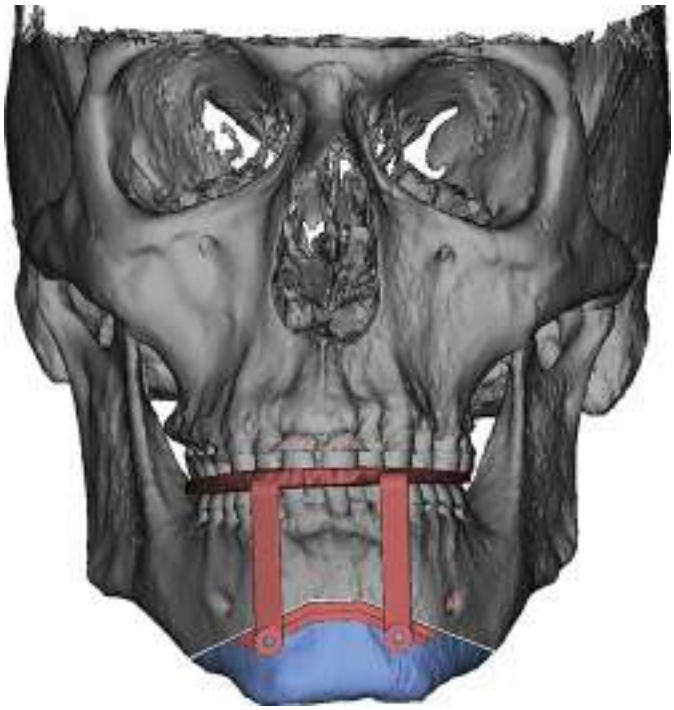

FIG. 58.3 Virtual planning for the genioglossus osteotomy.

7. Once the bone is reached, a #9 periosteal elevator is then used to gently reflect the mentalis muscle and periosteum both superiorly and

inferiorly. The scalloped bone of the mandibular incisors is located to give reference of the teeth locations with care to not perforate the gingiva overlying the alveolar bone superiorly. Elevation of the tissue also continues inferiorly to expose the inferior border of the mandible. At this time, a symphyseal retractor can be placed to retract the tissues inferiorly. Dissection continues laterally with care to avoid the mental nerve and foramina. This is extended to the first molar region laterally to provide a "pocket" in which the reciprocating saw is placed.

FIG. 58.4 Positioning guide for genioglossus advancement.

8. At this point, the "marking guide" was then placed between the teeth and allowed us to see the planned osteotomy outline that would include the genial tubercles and the genioglossus muscle.

9. The mandibular bone is then osteotomized with a sagittal safe oscillating saw blade enough to make marks in the outer cortex under copious sterile saline containing clindamycin (900 mg per 1 L saline).

10. The marking guide is removed from the teeth and then the osteotomy is then finished in a bicortical fashion with a standard short reciprocating saw blade under clindamycin irrigation. One side is done in a bicortical fashion with care exerted to not sink the tip too deep into the floor of mouth. The opposite side is then osteotomized to completion. The

anterior, inferior border segment is then freed and mobilized with a Dingman bone clamp. Any bleeding areas should be investigated and controlled at this point.

11. Next, the positioning guide was then placed between the teeth and its inferior extension screwed into the mandible to give reference of the intended final position of the advanced segment (Fig. 58.4).

12. Due to significant muscular tension after advancing the segment, fixation in this patient was accomplished with three 2.0-mm bicortical screws and two prebent GA fixation plates (the surgeon should use his or her judgment on the type and amount of adequate fixation). Following this, the positioning guide was removed and the area irrigated with clindamycin saline solution.

13. As a final step, if the advanced segment creates a large "step" in the mandible and is likely to result in a cosmetic deformity, a surgeon can then use a MedPor chin implant, carved to fill the defect and allow for a smooth transition (Fig. 58.5).

14. Closure is then carried out first by suspending the mentalis muscle with a 3-0 or 4-0 Vicryl suture taking care not to *cheese wire* the sutures through the muscle with excessive tension. This is then followed by closure of the mucosal incision with a 3-0 chromic gut suture.

15. The jaws, if not already, are then unwired and any temporary bone screws removed. The throat pack is removed and the oropharynx suctioned. A "jaw bra" or facial support dressing is then placed on the patient, and the patient is extubated.

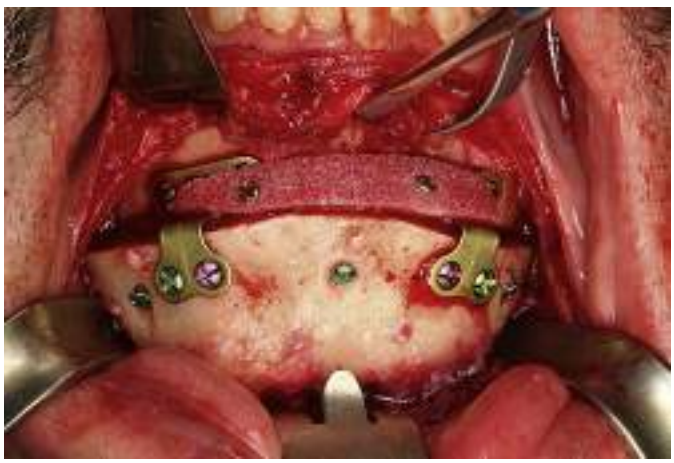

FIG. 58.5 Fixated genioglossus advancement with transitional Medpor graft.

Common Errors in Technique

1. Failure to properly position the incision. An incision too superior in the vestibule next to the attached gingiva will cause the closure to be exceedingly difficult and risk dehiscence. Incision too inferior or anterior into the lip can result in excessive scarring of the lower lip and a large amount of annoying tissue "drape" over the more superior site of the osteotomy.

2. Improper positioning of the osteotomy—This can result in damage to the tooth roots, mandibular fracture, or damage to the mental nerves (osteotomy positioned too high) or inability to capture the entire area of the genial tubercles/genioglossus muscle origin (osteotomy placed too low). In addition, beginning the osteotomy anterior to the second premolar/first molar area risks creating too much of a sudden transition and can result in "notching" of the mandible at the inferior border. This can be quite noticeable and unaesthetic in thinner individuals.

3. Allowing the tip of the reciprocating saws to be too deep into the soft tissues of the floor of the mouth while making the osteotomy. This can result in damage to the mylohyoid or genioglossus muscles and can also result in hemorrhage from multiple sources.

4. Exerting excessive force on the mandibular free segment containing the genial tubercles. This can result in avulsion of the genioglossus muscle.

Postoperative Period

Postoperative Management

1. Be certain that no active bleeding exists from the incision site or the floor of mouth.

2. Ensure airway patency. Special consideration should be given to a short course of high-dose steroids to minimize edema of the airway.

3. Patients often have a mild to moderate level of pain due to some

temporary neuropraxic type injury to the mental nerves that have been retracted during surgery. Patients may be given intravenous acetaminophen initially, which can then be transitioned to liquid or pill form when taking PO. In addition, a low level of narcotics can be given to the patient postoperatively. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ketorolac, can be given on POD1, provided there is no active bleeding. Resumption of any home antiplatelet or anticoagulant medications should be determined based on the severity of the illness being treated by said medications and by the surgeon's own judgment.

4. Admit the patient to the intensive care unit for the first 24 hours for close monitoring. If the patient does very well postoperatively, he or she could potentially be discharged on POD1. Otherwise, he or she could be transferred to a monitored bed with continuous pulse oximetry on POD1 if doing well but not yet meeting other discharge criteria (i.e., continuing to have elevated postoperative pain and taking inadequate PO intake).

5. Patients are started on a clear liquid diet the night of surgery. The diet is then advanced to full liquids/blenderized on POD1. The patient is then advised to continue a blenderized, nonchew diet for the next 6 weeks to minimize the risk of late postoperative mandibular fracture. Along these same lines, the patient is prohibited from engaging in any heavy lifting, strenuous exercise, or contact sports that could predispose him or her to fracture.

6. The patient is often given a 24-hour course of prophylactic antibiotics.

7. The patient is advised to brush the teeth gently on POD1 and to avoid the incision. He or she is also given an oral chlorhexidine rinse to swish with twice per day for 7 days.

8. The patient should be seen in clinic for a follow-up appointment at 1 to 2 weeks postoperative. At that time, standard postoperative panoramic and lateral cephalometric radiographs are taken.

Complications

1. Hemorrhage from the floor of the mouth from the genioglossus muscles, the mylohyoid muscles, or the lingual or sublingual arteries—This often occurs when patients have remained on antiplatelet or anticoagulant medications or when the tip of the reciprocating saw is

placed too deep into the floor of mouth. This complication usually presents during surgery but can emerge in the postoperative hours. It is advisable to avoid this by not allowing the saw blade to be inserted too deeply. If bleeding is noted, the surgeon should determine if it is from the muscle, which can be managed with local measures such as local anesthesia with epinephrine and Gelfoam, or arterial/venous, which would need to be managed by tying or clipping the vessel(s) in question.

2. Fracture of the mandible—If the inferior border osteotomy is placed too superior, leaving minimal to no mandibular basal bone and only mandibular alveolar bone to provide continuity. Should this happen intraoperatively, rigid fixation using fracture plates or possibly a reconstruction bar should be used to stabilize the segments. Although the patient technically could be left in maxillomandibular fixation, this is not ideal if the patient is undergoing the surgery to improve his or her already compromised airway.

3. Damage to the mental nerves—Damage to the nerves can occur during the dissection to the mandible or during the osteotomy. If this is recognized intraoperatively, the nerve endings should be freed up to remove any tension and sutured together under loupe or microscope magnification using a 7-0 or 8-0 Neurilon-type suture or equivalent.

4. Avulsion of the genioglossus muscles from the genial tubercles—If the osteotomized segment containing the genial tubercles is placed under significant tension, the muscles can be avulsed from the tubercles. Should this happen, the muscle would need to be reattached with a strong, slowly resorbing suture to the genial tubercles and the GA aborted while the patient heals.

5. Perforation of the lower lip or labiomental groove—This complication can occur if the surgeon is not careful during the intraoral dissection made to access the mandible. Should this happen, the surgeon should carefully close the laceration in layers.

6. Damage to the mandibular dentition—Damage to the teeth can occur during the osteotomy if the osteotomy is made too superior. The apices of the teeth can be cut off the roots, endangering the vitality of the teeth. Should this happen, the surgeon should be prepared to refer the patient to an endodontist for subsequent monitoring. The patient should be advised that the teeth may become necrotic and that the teeth may be

lost.

7. Unaesthetic drooping or ptosis of the mentalis muscle (i.e., the "witch's chin" deformity). This results from failure to resuspend the mentalis muscle. This can be avoided by making sure to resuspend the muscle prior to closure and by having the patient wear some type of facial support/pressure dressing with light pressure on the chin, pushing it into the symphysis and being slightly superior. This should be worn continuously for 1 week, removing only for showers and eating if necessary. If the deformity occurred in the postoperative period, this requires a resuspension procedure, which can be difficult to correct secondarily.

8. Unaesthetic "notching" of the inferior border of the mandible. This can occur when the osteotomy is not started far enough posterior to gradualize the segment of bone. If this is noticed postoperatively by the patient, one solution would be to inject soft tissue fillers into the region of notching.

9. Infection of the hardware retaining the osteotomized segment. Management of this would include removal of the hardware and a possible redo of the operation. This can be prevented with careful incision design and soft tissue closure of the mandibular vestibule.

10. Avascular necrosis of the osteotomized segment. This is a dreaded, but fortunately, extremely rare consequence of this surgery. This should be avoided by using gentle manipulation of the osteotomized segment and minimizing the amount of muscle and periosteum "stripping" that is performed.

11. Nonunion of the osteotomized segment. Management would require a redo of the operation with new fixation.

12. Loss of fixation of the advanced segment. This must be managed by removing the previously placed rigid fixation and placing new fixation at the site.

Alternative Management Plan

1. Bilateral sagittal split osteotomies (BSSOs) with advancement and simultaneous GA

2. Bimaxillary advancement (LeFort I and BSSO) with or without GA

3. GA with simultaneous hyoid suspension

4. GA with other simultaneous sleep surgery procedures (i.e., tongue-base reduction, UPPP, tonsillectomy)

5. GA using a different, previously described osteotomy design such as the mortised GA or the Stryker Liebinger GBAT system (Stryker Leibinger, Kalamazoo, Michigan)

Discussion

Evidence-Based Medicine Question

Is the sliding GA osteotomy done in conjunction with computer-aided planning and design as effective as other surgical techniques to advance the genioglossus muscle?

Historically, in the literature, GA has often been discussed in conjunction with surgical hyoid suspension. There has been very little evidence in the sleep medicine literature regarding isolated GA procedures. In addition, the GA is often combined in multiple studies with a simultaneous UPPP, which has been reported to result in a success rate of around 50% to 80%.[5] In discussing an isolated GA, it is important to reiterate that the anatomic basis of the surgery is the attachment of the genioglossus muscle to the genial tubercles of the anterior mandible. For the surgery to be a success, the patient must have an obstruction in the retrolingual/hypopharyngeal region, the entire genial tubercles and insertion of the genioglossus muscle must be captured in the advanced segment to maximize the outcome, and the patient cannot have severe sleep apnea or morbid obesity, as these would likely result in failure to improve the sleep apnea. We have presented a novel case in which the GA was combined with advanced imaging (CBCT), virtual surgical planning to locate the genial tubercles to ensure maximum muscle advancement, and custom 3D printed marking and positioning guides. Following C.E.'s surgery, his OSA symptoms resolved and he has shown remarkable improvement in quality of life and a reduction in his RDI scores. He no longer has daily headaches and feels rested in the morning from sleep.

Editorial Comment

GA is a long-standing tool in the surgical treatment armamentarium for the management of OSA that is refractory to medical therapy. Particularly when employed as part of a multilevel treatment plan, GA has decades of data to support its incremental effectiveness in improving OSA surgery outcomes in properly selected patients. Critical to the successful execution of the procedure, as well as to the minimization of potential risks, is the accurate isolation of the genial tubercle and capture of the entire genioglossus tendon. Advances in preoperative imaging and computer-assisted virtual surgical planning, in addition to surgeon experience, appear to be related to improved outcomes and reduced morbidity.

Ryan Soose

Review Questions

1. The genioglossus muscles originate from what structure?

   a. Mandibular lingulae

   b. Sigmoid notch

   c. Coronoid processes

   d. **Genial tubercles**

2. The major blood supply to the genioglossus muscle is from what arteries?

   a. Masseteric

   b. **Lingual**

   c. Facial

   d. Superior thyroid

3. The major nerve at risk from the genioglossus advancement procedure is the

   a. Marginal mandibular branch of the facial nerve

b. Cervical branch of the facial nerve

c. **Mental branch of the inferior alveolar nerve (trigeminal nerve)**

d. Great auricular nerve

Maxillomandibular Advancement for Obstructive Sleep Apnea

Richard Bauer III , and Raj C. Dedhia

Introduction

The fundamental principle of maxillomandibular advancement (MMA) is to move the muscular attachments of the hard palate, tongue, and suprahyoid soft tissue in an anterior direction by advancement of the tooth-bearing segments of the maxilla and mandible.[1] This maneuver enlarges the bony vault, effectively improving retropalatal, lateral wall, and retroglossal airway collapse.

MMA has been used effectively for adults with obstructive sleep apnea (OSA) since the 1980s. During that period, Drs. Robert Riley and Nelson Powell modified orthognathic (i.e., for treatment of occlusion and cosmesis) techniques for telegnathic (i.e., for treatment of OSA) treatment.[2] Over the past 30 years, the data consistently demonstrate greater than 90% success rates, with success defined as postoperative apnea-hypopnea index (AHI) less than 20 and a 50% reduction in baseline AHI.[3,4]

Although this surgery represents a highly effective modality, its relative invasiveness and prolonged recovery often deter surgeons and patients alike from using MMA as a first-line surgical treatment. However, in otherwise healthy OSA patients with significant retrognathia or maxillary hypoplasia, this surgery can be first line because it provides orthognathic in addition to telegnathic benefits.

Key Operative Learning Points

- Proper fabrication of intermediate and final occlusal splints is critical to

achieving precise results.

- The Le Fort I maxillary osteostomy must be carried out above canine roots and parallel to occlusal plane.
- The bilateral sagittal split mandibular osteotomy should be placed at the posterior aspect of the second molar to allow for enough room for plate fixation, if needed.

Preoperative Period

History

- A comprehensive sleep medicine history is the critical first step before considering surgical therapy for any OSA patient.
- Approximately one-third of OSA patients have been reported to have another primary sleep disorder or sleep-modulating medical comorbidities, such as psychophysiologic insomnia, chronic pain, shift work sleep disorder, restless legs syndrome, or narcolepsy. Medications that negatively affect control of breathing (e.g., opiates or benzodiazepines) or alter sleep architecture or continuity directly (e.g., antidepressants) must also be taken in account in evaluating a patient's candidacy.
- In addition to a sleep medicine history, documentation of a general medical history is paramount.
- Patients must be in good health overall because this surgery can result in significant blood loss and requires approximately 4 to 6 hours of general anesthesia.
- Patients must also be mentally well with a strong support network. The first 1 to 2 months of the recovery process are particularly challenging given difficulties with trismus and persistent perioral numbness. The perioral numbness can cause significant social impairment with unacceptable drooling and difficulty kissing.
- If patients have a history of anxiety or depression, we recommend that the patient see a mental health professional prior to surgery. Empiric medical treatment prior to surgery should be strongly considered.

Physical Examination

1. Nose

    a. Evaluate width of nasal base

        1) Patients should be informed of some degree of widening of nasal base with maxillary advancement.

    b. Acquired nasal deformity, septal deviation, turbinate hypertrophy, rhinitis, nasal polyps, and other nasal valve pathology may increase upper airway resistance and directly contribute to sleep-disordered breathing.

        1) If nasal obstruction requires treatment, it should be performed AFTER MMA because the healing from the maxillary advancement may disrupt septal alignment.

2. Facial skeleton evaluation

    a. Maxilla

        1) Evaluate transverse, vertical, and anteroposterior dimensions.

            a) Multipiece Le Fort osteotomy or a surgically assisted rapid palatal expansion (as a separate initial procedure) may be required to improve the transverse dimension.

            b) Maxillary impaction should be considered in cases of vertical maxillary excess.

    b. Mandible

        1) Evaluate width of mandibular vault and retrognathia.

            a) Retrognathia should be differentiated from microgenia based on occlusal relationship and reference of the lower incisors and chin to the cranial base.

    c. Dentition

        1) Use of Angle occlusion at the first mandibular and maxillary molars and canines represents occlusal relationship and can assist in determining any skeletal malocclusion.

        2) Evaluate for open bite deformity or buccal/lingual crossbite.

        3) If correction of malocclusion is indicated, consider preoperative

orthodontics.

4) Evaluate the health of teeth based on enamel, periodontal status, and presence of extensive restorations. Crown and bridge work may alter plans for maxillomandibular fixation.

3. Soft tissue evaluation

a. Transoral examination

1) Evaluate the position of the tongue and soft palate.

b. Fiberoptic examination

1) Retropalatal space

a) Space from the posterior nasal spine to posterior pharyngeal wall will be increased with maxillary advancement.

b) If previous uvulopalatopharyngoplasty (UPPP), assess for soft palate scarring or nasopharyngeal stenosis.

2) Lateral wall collapse (Müller maneuver or under sedated endoscopy) as MMA provides tension to lateral walls to prevent collapse

3) Retrolingual and hypopharyngeal space. Both tongue base and epiglottic obstruction can be treated with MMA.

4) Lymphoid hyperplasia (e.g., palatine or lingual tonsil hypertrophy). Excessive intraluminal lymphoid tissue may need to be removed simultaneously or in a staged fashion with MMA.

Imaging

1. Photodocumentation

2. Plain films—primarily orthopantomogram and lateral cephalometric radiograph

3. Computed tomography (CT) or cone beam computed tomography (CBCT)

Computer-Assisted Planning and Splint Fabrication

1. Imaging allows improved understanding of deformities in multiple dimensions.

2. Virtual planning is developing into the standard for treatment of complex dental and facial reconstructions.

3. Virtual planning provides insight to anticipated anatomic relationships at osteotomies prior to surgery, allowing for efficient and detailed preoperative plans.

4. Laboratory time can be eliminated with accurate splints fabricated for intraoperative MMF. Splints can be fabricated to individual specifications (i.e., sandwich splints for multipiece double jaw surgery or addition of a palatal strap for maxillary widening).

5. Accurate and efficient interdental osteotomy guides can be fabricated from the patient data to prevent root damage.

Indications

1. Moderate to severe OSA with failure of medical device therapy

2. Mild to severe OSA with craniofacial anomaly

Contraindications

1. Central sleep apnea

2. Bisphosphonate medications use

3. Uncontrolled medical comorbidities

4. Recent history of maxillary or mandibular surgery with potential compromise of skeletal blood supply (e.g., transpalatal advancement pharyngoplasty)

5. Severe temporomandibular joint (TMJ) dysfunction

Preoperative Preparation

1. Thorough craniofacial evaluation with dental and occlusal records

2. Preparation of the patient for recovery and diet modifications

3. Prior to MMA, an orthopantomogram and lateral cephalometric radiographs are important to identify TMJ morphology, health of the dentition, and relationship of the maxilla and mandible to the cranial base.

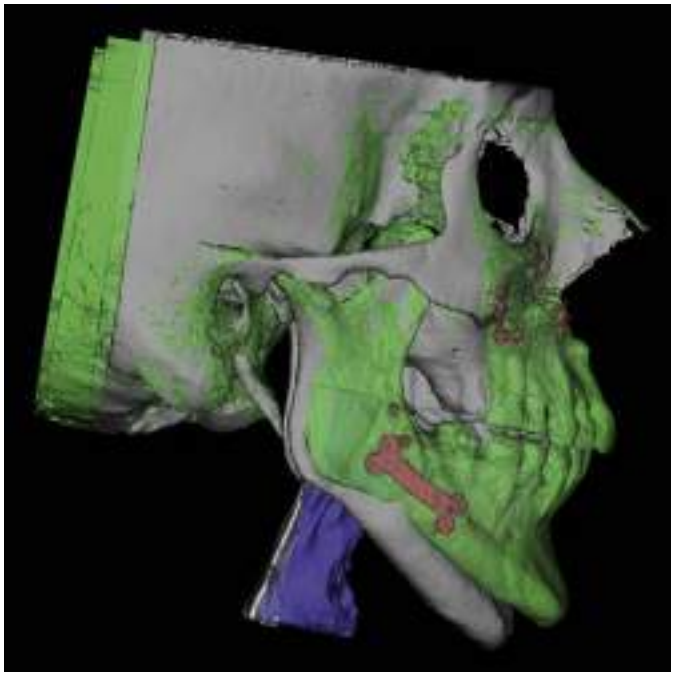

FIG. 59.1 The cone beam computed tomography data show preoperative and postoperative overlays of the skeletal and airway changes. Note the anterior and superior repositioning of the lower third of the face.

- We use three-dimensional (3D) planning for MMA. This uses a CBCT and third party surgical planning service. Additional data from the CBCT can be obtained, specifically airway analysis in three dimensions. It should be noted here that the CBCT data are obtained while the patient is upright and awake, and this may alter the depiction of the airway significantly in the sleep apnea patient (Fig. 59.1).

  The previous CBCT data show preoperative and postoperative overlays of the skeletal and airway changes.

- The presurgical plan generated from the virtual planning session can be used to print intermediate and final occlusal splints and

postsurgical models.

Operative Period

Anesthesia

Anesthesia for MMA should be planned with the anesthesiologist in advance of the surgery. Nasal intubation is imperative, and a hypotensive anesthetic (provided this is appropriate based on the patient's medical history) facilitates a decrease in blood loss. Oxymetazoline nasal spray is used prior to the induction of nasal endotracheal anesthesia.

Positioning

The patient is placed in a supine position. We have found that morbidly obese patients with significant neck circumference and broad shoulders placed on a Mayfield head rest provide better working conditions for the operator and assisting surgeon.

Perioperative Antibiotic Prophylaxis

- Those not allergic to penicillin-based drugs—ampicillin/sulbactam (Unasyn)—this medication provides excellent coverage against most oral and sinus bacteria

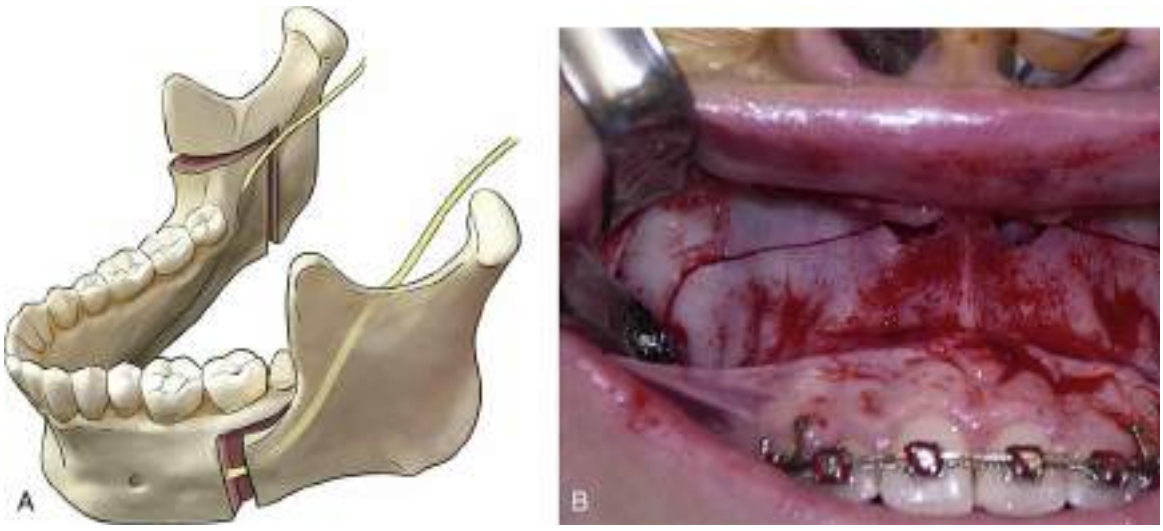

FIG. 59.2 **A,** Standard bilateral sagittal split osteotomy and **B,** Le Fort osteotomy.

- Allergies to penicillin-based drugs—clindamycin (Cleocin)—this medication provides good coverage against many oral bacteria

Monitoring

- Standard anesthesia and cardiopulmonary monitoring
- Foley catheter
- Consider placement of arterial line (real-time blood pressure monitoring).

Instruments and Equipment to Have Available

- Obwegeser retractors—small, medium, and large upturned (toe-out) and downturned (toe-in)
- Freer elevators—small and large curved
- Periosteal elevators
- Electrocautery with Colorado tip, spatula tip
- Osteotomes—single guarded, spatula, fiber handle, septal, and curved

- Rongeur forceps
- Tessier retromaxillary elevator
- 25-gauge wire for maxillomandibular fixation
- Reciprocating saw
- Drill with 1.2-mm cross-cut carbide, Lindemann, 702 and pineapple burrs
- Suture—4.0 Prolene suture, 3.0 Vicryl on SH needle, 3.0 chromic gut, 5.0 fast gut suture
- Erich arch bars, 25-g wire
- Heavy dental elastics

Key Anatomic Landmarks

- Le Fort I osteotomy must occur superior to the apex of bilateral canine roots.
- Lingula demarcates safe level to perform sagittal osteotomy as inferior alveolar nerve enters canal inferior to this structure.

Prerequisite Skills

- A strong understanding of rigid fixation and a command of orthognathic surgery are critical. The Le Fort I maxillary osteotomy and the bilateral sagittal split mandibular osteotomies are the foundation of this treatment.

Operative Risks

- Bleeding
- Loss of airway
- Malocclusion
- Fracture

Surgical Technique

The images above depict a Le Fort I maxillary osteotomy and standard bilateral sagittal split osteotomy (BSSO) of the mandible (Fig. 59.2).

Arch Bar Placement

- A throat pack is placed intraorally.
- 10mL of 0.5% Marcaine with 1:200,000 epinephrine is injected along the planned maxillary incision.
- Erich arch bars are secured to the upper and lower teeth with 25-g wire and Ivy loops.

Le Fort I Osteotomy

- Bovie electrocautery is used to make an incision from zygomatic buttress to zygomatic buttress, leaving a 10-mm cuff of unattached gingiva.
- The periosteum is elevated from the posterior maxilla to the piriform aperture.
- The nasal mucosa is elevated from the maxilla as far posterior as possible.
- The osteotomy is placed superior to the canine roots and parallel to the occlusal plane.
- A reciprocating saw is used to make the osteotomy from posterolateral maxilla to piriform aperture with a Freer elevator placed in the nasal cavity to protect the nasal mucosa.
- The process is repeated on the other side.
- A septal osteotome is used to separate the nasal septum from the underlying maxilla (below the maxillary crest) and a chisel for the medial maxillary buttress.
- A pterygoid osteotome is used to complete the pterygomaxillary separation.

- At this time, the maxilla is manually downfractured and should be freely mobile.

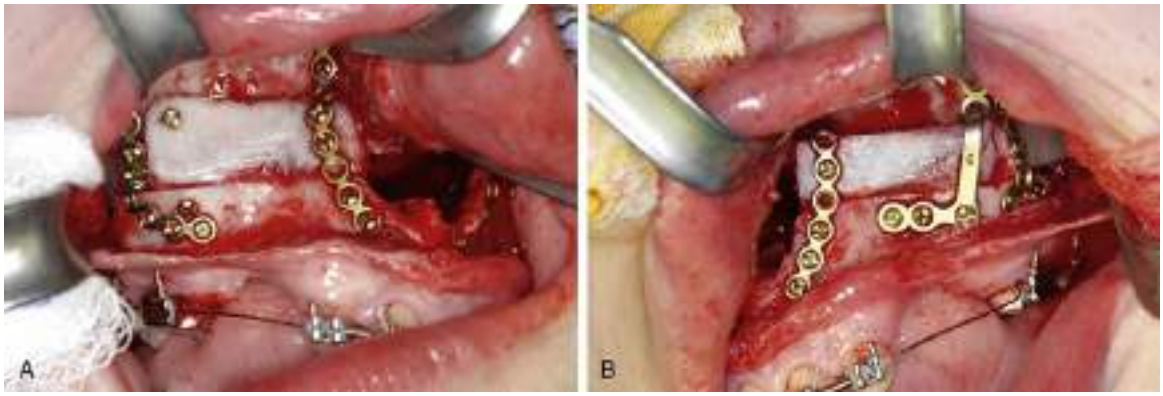

FIG. 59.3 Cadaveric iliac crest interpositional blocking grafts for long-term stability. **A,** Right Maxilla **B,** Left Maxilla.

- The bilateral palatine vessels are identified and ligated or cauterized.
- Bony interference is removed with rongeur forceps and a surgical bur.
- The intermediate splint is introduced until the proper fit is achieved and secured with 24-g wire.
- 1.7 or 2.0 midface plates × 2 are manipulated and placed on each medial maxillary buttress, followed by 2-L plates on the zygomatic buttress, secured with screws.
- Ensure that the midline is maintained.
- The field is irrigated, suctioned, and packed with Ray-tec sponges.

Bilateral Sagittal Split Osteotomy

- 10mL of 1% Lidocaine with 1:100,000 epinephrine is injected along the planned mandibular incisions.
- Bovie electrocatuery is used to make a incision down to right ramus of the mandible along oblique ridge.
- Elevate the periosteum on buccal cortex and use a notch retractor to lift the insertion of the temporalis on the coronoid.

- The lingula is identified on the lingual cortex, and a flap superior to this is elevated.
- A reciprocating saw or Lindemann bur is used to make a medial corticotomy followed by the vestibular osteotomy, with care taken superiorly to avoid damage to the nerve.
- These osteotomies are joined using the reciprocating saw or 702 bur.
- A mallet and osteotomes are used to carefully complete the osteotomy.
- The inferior alveolar nerve should be noted in the distal segment.
- A similar procedure should be carried out on the left side. All wounds are thoroughly irrigated.
- The patient is then placed in the final occlusion splint, secured with 24- or 26-g wire.
- Bicortical positioning screws or screws for plating can be placed via a transcutaneous trochar. True rigid fixation is imperative for large advancements typically encountered in surgery for sleep apnea.
- The MMF is removed, and occlusion is checked.
- All wounds should be irrigated. Hemostasis is obtained.

Closure

- For mandible, 3.0 chromic gut used to re-approximate periosteum and running, locking 3.0 chromic gut for mucosa
- For maxilla, 4.0 Vicryl to re-approximate muscle
- The mucosa is closed using 3.0 chromic gut in a running fashion.
- Oropharynx is thoroughly suctioned and throat pack removed.
- Trochar incisions are closed with 5.0 fast gut.
- A facial support (jaw bra) dressing is placed.
- The patient is returned to anesthesia.

Common Errors in Technique

Fixation for this procedure may vary depending on how large the movements are. Midface plates and screws are standard for the maxillary Le Fort fixation. Positional and/or lag screws are the minimum for the mandible; however, the authors feel that most mandibular advancements are large and that counterclockwise movements to enhance genioglossus advancements are common; therefore more rigid fixation with plates and screws are standard in our practice.

Complications

- Permanent paresthesia (12%)—risk minimized by careful identification and protection of the inferior alveolar nerve during sagittal split osteotomy
- Malocclusion—premature contact is common (44%) in the first 6 weeks, whereas long-term malocclusion is rare
- Hardware infection (1% to 33%)—the plates and screws can be safely removed 3 months after surgery, if necessary
- Nonunion/malunion (3%)—consider bone grafts for particularly large advancements to minimize risk for malunion (Fig. 59.3)

Evidence-Based Medicine Question

Does MMA provide a safe and stable long-term treatment option for moderate to severe sleep apnea?

- MMA is a clinically effective long-term treatment for patients with moderate to severe OSA because it predictably produces substantial and sustained reductions in AHI, blood pressure (BP), and subjective sleepiness, with concomitant significant improvements in quality of life (QOL).[5]
- Successful outcomes are routinely achieved with minimal short-term and long-term treatment-related adverse outcomes.

Editorial Comment

For decades Orthognathic surgery has been used successfully to manage

OSA. Advances in preoperative imaging and virtual planning, as well as refinements in intraoperative technique, have led to further improvements in outcomes. The published high surgical success rates warrant consideration of this treatment modality in properly selected patients, particularly those with severe refractory OSA or those with pre-existing skeletal deficiency. Nevertheless, the increased potential morbidity and risk compared with other OSA treatments also limit the generalizability and widespread use of skeletal advancement surgery in a large portion of the OSA population, particularly the milder end of the disease spectrum.

Office-Based Procedures

Fine-Needle Aspiration Biopsy of a Mass in the Head and Neck

Jason I. Kass

Introduction

When evaluating a patient with a mass in the head and neck, the fine-needle aspiration biopsy (FNAB) plays a critical role in the initial workup. It can help establish a diagnosis, among a wide variety of pathology, including infectious, benign, and malignant lesions. Needle biopsy, first popularized in the 1920s by Dr. Hayes Martin at Memorial Sloan-Kettering Hospital, has been used for more than 100 years.[1] While he used large-bore needles under local anesthesia, it did not gain widespread acceptance in the United States until finer needles were available. Advances in cytology have made pathologists more comfortable in making a diagnosis, allowing head and neck surgeons to avoid unnecessary open biopsies.

FNAB is easily performed in the office, with high diagnostic accuracy, for both benign (95%) and malignant (87%) lesions. The technique can be used in a variety of sites in the head and neck, including the salivary glands, thyroid, and lymph node metastases. With a preoperative diagnosis, a definitive surgical plan prior to treatment can be established and discussed with the patient. FNAB is a minimally invasive technique, which allows for repeat sampling in the cases of a nondiagnostic specimen. It is safe, accurate, and cost-effective.

Fine-Needle Aspiration Biopsy for Thyroid

Disease

Thyroid nodules, particularly in women, are a common finding. The American thyroid association (ATA) recommends a FNAB in all euthyroid and hypothyroid patients with suspicious lesions seen on a screening ultrasound (Table 60.1).[2] When evaluating thyroid lesions, the FNAB sample can be used for both histologic and molecular analysis. The specimens can also be stained and evaluated at the time of FNAB. This can provide both qualitative assessment of the specimen and often confirms the diagnosis. Thyroid cytopathology is typically reported using the Bethesda system (Table 60.2). Cytopathology in benign disease has an estimated risk of malignancy less than 3%, while those that are suspicious for malignancy vary between 60% and 75%. Cytopathology in cases of malignancy is 99% accurate. Not all thyroid cancers can be diagnosed by FNAB. Follicular adenomas are indistinguishable from carcinomas on needle biopsy. Therefore the report of a follicular neoplasm only carries a 15% to 30% risk of malignancy.

Fine-Needle Aspiration Biopsy for Salivary Gland Disease

Lesions of the parotid and submandibular glands can be readily accessible to sampling by FNAB. While not every mass needs to be biopsied, any patient who presents with pain, facial weakness, numbness, or a mass in the parotid gland should have an FNAB. FNAB can also support a decision not to operate, in patients with a normal clinical examination and benign cytopathologic diagnosis. For example, a Warthin tumor has an exceedingly low malignant potential and in many cases can be observed. FNAB has very high overall accuracy (90% to 95%) at distinguishing benign from malignant lesions; however, it is not reliable at determining the malignant subtype and tumor grade. In some low-grade malignancies, such as acinic cell carcinoma, it can be misinterpreted as benign or non-neoplastic. Low-grade lymphomas can be missed and erroneously reported as inflammation. Therefore a negative diagnosis must be viewed within the clinical context. If there are suspicious clinical or radiographic findings, either a repeat FNAB or excisional biopsy should be considered.

Fine-Needle Aspiration Biopsy for the Mass in the Neck

All palpable masses in the neck, in both adults and children, can be safely assessed with an FNAB.[3] Additionally, in most cases, ultrasound or computed tomography (CT) guidance can be used to localize and biopsy challenging or nonpalpable lesions. With lymphadenopathy, a specific diagnosis is obtained in 82% to 96% of cases. Cell blocks from the FNAB can be used for either immunohistochemistry or polymerase chain reaction (PCR)-based analysis. When a lymphoma is suspected, FNAB can rapidly establish a diagnosis and often avoid open neck biopsies.[4] Improvements in immunologic methods have allowed an FNAB specimen to be sufficient to establish the diagnosis of lymphoma with at least two needle passes.[5] In cases when an open biopsy is necessary to determine a gene rearrangement, reactive, inflammatory, and metastatic tumors are excluded, limiting the confirmatory diagnostic tests.

Key Operative Learning Points

- Distinguishing benign from malignant cervical masses, rapid assessment, potential avoidance of surgical intervention, low complication rates, and cost-effectiveness have made FNAB diagnosis of masses in the head and neck the standard of care.
- FNAB for thyroid follicular lesions cannot differentiate benign from malignant neoplasms.
- A cystic mass in the lateral aspect of the neck, in an adult, with squamous cells should be considered malignant until proven otherwise. These masses are usually a cystic form of metastatic squamous cell carcinoma, usually from the base of the tongue or tonsil, and should not be mistaken for a branchial cleft cyst.

TABLE 60.1

Sonographic Patterns, Estimated Risk of Malignancy, and Fine-Needle Aspiration Guidance for Thyroid Nodules

Sonographic Pattern	US Features	Estimated Risk of Malignancy, %	FNA Size Cutoff (Largest Dimension)
High suspicion	Solid hypoechoic nodule or solid hypoechoic component of a partially cystic nodule with one or more of the following features: irregular margins (infiltrative, microlobulated), microcalcifications, taller-than-wide shape, rim calcifications with small extracapsular soft tissue component, evidence of ETE	~70–90*	Recommend FNA at ≥1 cm
Intermediate suspicion	Hypoechoic solid nodule with smooth margins without microcalcifications, ETE, or taller-than-wide shape	10–20	Recommend FNA at ≥1 cm
Low suspicion	Isoechoic or hyperechoic solid nodule, or partially cystic nodule with eccentric solid areas, without microcalcifications, irregular margins or ETE, or taller-than-wide shape	1–4	Recommend FNA at ≥1.5 cm
Very low suspicion	Spongiform or partially cystic nodule without any of the sonographic features described in low, intermediate, or high suspicion patterns	<1	Consider FNA at ≥2 cm. Observation without FNA is also a reasonable option
Benign	Purely cystic nodules (no solid component)	~0	No biopsy†

ETE, Extrathyrodial extension.

US-guided FNA is recommended for cervical lymph nodes that are sonographically suspicious for thyroid cancer.

* The estimate is derived from high volume centers; the overall risk of malignancy may be lower, given the interobserver variability in sonography.

† Aspiration of the cyst may be considered for symptomatic or cosmetic drainage.

TABLE 60.2

The Bethesda System for Reporting: Thyroid Cytopathology: Diagnostic Categories and Risk of Malignancy*

Diagnostic Category	Estimated/Predicted Risk of Malignancy by the Bethesda System (%)*	Actual Risk of Malignancy in Nodules Surgically Excised, % Median (Ranges)†
Nondiagnostic or unsatisfactory	1–4	20 (9–32)
Benign	0–3	2.5 (1–10)
Atypia of undetermined significance or follicular lesion of undetermined significance	5–15	14 (6–48)
Follicular neoplasm or suspicious for a follicular neoplasm	15–30	25 (14–34)
Suspicious for malignancy	60–75	70 (53–97)
Malignant	97–99	99 (94–100)

* As reported in The Bethesda System by Cibas ES, Ali SZ: The Bethesda System for reporting thyroid cytopathology. Am J Clin Pathol 132:658–665, 2009, http://dx.doi.org/10.1309/AJCPPHLWMI3JV4LA.

† Based on the meta-analysis of eight studies reported by Bongiovanni M, Spitale A, Faquin WC, et al: The Bethesda System for reporting thyroid cytopathology: A meta-analysis. Acta Cytol 56:333–339, 2012. The risk was calculated based on the portion of nodules in each diagnostic category that underwent surgical excision and likely is not representative of the entire population, particularly of

nondiagnostic and benign diagnostic categories.

Preoperative Period

History

- History of present illness
  - Initial appearance of the mass in the head and neck
  - Change in size over time
  - Associated symptoms (pain, numbness, change in voice, facial weakness)
  - Presence of lymphadenopathy beyond the head and neck
- Past medical history
  - Radiation exposure
  - Previous attempts at biopsy
  - Previous treatment, particularly for cancer of the head and neck, or prior drainage of a cystic neck mass
- Family history
- Travel history
- Infectious history
- Medications
  - Anticoagulants

Physical Examination

- Palpable mass

- Mass characteristics (pain, fluctuance, overlying skin color changes)

Imaging

- None required for palpable masses
- Ultrasound-guided FNAB for nonpalpable masses and most thyroid nodules

Indications

- Masses in the neck (cystic and solid)
- Parotid lesions
- Thyroid nodules
- Palpable subcutaneous facial masses, including scalp

Contraindications

- There are no specific medical contraindications to the procedure.
  - A small hematoma may occur if the patient is on anticoagulants. Even vascular masses including carotid body tumors may be biopsied with a fine-gauge needle using manual external pressure to minimize bleeding. Surgeons may prefer not to perform these biopsies if the patient is also anticoagulated.

Preoperative Preparation

Informed consent should be obtained prior to performing an FNAB. Risks include a small amount of bleeding and/or bruise, infection, and a nondiagnostic specimen.

Operative Period

Anesthesia

- Local anesthesia is optional, and most adult patients are able to tolerate the small gauge needle without discomfort.
- For increased comfort, I infiltrate the skin and subcutaneous tissue with 1% lidocaine with a 1:100,000 dilution of epinephrine.
- For children, sodium bicarbonate can also be included in a 1:10 dilution to buffer the lidocaine.
- Buffered lidocaine is nearly painless and very well tolerated.

Positioning

- Thyroid biopsy
  - Extend the neck with a pillow under the shoulders.
  - The individual performing the FNA may be more comfortable standing on the opposite side of the mass.
- Mass in the neck or parotid
  - Turn the head so that the mass is as superficial as possible.
  - For neck nodes, pushing from behind the sternocleidomastoid may make the mass more superficial (Fig. 60.1).

Perioperative Antibiotic Prophylaxis

- Antibiotics are not indicated. Cleaning the skin with an alcohol swab is sufficient.

Monitoring

- The procedure is performed with local injection with the patient awake, so monitoring is not required.

Instruments and Equipment to Have Available

- 20-mL syringe

- Syringe holder (optional)
- Glass slides with the patient's name written on the frosted end
- 1- to 1½-inch 21- to 25-gauge needles
- 95% alcohol or a spray fixative to fix the aspirate
- Alcohol swabs and gauze pad
- Balanced salt solution for rinsing the needle
- Small adhesive bandage (Fig. 60.2)

Key Anatomic Landmarks

- For nonultrasound guided FNAs, the mass should be palpable. While specific landmarks depend on the nearby structures, it is often helpful to identify the carotid artery and carotid bulb when performing an FNA on the lateral neck.

FIG. 60.1 The patient is positioned comfortably with a headrest. The surgeon may stand opposite the mass to secure it manually. The needle is introduced and multiple (15 to 20) short passes are made until material is observed within the needle hub. If excessive blood is noted, suction can be reduced or eliminated and passes continued through the mass.

FIG. 60.2 Cytology slides, fixative, a 20-mL syringe with a holder, and a 22- to 25-gauge needle.

Prerequisite Skills

- No specific prerequisite skills are required; however, beginners have higher rates of nondiagnostic specimens.

Operative Risks

- The procedure is generally very safe. Risks include a small amount of bleeding and/or bruise, infection, and a nondiagnostic specimen. As with any in-office procedure, the surgeon should also be prepared to manage vasovagal syncope, should it occur.

Surgical Technique

- Aspiration technique
  - 20-cubic centimeter syringe with 1 mL of air placed in a syringe holder
  - Clean the area over the proposed puncture site with an alcohol swab.
  - If you are injecting local anesthesia, infiltrate the skin around the biopsy site with 1% lidocaine with a 1:100,000 dilution of epinephrine.

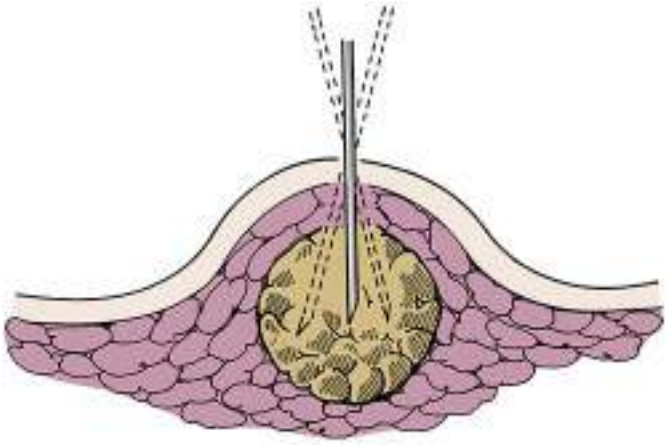

FIG. 60.3 The needle is moved in and out of the mass in short vibratory strokes for a distance of 2 to 3 mm.

- Localize the mass with the thumb and index finger of the nondominant hand and prevent it from moving. Stretching the skin also acts to decrease the pain.
- Place the needle inside the mass and pull back on the syringe, creating a vacuum.
- The needle is rapidly moved into and out of the mass in short distances, so as not to lose the vacuum. Care is taken not to move the direction of the needle, because it is more uncomfortable and can tear small blood vessels. This will make the specimen bloody and more difficult to interpret (Fig. 60.3).
- Watch the hub of the needle. Once material is seen in the hub, the vacuum on the syringe is released and the needle is withdrawn.
- This is repeated 3 to 4 times to ensure an adequate specimen is obtained.
- Gentle pressure is placed over the puncture site, and then an adhesive bandage can be placed.

- Nonaspiration technique
  - As noted previously, except the needle is place into the mass, and *no* vacuum pressure is applied. This can be useful for thyroid specimens or where negative pressure leads to a bloody specimen.
  - The nonaspiration technique can be performed with just the needle and no syringe attached.

Specimen Handling

- The content of the needle is pushed onto two glass slides, with the beveled edge of the needle touching the slide.
- The slides are then touched together to create a smear of the aspirated material on each slide.
- They are then quickly wet-fixed, using a 95% ethyl alcohol spray, held 8 to 10 inches from the slide.
- The needle should then be rinsed in a balanced salt solution (not normal saline). This specimen can be processed for microbiology or immunophenotyping by flow cytometry.
- It is preferable if the slides can be processed while the patient is present, to determine specimen adequacy. Obtain another pass if the slides are inadequate. One method for scoring specimens is provided in Box 60.1. Although it was originally designed for analysis of thyroid cytology at the University of Pittsburgh, it can be applied to other types of specimens.

Common Errors in Technique

- Exposure of cytology slides to air for prolonged periods before fixation leads to an air-drying artifact, which limits the quality of the specimen.

BOX 60.1 Thyroid Cytology Report of the Adequacy of Analysis

Satisfactory for Interpretation

The specimen fulfills one of the diagnostic patterns listed.

Less than Optimal

The specimen is at least modestly cellular but does not fulfill all requirements for the diagnostic categories listed (nonspecific pattern).

Unsatisfactory

The specimen fails to show one of the patterns listed.

Recommended Semiquantitative Grading of Adequacy

Background Grade

0—Bloody background with little or no colloid

1—Bloody background with little or no colloid, and macrophages and/or inflammatory elements

2—Definite areas of sharply demarcated watery colloid with typical wrinkles/crackled features on at least one slide, with or without a bloody background, with or without macrophages and inflammatory elements

3—Abundant sharply demarcated watery colloid with typical wrinkles/crackled features on many slides, with or without macrophages and inflammatory elements, minimal or no blood

Cellularity Grade

0—Less than 8 to 10 cellular fragments (at least 10 cells) on two slides

1—≥8 to 10 cellular fragments (at least 10 cells) on two slides

2—Cellular fragments (at least 50 cells) on 50% of the slides reviewed

3—Cellular fragments (at least 50 cells) on 100% of the slides reviewed

Cellular Preservation Grade

0—All slides are poorly preserved and difficult to evaluate because of mechanical disaggregation, obscuration as a result of thick/bloody preparation, air drying, and so on.

1—Most slides are poorly preserved and difficult to evaluate because of mechanical disaggregation, obscuration as a result of thick/bloody preparation, air drying, and so on.

2—Most slides are well preserved and difficult to evaluate because of mechanical disaggregation, obscuration as a result of thick/bloody preparation, air drying, and so on.

3—All slides are well preserved without mechanical disaggregation; obscuration is due to thick/bloody preparation, air drying, and so on.

Semiquantitative Adequacy Score (Add Grade from Each Category)

4 or less = *Inadequate*—Repeat FNA

5 = *Inferior*—Sensitivity of the study may be less than standard. Additional studies, including repeat fine-needle aspiration, should be considered.

6–7 = *Satisfactory*—Specimen quality supports an optimally sensitive study.

8–9 = *Superior*—Specimen quality supports an optimally sensitive study.

Courtesy Paul Ohori, MD.

- Using high suction (negative pressure) in the syringe will lead to bloody cytologic specimens that can be difficult for the cytopathologist to interpret.
- A single negative FNAB should not be overweighed in the context of other suspicious clinical data. Concern for malignancy should prompt further cytologic or histologic analysis of the neck mass.

Postoperative Period

Postoperative Management

- A small adhesive bandage is usually sufficient to cover the biopsy site. In patients who are anticoagulated, applying pressure for several minutes is helpful.

Complications

- The most common complication is a nondiagnostic specimen. Infection and hematoma can occur but are uncommon.

Alternative Management Plan

- If the mass is not clearly palpable or the surgeon isn't confident, he/she can sample the mass, and interventional radiology or ultrasonography can assist with a targeted biopsy.
- If the tissue architecture is important, or more tissue is required, a core needle biopsy can be performed.
- In the setting of two or more nondiagnostic FNAB, an open biopsy can be used to establish a diagnosis.

Discussion

Evidence-Based Medicine Question

How successful are ultrasound-guided FNAB at obtaining an adequate specimen? Do immediate cytology and specialist radiologists improve the adequacy of FNAB?

These questions were recently addressed by a meta-analysis[6] and a retrospective review of 398 specimens obtained over a 6-month period.[7] Ganguly et al. found 78 studies that specifically stated their sample inadequacy rate for ultrasound-guided FNAB. Overall specimen inadequacy rate was 9.3%, with on-site cytopathologists having a lower rate of 6%. This literature suggests that the most accurate diagnoses are obtained when a pathologist is available to immediately review the slides and determine whether another pass should be performed.

The single-institution study by Sharma et al.[7] compared four different groups: (A) FNAB all performed by radiologists with cytology support, (B) FNAB all performed by all radiologists without cytology support, (C) FNAB performed by biopsy-subspecialized radiologists with cytology support, and (D) biopsy-subspecialist radiologists without cytology support. This group found that when cytology support was present, there was a significantly lower rate of inadequate specimens. When no cytologist was present, the radiologists with more training in performing FNAB obtained better specimens. Specimen inadequacy ranged from 10% (group C) to 44% (group B).

Taken together, the literature suggests that while there is a learning curve to achieve proficiency, there is also a ceiling to the success rate. A recent review of surgeon-performed ultrasound-guided FNAB of thyroid nodules at the University of Toronto[8] examined 423 consecutive cases from 2010 to 2015. They found dramatic increases with experience (from 70.8% to 94.3%) but at their best still had a 6% specimen inadequacy rate. Reasons for nondiagnostic specimens included an inadequate number of cells, absence of follicular cells, cystic lesion, and bloody specimen.

Editorial Comment

The chapter provides a comprehensive, evidence-based overview of FNAB for thyroid, salivary gland, and neck neoplasms. While FNAB provides a cost-effective, minimally invasive mechanism to establish a working diagnosis and plan further management, it must be remembered that FNAB findings need to be correlated with clinical findings. If FNAB results do not correlate with clinical findings or intuition for a malignant neoplastic process, this index of suspicion must be further investigated with additional FNAB, core biopsies, or an open biopsy. The authors have emphasized this as well. Like ultrasonography, FNAB is operator dependent, and this technique must be cultivated and practiced to get reliable results. Head and neck ultrasound is an important aspect of head/neck examination and complements in-office FNAB. Head/neck surgeons are incorporating head/neck ultrasonography into their practices, which along with an on-site cytopathologist provides a one-stop cost-effective and efficient diagnostic option for neck masses. Witt et al. demonstrated that surgeon-performed ultrasound-guided biopsy with an on-site cytopathologist improves adequacy and accuracy of FNAB results, as compared with surgeon-performed FNAB without surgeon-performed ultrasound guidance.[9]

Rohan R. Walvekar

Access the review questions online at http://www.expertconsult.com

Review Questions

1. Using the 2015 ATA guidelines, which thyroid nodule should undergo FNAB?

   a. A solid hypoechoic nodule with irregular margins and

microcalcifications 0.8 cm in size

b. A purely cystic nodule 5 cm in size

c. A partially cystic, partially solid nodule 1.3 cm in size

d. **A hypoechoic solid nodule without microcalcifications 1.0 cm in size**

2. Even in experienced hands, with ultrasound guidance and immediate cytology, what is an expected rate for nondiagnostic specimens?

a. 10%

b. **6%**

c. 1%

d. 15%

3. A 50-year-old man presents with a 1-cm lesion of the left parotid with subtle weakness of the left midface. FNAB produces an adequate specimen that shows inflammatory cells and is reported as benign. What is your next step?

a. Reassure the patient; however, follow up in 3 months for a repeat examination.

b. Reassure the patient of the benign FNAB and follow up as needed.

c. **Repeat FNAB.**

d. Plan for superficial parotidectomy with left selective neck dissection.

Management of the Unknown Primary Cancer

Vikas Mehta, and Umamaheswar Duvvuri

Introduction

Many patients with squamous cell carcinoma of the head and neck (SCCHN) present with metastasis to the cervical lymph nodes. Metastatic carcinoma in the neck without an identifiable primary cancer is defined as a squamous cell carcinoma of the head and neck of unknown primary origin (SCCHNUP). Patients with isolated supraclavicular metastatic carcinoma usually have a primary source from the skin or infraclavicular sites of origin (stomach, breast, lung, esophagus, and ovary) and are thus not the focus of this chapter. Retrospective studies suggest that SCCHNUP is a relatively rare disease, affecting between 1% and 3% of new cases of SSCHN.[1] However, as the incidence of human papillomavirus (HPV)–associated oropharyngeal cancer, which is known to metastasize to the lymph nodes with low-volume primary disease, continues to rise, SCCHNUP will likely increase in incidence as well. Since these patients provide a particularly challenging diagnostic problem to the head and neck surgeon, a systematic approach including a thorough physical examination, appropriate imaging, and surgical evaluation is necessary to identify the site of the primary cancer.

Patients who present with SCCHNUP can be treated with either surgery followed by adjuvant treatment or primary nonsurgical therapy. The identification of the primary cancer can help better define the targeted areas for radiation therapy and provide more accurate staging and prognostic information for these patients. A diagnostic regimen that includes transoral surgery (TOS) of the base of the tongue (BOT) has demonstrated a diagnostic ability of approximately 90% of the primary cancers that otherwise would go undetected by contemporary diagnostic

tools.[2,3] This chapter delineates the evaluation and management of patients with squamous cell carcinoma metastatic to the neck from an unknown primary cancer and provides new insights into the application of transoral robotic technologies for the diagnosis and treatment of patients with SCCHN of unknown primary origin.

Key Operative Learning Points

- Initial evaluation of a SCCHNUP patient should include a thorough history and physical examination, positron-emission tomography (PET) scan, molecular testing of the fine- needle aspiration biopsy (FNA) specimen, and examination under anesthesia (EUA) with palatine tonsillectomies.
- Transoral robotic surgery (TORS) of the BOT can be safely undertaken if these methods fail to identify the primary cancer and has shown a success rate in almost 90% in those cases.
- Care must be taken to remove all of the lingual tonsillar tissue, including the lymphoid areas within the glosso-tonsillar sulcus, since these occult tumors can be only a few millimeters in size.

Preoperative Period

History

- The most common presenting symptom in Squaous cell carcinoma unknown primary (SCCUP) is a painless mass in the neck. Nearly 40% of patients come to medical attention with a single enlarged lymph node, which is most commonly located in level 2, suggesting an occult primary cancer location in the oropharynx.[4]
- Lymphadenopathy in level 3, without involvement of level 2, suggests a primary site in the supraglottic larynx or hypopharynx.[4]
- Patients with SCCHN are traditionally heavy tobacco and/or alcohol abusers. Recently, however, a larger number of patients who report never having been smokers, or who have stopped smoking in the distant past, and have a minimal history of alcohol intake are

presenting with SCCHN. These patients often have a cancer that is related to the HPV, an etiologic factor contributing to the development of their cancer. Taking a thorough history on risk factor exposure that includes not only current alcohol and tobacco consumption but also questions regarding remote history of tobacco consumption or high-risk sexual behaviors is important, since these factors may also contribute to the diagnosis of an HPV-related malignancy.

- Female patients should be asked about their gynecological history, with a specific focus on abnormal Pap smears.
- It is also important to ascertain whether these patients have complaints of hoarseness, dysphagia, odynophagia, weight loss, or otalgia, all of which may point to the site of the primary cancer.
- A dermatologic history may also be relevant, and patients should be questioned about prior skin surgery or head and neck cutaneous squamous cell carcinoma.

Physical Examination

- A thorough examination of the head and neck is warranted in all patients who present with occult nodal metastasis.
- The physical examination should include palpation of the neck to determine whether the lymph nodes are fixed to the skin or underlying structures or if they are freely mobile. Palpation should also include examination of the thyroid and tracheal regions, as well as the nodal lymphatic basins of levels I through VI.
- Many cases of SCCHNUP are initially diagnosed by excision of a mass in the neck, which is ultimately confirmed to be SCCHN. In these cases, the physical examination can be challenging, since postsurgical scarring and induration can negatively impact palpation and examination of the residual cervical lymph nodes.
- An examination of the oral cavity and oropharynx should be performed, ideally with indirect mirror-laryngoscopy to examine the BOT and tonsillar fossae. Bimanual palpation of the BOT and tonsillar fossae is also required.
- The physical examination should also include a careful evaluation of

the cutaneous structures of the head and neck, since previously treated primary malignancies of the skin can present with isolated metastatic SCC. Physical stigmata of prior skin resections, such as scars or white spots from liquid nitrogen–induced cryoablation, should also be documented.

- Once this portion of the physical examination is concluded, these patients should all be subjected to flexible fiberoptic nasopharyngolaryngoscopy. This provides a better view of the BOT, tonsil fossae, glottis, hypopharynx, and supraglottic structures. It is important to evaluate vocal fold mobility and to look for areas of salivary pooling or submucosal masses in the postcricoid area. The nasopharynx should also be examined to exclude the possibility of an occult nasopharyngeal carcinoma.

Imaging

- Computed tomography (CT) and/or magnetic resonance imaging (MRI) with contrast is generally considered to be the first-line imaging for patients with SCCHNUP.
- If the CT and MRI do not identify the primary cancer, a PET with integrated CT (PET/CT) may be useful. If a PET/CT scan is performed, it should be done before panendoscopy, since the PET can potentially guide the surgeon, and the biopsies or surgical interventions may in fact induce FDG avidity on the PET/CT scan, thus resulting in a false positive. With addition of PET and fusion PET/CT images, a recent meta-analysis of patients with unknown primary cancer demonstrated an improved detection rate of 37.5% by adding PET/CT to the standard evaluation, with a sensitivity and specificity of 84% overall.[5]

Indications

Patients who present with a diagnosis of SCCHNUP are candidates for this procedure. The diagnosis of SCCHNUP should be established on the basis of pathologic evaluation of enlarged cervical lymph node(s).

Contraindications

There are no contraindications to surgery based on anatomic factors. However, patients who have significant medical comorbidities that may preclude the administration of general anesthesia may not be candidates for surgery. Those patients who have a demonstrable primary cancer that appears deeply invasive on preoperative imaging do not require robotic surgery to identify the primary cancer.

Preoperative Preparation

- Even with an extensive investigation and a thorough physical examination, a primary cancer may not be found. New diagnostic procedures can potentially aid in the identification of the primary cancer or at least suggest a subsite from which the primary cancer could have arisen.
- The majority of primary cancers that are identified among patients with SCCHNUP are located within the oropharynx.[6]
- Furthermore, recent studies suggest that a large percentage (up to 70%) of SCC of the oropharynx are HPV related, and only a small percentage of cancers from nonoropharyngeal sites in the head and neck are HPV related.[7] Therefore, detection of HPV within tissue biopsies from the lymph node strongly suggests the oropharynx as the primary source. Immunohistochemical analysis of p16 is a valuable biomarker and can identify those cancers that are associated with HPV infection. HPV in situ hybridization also provides confirmatory data that validate HPV etiology.
- Detection of HPV or Epstein-Barr virus (EBV) in the FNA from a metastatic lymph node may be useful and can provide prognostic information. EBV is also a sensitive marker for nasopharyngeal carcinoma, and positivity on lymph node aspirates for EBV strongly suggests a primary nasopharyngeal source. It should be noted that nasopharyngeal carcinoma typically metastasizes to the posterior neck (level 5), and isolated level 5 nodal metastases in a patient should raise the index of suspicion for an occult primary in the nasopharynx. However, despite the relatively high frequency of HPV and EBV positive cancers of the oropharynx and nasopharynx, respectively, a negative result does not necessary exclude the oropharynx or nasopharynx as the source of the primary cancer.

- Care must also be taken in relying solely on these biomarkers, as cutaneous malignancies have been shown to be p16 positive,[4] and nasopharyngeal cancers have demonstrated HPV positivity.[8]

Operative Period

Patients in whom the unknown primary cancer remains occult despite having an extensive evaluation, including PET/CT scan, tonsillectomy, and directed biopsies of the nasopharynx/BOT, may benefit from a robotic BOT resection to identify the primary cancer. In prior series, the lingual tonsillectomy has demonstrated an approximately 90% success rate in finding the primary tumor when the standard methods have failed.[2,3] This method is especially useful when HPV positivity has been demonstrated in the metastatic node. The overall goal of the robotic BOT resection procedure is to use an en bloc resection approach under high magnification to remove all lingual tonsil tissue from the inferior portion of Waldeyer's ring as a method of identifying the primary cancer.

Anesthesia

General anesthesia. A small (6-0) regular endotracheal tube can be used intraorally with the tube taped to the contralateral side of the mouth from the mass in the neck. If robotic surgery is being considered after a prior EUA and directed biopsies, nasotracheal intubation can also be considered to further optimize surgical space for TORS but is not a requirement for TORS.

Positioning

- The table should be turned 180 degrees and the upper and lower teeth protected with a nasal splint that is bisected and molded to the teeth.
- A 2-0 silk suture is then placed in the midline of the tongue, which is a half mattress to allow for traction to be placed on the tongue.
- Both arms are then tucked for the patient (Fig. 61.1).

Perioperative Antibiotic Prophylaxis

- Clean contaminated surgery
- Antibiotics are administered during induction of anesthesia and continued for 24 hours.
- Choices
  - Clindamycin
  - Amoxicillin-clavulanate
  - Cephalosporin and metronidazole

Monitoring

- The surgeon and surgical team including anesthesia need to work together to monitor the patient during robotic surgery. For example, attention should be directed to ensure that robotic instrumentation is not clashing with mouth retractors or each other or causing trauma to the patient. In addition, care must be taken to avoid inadvertent extubation during the procedure from manipulation of the endotracheal tube by the surgeon or the assistant.

FIG. 61.1 Depiction of the placement of robotic instruments in the transoral robotic surgery approach for base of tongue resection. The patient's mouth is retracted using a Dingman retractor with a flat blade. The

da Vinci robot is then docked with instruments in the patient's mouth.

- Particular attention is required to ensure that the height of the operating room table is not changed during the procedure. The robotic instruments are docked in the oral cavity in a fixed position. Relative movement of the patient to the instrument position (up-toward and down-away from the instruments in a sudden fashion) can cause inadvertent damage to the oral cavity or pharyngeal tissues.

Instruments and Equipment to Have Available

- Operating headlight
- Tooth guard
- Dingman, Crowe Davis, or Feyh-Kastenbauer (FK) retractor with various size flat tongue retractor blades
- da Vinci Robotic System (Intuitive Surgical)
- 5-mm spatula tip monopolar cautery
- 5-mm Maryland dissector
- 2-0 silk suture
- The patient's mouth is opened using a mouth gag with the flat retractor blade. It should be noted that the exposure obtained should demonstrate the circumvallate papillae and the lateral pharyngeal walls (Fig. 61.2). Once this exposure is obtained, the mouth gag is then suspended from a Mayo stand.

Key Anatomic Landmarks

- Circumvallate papillae
- Glossotonsillar sulcus and lingual artery
- Vallecula and epiglottis

Prerequisite Skills

- Experience with open head and neck surgery procedures
- Transoral robotic surgery training

Operative Risks

- There is a potential risk of injury to the lingual artery, which can result in significant bleeding. However, the robotic lingual tonsillectomy procedure does not resect a significant portion of intrinsic tongue musculature, and therefore the lingual artery is not at significant risk in many of these cases.

FIG. 61.2 The exposure of the oropharynx is obtained using a Dingman mouth retractor with a flat blade. The endotracheal tube is sutured to one side. The lateral pharyngeal walls and the circumvallate papillae are exposed.

- There is, however, the possibility of experiencing some postoperative bleeding when the eschar that covers the surgical defect sloughs off. Most bleeding can be treated with observation or topical cautery if it occurs from a more anterior portion of the BOT.
- More active bleeding or bleeding from a deeper portion of the surgical

wound may require control of the bleeding in the operating room. Neither author of this chapter has ever had to take a patient back to the operating room for surgical management of postoperative bleeding in a TORS SCCHNUP patient.

- Potential damage to the oral cavity from the mouth gag and/or robotic instruments

Surgical Technique

- A direct laryngoscopy and examination should be performed under anesthesia to evaluate the oral cavity, oropharynx, larynx, and hypopharynx.
- If a nasopharyngeal cancer is suspected, a dedicated nasal examination with an endoscope and biopsies can be useful.
- An esophagoscopy should also be performed, along with laryngoscopy.
- Bimanual palpation of the mucosal surfaces of the BOT and tonsil while the patient is under anesthesia is essential to obtain a better examination of these areas, since the tumors often grow in an endophytic fashion within the tonsillar crypts.
- Directed biopsies to the areas of clinical suspicion of the BOT should be performed to try to identify the occult primary cancer.
- If an obvious cancer is not seen, a bilateral palatine tonsillectomy should be performed in patients with adequate lymphoid tonsil tissues as part of the initial evaluation. Approximately 10% of cancers of the tonsil will have contralateral cervical lymph node metastases, and thus a prophylactic bilateral palatine tonsillectomy for these patients is necessary.[9] In those patients in whom the radiographic imaging and initial operative endoscopy do not reveal the primary cancer, additional evaluation is warranted. Intraoperative consultation with the pathologist for the evaluation of palatine tonsils is generally of limited value, since many cancers of unknown primary origin tend to be very small. We prefer therefore to send the palatine tonsils for permanent section evaluation.

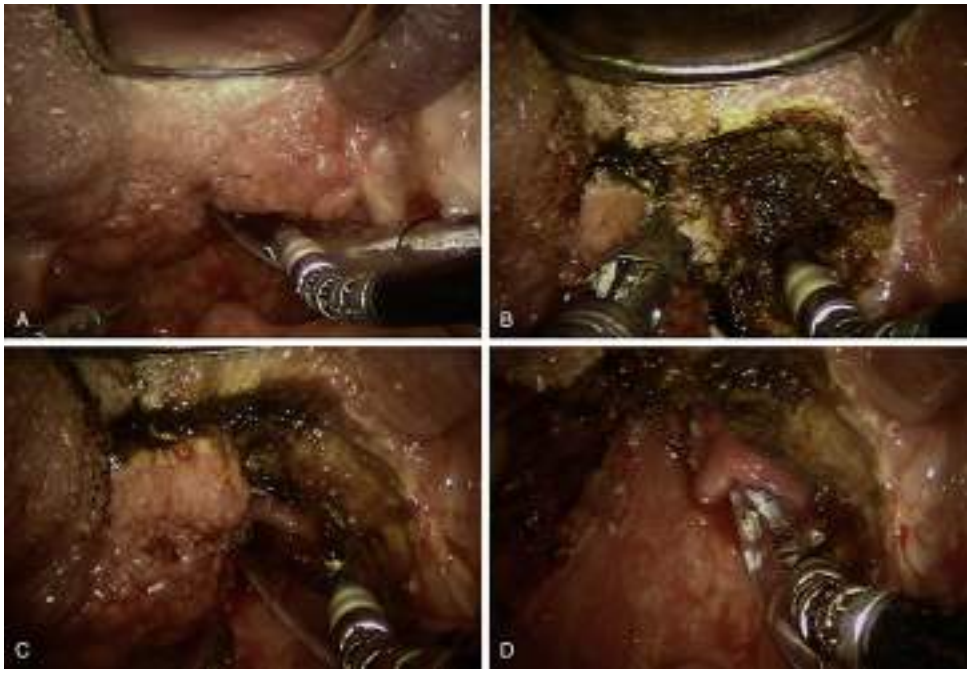

FIG. 61.3 **A,** The view of the lingual tonsils with the retractor in place. **B,** The initial incision is made along the circumvallate papillae from the left to right side. The lingual tonsil is then bisected in the midline, and a unilateral lingual tonsillectomy is performed. The dissection plane is to the level of the musculature of the base of the tongue (BOT). The dissection is then carried from midline to lateral, taking care to transect the glossotonsillar fold and remove any tonsil tissue that is present in the glossotonsillar sulcus. The dissection is then carried inferiorly to the level of the vallecula. **C,** The unilateral portion of the BOT is then removed. **D,** Once the dissection is completed on one side, a similar procedure is performed on the contralateral BOT. Here the bilateral lingual tonsils have been removed.

- If these measures fail to find the primary source, the BOT should then be addressed, and a robotic assisted lingual tonsillectomy can be performed in these patients at the same sitting as the performance of the palatine tonsillectomies, especially if the neck metastases have been shown to be HPV positive.

Surgical Technique: Transoral Robotic

Surgery

- After opening the mouth and exposing the BOT, the surgical robot is brought into the field. The arms of the surgical robot are then brought into position and introduced into the patient's mouth for the TORS approach. We use a 5-mm Maryland and a 5-mm cautery Bovie to perform the dissection.
- The initial incision is made along the circumvallate papillae from the left to right side.
- The lingual tonsil is then bisected in the midline, and a unilateral lingual tonsillectomy is performed (Fig. 61.3).
- The dissection plane is to the level of the musculature of the BOT. Since this is a diagnostic procedure as well as a resection of a relatively small cancer, the muscle of the BOT should not be violated or resected. By avoiding the muscle, inadvertent entry into the lingual artery and/or unnecessary morbidity can be avoided.
- The dissection is then carried from midline to lateral taking care to transect the glossotonsillar fold and remove any tonsil tissue that is present in the glossotonsillar sulcus. It should be noted that leaving lymphoid tissue at the area of the glossotonsillar sulcus could result in missed diagnosis, since many occult primary cancers can be quite small (on the order of a few millimeters in size).[2]
- The dissection is then carried inferiorly to the level of the vallecula. The area of the vallecula is easily identified by the appearance of minor salivary glands, which appears as small white lobular tissue, at the area of the vallecula. There are often small blood vessels in this area that supply the mucosa and can be easily controlled with electrocautery. Care must be taken not to transect the epiglottis or inadvertently injure the supraglottic structures (see Fig. 61.3).
- Once the dissection is completed on one side, a similar procedure is performed on the contralateral BOT.
- This specimen is then oriented on the back table with suture and ideally inked for orientation for the pathologist (Fig. 61.4). The tissue is then delivered to the pathologist for consultation and microscopic evaluation using frozen section technique.

- We prefer to start the dissection by performing ipsilateral resection of the BOT to the nodal metastasis in the initial setting. If the primary is grossly identified in the resection specimen, the contralateral half can occasionally be spared. However, it is known that cancer of the BOT can have bilateral metastasis. We have documented an approximate 8% rate of nodal metastasis from an occult cancer of the BOT in the contralateral half. For this reason, we prefer to offer bilateral lingual tonsillectomy for patients with metastatic carcinoma from an unknown primary site.

FIG. 61.4 A typical resection specimen is shown. The entire extent of the base of the tongue is resected from the left glossotonsillar sulcus to the right glossotonsillar sulcus and inferiorly to the valleculae.

FIG. 61.5 The appearance of the tongue base 2 months after robotic assisted resection. This is the appearance prior to initiation of radiation therapy. The vallecula is preserved, and the tongue base is well healed.

- The wound is irrigated with cool saline and suctioned clear. A orogastric tube is passed down to the patient's stomach, and the stomach contents are evacuated. Floseal can be applied to the base of tongue to prevent oozing, but this is not required if no oozing is noted.

Common Errors in Technique

- As mentioned previously, a common mistake is not resecting all of the tonsillar tissue, especially within the glossotonsillar sulcus. These tumors can be only a few millimeters in size and thus require a complete lingual tonsillectomy.
- Care should be taken to avoid damaging the supraglottic structures.
- Avoid developing a plane that is too deep into the tongue that risks causing unnecessary bleeding, increases risk of postoperative hemorrhage by possibly damaging the lingual artery, and increases postoperative pain/dysphagia.

Postoperative Period

Postoperative Management

- Patients who have undergone TORS for an unknown primary cancer are extubated in the operating room or upon transfer to the postoperative recovery unit.
- The patients are then managed in the hospital overnight with intravenous pain medication as well as GI prophylaxis with proton pump inhibitors and an H2 blocker. We also treat patients with sucralfate to minimize exposure of the open wound at the BOT to gastric contents.
- The patients are fed a soft diet on the day of surgery. It should be noted that clear liquids are often the most difficult to swallow in the immediate postoperative period.
- Routine placement of a nasogastric feeding tube in these patients has not been necessary.
- Patients are then free to follow any diet they can tolerate as soon as they are able to have their pain under good control.
- Patients are usually discharged from the hospital on the first postoperative day.

Complications

- In general, the risks and type of complications observed with transoral robotic resection of the BOT for an unknown primary cancer are similar to those seen with other transoral approaches for resection of the BOT.
- There is a potential risk of injury to the lingual artery, which can result in significant bleeding. However, the robotic lingual tonsillectomy procedure does not resect a significant portion of intrinsic tongue musculature, and therefore the lingual artery is not at significant risk in many of these patients. There is, however, the possibility of experiencing some postoperative bleeding when the eschar that covers the surgical defect sloughs off. Most bleeding can be treated with observation or topical cautery if it occurs from a more anterior portion of the BOT. However, more active bleeding or bleeding from a deeper

portion of the surgical wound may require control of the bleeding in the operating room.

- Neither author of this chapter has ever had to take a patient back to the operating room for surgical management of a postoperative hemorrhage in a TORS SCCHNUP patient.

Alternative Management Plan

The patient could be offered primary chemoradiation to both necks and Waldeyer's ring. This has been shown to be effective in controlling the disease but carries significant morbidity due to severe dysphagia and xerostomia.

Discussion

Evidenced-Based Medicine Question

What are the oncologic, quality-of-life, and cost implications of performing the lingual tonsillectomy to identify the primary source?

Patients typically experience pain and dysphagia after robotic assisted surgery of the BOT. The pain lasts between 2 days through 3 weeks as the wound heals (Fig. 61.5). Most patients do have dysphagia but are able to tolerate oral intake as early as postoperative days 1 to 2. Patients typically work with a speech pathologist with some basic swallowing exercises to facilitate early resumption of swallowing. The long-term risk of feeding tube dependence is highly correlated with the modality that is used to complete the definitive treatment of these patients. Those patients who undergo extensive chemoradiotherapy for the management of the disease tend to have a higher rate of feeding-tube dependence.[10]

Patients who have a small volume primary cancer can often be treated with surgery alone by definitively resecting the primary cancer with clear margins and performing an appropriate neck dissection. The neck dissection is typically postponed for 1 to 2 weeks after the primary TORS procedure to allow for final pathology reports to identify the presence of a close or positive margin, which can be addressed at the time of the neck dissection. As mentioned previously, the TOS lingual tonsillectomy has

identified the primary site of tumor in approximately 90% of SCCHNUP patients that have failed the traditional evaluaion.[2,3] The average size of the cancer in our series was approximately 5 to 6 mm, and the vast majority of these lesions were HPV related.[2]

De-escalation protocols are currently being investigated for HPV-associated, low-risk oropharyngeal cancer. In those nonsmoking HPV+ patients with T1N1 or N2a disease without macroscopic extracapsular extension, resection of the BOT with negative margins and subsequent neck dissection are currently being investigated as sole therapy in different trials. In our anecdotal experience, patients treated in this fashion have excellent oncologic and functional results and return to work quickly without suffering from the long-term problems associated with chemoradiation. In those patients with adverse risk factors (HPV negative, tobacco abuse, N2b or higher, extracapsular spread), adjuvant treatment with radiation or chemoradiation is often necessary. However, the TORS lingual tonsillectomy affords the opportunity to obtain a definitive diagnosis and helps direct the radiation field to the primary site only, thereby avoiding radiation to the entire Waldeyer's ring. This has been shown to improve both functional and oncologic outcomes. The authors choose to perform a neck dissection based on the clinical nodal status and if there is a possibility of avoiding adjuvant chemotherapy.

The TORS BOT procedure is a safe and effective way of managing patients with SCCHN from an unknown primary, provided that the key surgical steps and oncologic principles are adhered to. The use of minimally invasive surgeries facilitates the identification of the unknown primary cancers, provides patients with prognostic information, and allows for patients to be stratified to clinical trial protocols. It is also possible to definitively resect the primary cancer and remove all active cancer from the neck, thus avoiding adjuvant therapy in select patients. The long-term sequelae of dysphagia may be reduced in those patients who can be treated with adjuvant dose of radiation after surgical therapy, especially if the primary site is identified.

Editorial Comment
